Abortion, Equine Infectious

BASIC INFORMATION

DEFINITION

Pregnancy loss after placental development around 40 to 45 days (may be more correctly termed "stillbirth" in term pregnancies after 320 days). Causes include bacterial, fungal, and viral organisms.

EPIDEMIOLOGY

RISK FACTORS

Risk factors vary by inciting cause:

- Viral abortions, including equine herpes virus (EHV) and equine arteritis virus (EAV), may occur sporadically or as "abortion storms." Contact with aborting animals and negative vaccine status are important risk factors for viral abortions.
- Environmental conditions, such as standing water in pastures, and contact with wildlife are known risk factors for leptospiral abortions.
- Poor perineal conformation and trauma to the reproductive tract may be risk factors for bacterial or fungal placentitis. Other sources of vaginal or cervical contamination, including iatrogenic contamination during reproductive examination, may also represent risk factors.

CONTAGION AND ZOONOSIS

- Direct contact with infected, viremic animals or with aborted tissue is the primary mechanism of transmission for viral diseases. Additionally, EAV may be transmitted by aerosol across short distances. Leptospiral organisms may be transmitted in urine or via the abortus; however, most leptospiral abortions are sporadic. Bacterial abortions are not known to be contagious.
- The zoonotic potential for equine viral or bacterial abortificants (or abortifacients) is low; however, appropriate personal protection should be used when handling fetal or placental tissue of aborted animals.
- *Leptospira* spp. are known to be zoonotic and cause human disease. Transmission from horses to humans has not been documented to the author's knowledge.

GEOGRAPHY AND SEASONALITY

- Viral abortions occur worldwide.
- Abortions caused by nocardioform organisms are most commonly seen in Kentucky but have also been reported in Florida, Europe, and South Africa.
- Abortions are more common in mid to late gestation (20–44 weeks), generally coinciding with the winter months; however, no direct seasonal influences have been identified.
- Leptospiral abortions are more prevalent in locations or seasons with heavy rainfall and standing water.

ASSOCIATED CONDITIONS AND DISORDERS

- Placentitis (ascending bacterial placentitis or nocardioform placentitis)
- Respiratory disease (EHV)
- Dystocia
- Retained fetal membranes

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Bacterial
- Viral
- Fungal

HISTORY, CHIEF COMPLAINT

- Acute abortion or stillbirth
- Precocious mammary development
- Vulvar discharge
- Premature separation of fetal membranes at birth

PHYSICAL EXAM FINDINGS

- Blood-tinged perineal area; protruding membranes from vulvar area or in vagina.
- Physical parameters of mares are generally within normal limits.
- The fetus may be fresh or autolyzed.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathophysiology of the disease is poorly understood for most causative organisms.
- Abortion may be associated with clinical disease in the mare (EAV, EIA) or in the absence of clinical disease.
- Ascending placentitis is generally induced by opportunistic organisms ascending from the vagina though the cervix. The bacteria colonize the fetal membranes and penetrate to the allantoic and amniotic fluids, gaining access to the foal either by fetal swallowing and respiratory movements or by umbilical penetration. Bacterial invasion initiates a cascade of hormonal and physical changes that precipitate premature parturition. At the time of parturition, the fetus may be premature, precociously mature, or septic.
- It has not been established how nocardioform organisms reach the uterus, but they are characteristically found at the most ventral aspect of the uterus. Nocardioform placentitis results in disruption of placental function and fetal hypoxia but is not known to cause fetal sepsis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ascending bacterial placentitis: *Streptococcus equi* subsp. *zooepidemicus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae* associated with placentitis, funisitis, and fetal sepsis; the fetus may be fresh or autolyzed.
- Nocardioform placentitis: *Crosiella equi*, *Lentzea kentuckyensis*, *Amycolatopsis* spp., and *Cellulosimicrobium cellulans* cause chronic placentitis and placental insufficiency without fetal sepsis; foals may be born alive but underdeveloped and emaciated.
- Leptospiral abortion: *Leptospira kennewick* (formerly *Leptospira pomona*), *Leptospira grippotyphosa*, *Leptospira bratislava* (host adapted to equines); associated with abortion of autolyzed fetal tissue, mild diffuse placentitis, and funisitis; the fetus may be icteric.
- Viral abortion: EHV, EAV, rarely EIA; fetuses may be fresh (EHV) or autolytic (EAV).
- Fungal abortion: *Aspergillus* spp., *Mucor* spp., *Candida* spp. associated with placental insufficiency or fetal infection; *Histoplasma* spp. are a rare cause of abortion.
- Mare reproductive loss syndrome results in fetal death and abortion or mummification early in pregnancy (day 45–60) and rarely in late-term abortion. The syndrome is associated with ingestion of Eastern tent caterpillars. The cetae (hairs) of tent caterpillars are capable of penetrating the intestinal tract and serving as vectors for opportunistic intestinal organisms.
- Other infectious causes of abortion: *Taylorella equigenitalis* (contagious equine metritis), *Neorickettsia risticii* (Potomac horse fever), *Salmonella abortus equi*.
- Noninfectious causes of abortion: Twin pregnancy, umbilical torsion, fetal malformation.

INITIAL DATABASE

- Complete blood count and chemistry panel are usually normal but may be indicated to determine other organ involvement.
- Electrolyte content of milk may be useful to predict timing to parturition in mares with precocious mammary development and milk production.

ElibEVet.com

- A progesterone (estimating total progestagens) or estrogen assay may be useful to predict timing to parturition or severity of disease in some cases.
- Transrectal palpation and ultrasonography should be performed to confirm the presence of a fetus if premonitory signs are noted or to confirm the complete evacuation of the uterus in a mare that presents after abortion.
- A thorough genital examination, including a culture swab of the uterus and a speculum examination of the caudal genital tract, may guide post-abortion treatment.

ADVANCED OR CONFIRMATORY TESTING

- Serologic tests for EHV, EAV, *Leptospira* spp., and *Neorickettsia* on maternal serum are available and may aid in the diagnosis of etiology after abortion.
- Necropsy of the fetus and fetal membranes represents the highest chance of achieving a diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Maintaining pregnancy to term (if premonitory signs are noted)
- Maximizing fertility of subsequent breeding attempts
- Preventing transmission of contagious organism to susceptible animals

ACUTE GENERAL TREATMENT

- See "Parturition, Premature Signs of" in this section for treatment of pregnant mares with suspected placentitis.
- Isolation of mares after abortion and removal of fetal tissues and fluids from the presence of other pregnant mares may reduce the risk of multiple abortions.
- Large-volume uterine lavage (30–40 L of nonsterile saline) may be warranted to evacuate retained fetal membranes or fetal tissues or to enhance bacterial clearance from the uterus.
- Antibiotic or antiinflammatory therapy may be warranted based on examination findings.

POSSIBLE COMPLICATIONS

- Dystocia
- Retained fetal membranes
- Retention of a dead fetus is a rare complication but warrants examination. A retained fetus that is undetected may result in mummification or maceration, which is associated with metritis and severe maternal disease or chronic infertility.

RECOMMENDED MONITORING

- Mares and abortuses, including the fetal membranes, should be examined carefully at the time of abortion to achieve an accurate diagnosis.
- Mares should receive regular nursing care, including monitoring of the rectal temperature to enhance diagnosis of secondary complications, such as retained fetal membranes and metritis.
- If clinically normal, mares should be examined by transrectal ultrasonography 5 to 8 days after abortion to monitor uterine involution.
- A complete breeding soundness examination may be warranted before subsequent breeding attempts.

PROGNOSIS AND OUTCOME

- Prognosis for survival of the mare is good.
- Prognosis for future fertility is good in the absence of predisposing anatomic conditions or secondary complications (eg, dystocia with ensuing damage to the reproductive tract, retained fetal membranes).
- Infection does not result in protective antibody formation for future pregnancies in most cases (except EAV).

PEARLS & CONSIDERATIONS

PREVENTION

- Vaccination of pregnant mares at 5, 7, and 9 months of gestation prevents abortion storms caused by EHV.
- Vaccination of at-risk horses reduces the transmission of EAV.
- Pregnant animals should be separated from young animals and competition animals to avoid transmission of disease.

CLIENT EDUCATION

Although there are no known strategies to prevent bacterial placentitis, client education regarding the importance of premonitory signs, including vaginal discharge and precocious mammary development, as well as routine diagnostic ultrasonography of late-pregnant mares may lead to a reduction in the incidence of abortion.

Abscess, Perirectal

BASIC INFORMATION

DEFINITION

Abscessation around the aboral rectum and the anus

EPIDEMIOLOGY

RISK FACTORS Anorectal lymphadenopathy can progress to abscessation. Anorectal lymphadenopathy is more common in horses 3 to 15 months of age.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES The abscesses can be located anywhere circumferentially around the rectum and anus.

HISTORY, CHIEF COMPLAINT

- Mild colic signs
- Depression
- Inappetence
- Decreased fecal output
- Tenesmus
- Dyschezia
- Dysuria

PHYSICAL EXAM FINDINGS

- Temperature is variable depending on the severity of the lesion; it is often elevated.
- Heart rate may be normal or may be elevated.
- Mucous membranes are variable depending on severity of compromise; they are often pale pink and moist.
- Colic signs are variable.

ETIOLOGY AND PATHOPHYSIOLOGY

- Progression of anorectal lymphadenopathy

ElibEVet.com

- Rectal puncture
- Rectal tears, especially those in the aboral nonperitoneal rectum
- Rectal inflammation
- Migration of an abscess after an intramuscular gluteal injection

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Anorectal lymphadenopathy
- Small colon impaction
- Rectal tear
- Nonstrangulating small colon or rectal obstruction
- Rectal neoplasia
- Rectal hematoma
- Urinary tract infection

INITIAL DATABASE

- Complete blood count: Leukopenia and leukocytosis are common; occasionally normal.
- Rectal evaluation: The firm abscess may be palpated in the perianal area or under the submucosa of the rectum.
- Ultrasonography: May see a well-circumscribed subcutaneous or submucosal mass.

ADVANCED OR CONFIRMATORY TESTING

- Perirectal abscess aspiration: This can be performed percutaneously or transrectally.
- Submit any aspirated fluid for cytology, culture, and sensitivity.
- *Escherichia coli* and *Streptococcus equi* subsp. *zooepidemicus* are commonly isolated.

TREATMENT

THERAPEUTIC GOAL(S)

- Systemic and local analgesia and antiinflammatories
- Abscess drainage
- Laxative diet
- Antibiotics based on culture and sensitivity

ACUTE GENERAL TREATMENT

- Occasionally abscessed anorectal lymph nodes in young horses can be treated with antibiotics, antiinflammatories, and laxative diets alone.
- Anorectal abscesses refractory to medical management or those in older horses frequently require surgical drainage.
  - Perform caudal epidural anesthesia with lidocaine (0.22 mg/kg)
  - Drain abscess
    - Lateral abscesses can be drained lateral to the anus.
    - Dorsal abscesses can be drained into the rectum.
    - Ventral abscesses can be drained into the vagina in mares or ventral to the anus in males.
  - Administer nonsteroidal antiinflammatory drugs (flunixin meglumine, 1.1 mg/kg).
  - Depending on the invasiveness of surgery, consider administering broad-spectrum antibiotics while awaiting the results of culture and sensitivity.
  - Feed a laxative diet and administer mineral oil via nasogastric tube.
  - Occasionally, abscesses extend into the abdominal cavity; these may require exploratory celiotomy and marsupialization or drainage into the vagina or rectum.

CHRONIC TREATMENT

- Analgesia and antiinflammatories
- Antibiotics
- Laxative diet and mineral oil
- Lavage daily with dilute antiseptic solution to open abscesses

POSSIBLE COMPLICATIONS

- Peritonitis
- Endotoxemia
- Laminitis
- Adhesions
- Colic
- Stricture formation
- Jugular thrombophlebitis
- Recurrence of abscess
- Perianal fistula
- Rectovaginal fistula

RECOMMENDED MONITORING

- Pain
- Fecal output and consistency and any blood on feces
- Signs of endotoxemia
- Colic

PROGNOSIS AND OUTCOME

- Prognosis for abscesses without abdominal involvement is favorable.
- Abdominal involvement reduces the prognosis as there is a higher risk of complications.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Actinobacillosis

BASIC INFORMATION

DEFINITION

- *Actinobacillus* spp. is a gram-negative group of bacteria that causes a variety of clinical syndromes in horses.
- *Actinobacillus equuli* subsp. *equuli*
- *Actinobacillus equuli* subsp. *haemolyticus*

EPIDEMIOLOGY

SPECIES, AGE, SEX All species of horses are susceptible. *A. equuli* is associated with sepsis of foals and is a common bacteria isolated from abortions caused by the eastern tent caterpillar (ETC).

RISK FACTORS

- ETC (*Malacosoma americanum*) ingestion and intoxication
- Failure of passive transfer of immunoglobulin in foals

GEOGRAPHY AND SEASONALITY ETC infestation of the environment may fluctuate from year to year and is associated with fruiting trees, hatching in the spring.

ASSOCIATED CONDITIONS AND DISORDERS Mare reproductive loss syndrome (MRLS)

ElibeVet.com

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Opportunistic infections of many organs and body systems of adults
- Septicemia of foals

HISTORY, CHIEF COMPLAINT

- Adults: History and chief complaint referable to the affected system: MRLS—abortion, pericarditis
- Neonates: Neonatal sepsis within the first 2 weeks of life

PHYSICAL EXAM FINDINGS

- Adults: Examination referable to the organ system affected consisting of abortion, metritis, mastitis, septicemia, arthritis, endocarditis, meningitis, pneumonia, and pleuritis
- Foals: Weakness, failure to suckle, hypothermia, and congested mucous membranes. If overwhelming liver infection is present, the foal may be icteric. Often fatal in foals.

ETIOLOGY AND PATHOPHYSIOLOGY

- *A. equuli* subsp. *equuli*: Causative agent of highly fatal septicemia in foals.
- *A. equuli* subsp. *haemolyticus*: Associated with opportunistic infections causing various diseases.
- Both subspecies are associated with abortion and pericarditis of mares with MRLS.
- Common commensal of the equine oral, pharyngeal, and intestine mucous membranes.
- Invasion of body cavities.
- With MRLS, it is hypothesized that ingestion of the ETC results in mucosal absorption of the exoskeleton and setae of the caterpillar. This allows concomitant bacterial infection of the pericardium and placenta.
- Neonatal sepsis likely occurs through ascending vaginal infections before and after foaling through the umbilical structures and respiratory and alimentary tracts.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other bacterial and viral infections that cause primary syndromes

INITIAL DATABASE

- Complete blood count: Leukopenia, hyperfibrinogenemia
- Serum biochemical analysis: Changes are a reflection of the organ system affected

ADVANCED OR CONFIRMATORY TESTING

- Aerobic culture and identification of body fluids or tissues from the affected site
- Blood culture of both adults and foals

TREATMENT

THERAPEUTIC GOAL(S)

- Antimicrobial treatment
- Supportive care depending on the body system affected

ACUTE GENERAL TREATMENT

- Broad-spectrum parenteral antibiotics pending culture and sensitivity
- Potassium penicillin G (22,000 IU/kg IV q6h) or procaine penicillin (22,000 IU/kg IM q12h) combined with appropriate aminoglycoside depending on the age of the horse. Many *A. equuli* isolates are susceptible to these antibiotics.
- Nonsteroidal antiinflammatory therapy: Flunixin meglumine (0.25–0.50 mg/kg IV q6–8h)
- Fluid and nutritional support as needed

CHRONIC TREATMENT

- As indicated by type of infection
- See "Pericarditis" in this section for treatment of pericardial effusion.

POSSIBLE COMPLICATIONS

A. equuli has several toxins in addition to the lipopolysaccharide components of the gram-negative cell wall that mediate signs of cardiovascular collapse, organ necrosis, and sudden death.

RECOMMENDED MONITORING

- Impending abortion of pasture mates, early foalings with weak foals
- Cardiovascular status
- Joints for bacterial infection in foals with sepsis

PROGNOSIS AND OUTCOME

- Prognosis and outcome in adults depend on the clinical syndrome.
  - Peritonitis is highly responsive if treated in the acute stage.
  - The prognosis for recovery from pericarditis and pleuritis is highly guarded.
- Prognosis for recovery of foals with *A. equuli* infection is guarded; the condition often is rapidly fatal.
- Prognosis for recovery of foals with localized infection such as joint sepsis is good to guarded.

PEARLS & CONSIDERATIONS

COMMENTS

Early recognition and treatment with penicillin combined with gram-negative antimicrobial therapy are essential.

PREVENTION

Preventative measures for MRLS are associated with control of ETC.

CLIENT EDUCATION

- Mare and foal care
- Farm hygiene
- Preventive measures for MRLS

ElibeVet.com

Adenovirus

BASIC INFORMATION

DEFINITION

A virus causing respiratory disease and occasionally diarrhea primarily in Arabian foals with severe combined immunodeficiency syndrome (SCID)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily affects Arabian foals with SCID, infecting the respiratory tract, gastrointestinal (GI) tract, liver, pancreas, and bladder.
- SCID foals are generally clinically affected by adenovirus at 1 to 3 months of age.
- Immunosuppression may predispose other foals to susceptibility to adenovirus, and adenovirus may contribute to development of bacterial pneumonia.
- There is a possible role in respiratory disease in adult horses.
- Coinfection with equine herpesvirus-1 or -4 or equine rhinitis virus may result in clinical respiratory disease in normal foals.
- Concurrent infection with rotavirus is often observed in foals affected with diarrhea.
- About 70% of yearlings and 2-year-old horses are seropositive.
- This is not a zoonotic disease.

CLINICAL PRESENTATION

PHYSICAL EXAM FINDINGS

- Infection is usually subclinical in normal foals and adult horses.
- Affected foals demonstrate signs of acute respiratory infection, including nasal discharge, conjunctivitis, and eventually bronchopneumonia (Figure 1).
- Thoracic auscultation is likely abnormal.
- The horse may be febrile and depressed.
- Infection of the GI tract results in low-grade diarrhea unless concurrent rotavirus infection is present, which then leads to severe diarrhea.

ETIOLOGY AND PATHOPHYSIOLOGY

- Two isolates have been identified: EAdV1 (associated with respiratory disease) and EAdV2 (associated with diarrhea).
- Transmitted by close-contact aerosolization or physical interaction.
- The virus replicates in respiratory epithelial cells, resulting in sloughing of cells and a hyperplastic response.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Streptococcus equi* subsp. *zooepidemicus*
- *Pasteurella* spp.
- *Bordetella bronchiseptica*
- *Rhodococcus equi*
- *Actinobacillus equuli*
- *Klebsiella pneumoniae*
- Aberrant parasite migration
- Equine influenza
- Equine herpesvirus
- Equine viral arteritis

INITIAL DATABASE

- Diagnosis primarily focuses on diagnosing SCID (characteristic signalment coupled with diagnostic test results).
- Foals with SCID have severe lymphopenia.
- Thoracic radiographs are consistent with pneumonia.

ADVANCED OR CONFIRMATORY TESTING

Diagnosis of SCID:

- Definitive diagnosis by genetic testing
- Persistent lymphopenia (<1000/μL)
- After 4 weeks of age, serial radial immunodiffusion may be performed to evaluate for the presence of immunoglobulin M (IgM) in the bloodstream.
- Hypoplasia of lymphoid tissue at necropsy
- If diagnosed with adenovirus, a lack of antibody response, as indicated by convalescent adenoviral titers to adenovirus, indicates SCID.

FIGURE 1 **A,** Nasal discharge in a 9-week-old specific-pathogen-free (SPF) foal 6 days after experimental intranasal/intraocular infection with EAdVI. **B,** Conjunctivitis in the same foal 6 days after infection. (From Sellon DC, Long MT: *Equine infectious diseases.* St Louis, Saunders Elsevier, 2007.)

ElibEVet.com

Diagnosis of adenovirus:
- Detect adenovirus in feces by electron microscopy with negative staining.
- Viral isolation may be performed with variable results from nasopharyngeal, conjunctival, or rectal swabs.
- A possible polymerase chain reaction test is in development.
- Antibody response can be evaluated with hemagglutination inhibition assays, and the virus can be typed based on serum neutralization assays.
- Immune precipitation and complement fixation tests have also been used for diagnosis.
- Histopathology: may be evaluated antemortem in nasal or conjunctival tissue; intranuclear inclusions observed.

TREATMENT

THERAPEUTIC GOAL(S)

Supportive treatment for non-SCID foals

ACUTE GENERAL TREATMENT

- No specific treatment is directed at the adenovirus itself.
- Foals with SCID will die despite any treatment.
- Foals without SCID should be placed on broad-spectrum antimicrobials because of the association with bacterial pneumonia.
- Foals without SCID with diarrhea may require supportive treatment consisting of IV fluids, plasma therapy, and possibly parenteral nutritional support.

POSSIBLE COMPLICATIONS

Foals without SCID may be predisposed by adenovirus infection to developing bacterial pneumonia.

PROGNOSIS AND OUTCOME

- Foals with SCID invariably die from their inability to respond to pathogens.
- Foals without SCID generally recover with appropriate treatment.

PEARLS & CONSIDERATIONS

PREVENTION

- Avoid breeding SCID foals. A genetic test is available to identify carriers of the SCID gene. One in four foals born to two carriers of the gene will be affected by SCID, and two of four will be genetic carriers.
- Ensure adequate passive transfer in foals without SCID.
- No vaccine is available.

AUTHOR: **SIDDRA HINES**

EDITORS: **MAUREEN LONG** and **DEBRA SELLON**

Adhesions, Abdominal

BASIC INFORMATION

DEFINITION

Fibrous connection between intraabdominal organs or intraabdominal organs and the body wall

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals are predisposed; however, adhesions are also seen in adult horses.

GENETICS AND BREED PREDISPOSITION Anecdotally, miniature horses are predisposed.

RISK FACTORS
- Foals
- Peritoneal inflammation
- Ischemic bowel
- Distended bowel
- Surgical manipulation
- Drying of the bowel during surgery
- Abrasion of the bowel during surgery
- Hemorrhage
- Peritonitis
- Presence of foreign material
- Bowel puncture

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT
- Horses with adhesions may be asymptomatic.
- Horses with adhesions may also present with inappetence, lethargy, and signs of colic.
- A high index of suspicion is necessary if the horse has a history of exploratory celiotomy.

PHYSICAL EXAM FINDINGS
- The heart rate is variable depending on the severity of the colic signs.
- The temperature is generally normal.
- Borborygmi are often reduced.
- The mucous membranes are generally pink and moist, but they may become tacky.
- Hydration is variable depending on the severity of colic.

ETIOLOGY AND PATHOPHYSIOLOGY
- Damage to the parietal or visceral peritoneum increases adhesion formation in two ways:
  - Increase in fibrin formation and deposition
  - Decrease in fibrinolytic activity
- Mechanism: disruption of the mesothelial cells leads to exposure of underlying connective tissue, blood vessels, collagen, lymphocytes, fibroblasts, mast cells, macrophages, and plasma cells.
  - Release of vasoactive substances (prostaglandin E2, serotonin, bradykinin, and histamine) from the exposed submesothelial tissue leads to increased vascular permeability and extravasation of a fibrinogen-rich inflammatory exudate.
  - Release of thromboplastin (tissue factor) and exposure of subendothelial collagen activate the intrinsic and extrinsic clotting cascade, leading to thrombin-mediated conversion of fibrinogen to fibrin.
    - Normally, fibrin tags are lysed by plasmin in 2 to 5 days and the mesothelial layer repairs, but inadequate fibrinolysis allows fibroblasts to produce collagen by day 4, leading to fibrous adhesions.
    - Increased production of plasminogen activator inhibitor reduces the conversion of plasminogen to plasmin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Nonstrangulating small intestinal lesions:
  - Impaction at an anastomosis site
  - Postoperative ileus
  - Stricture formation
  - Ileal impaction

ElibeVet.com

FIGURE 1 Fibrinous adhesions associated with septic peritonitis (appearance at exploratory laparotomy).

FIGURE 2 Mature fibrous adhesions, secondary to previous colic surgery, causing adherence and kinking of adjacent segments of jejunum (appearance at exploratory laparotomy; horse presented with recurrent colic).

- Very occasionally, adhesions cause strangulating lesions (ie, of the small intestine).

INITIAL DATABASE

- Complete blood count: Frequently normal
- Peritoneal fluid: frequently normal; occasionally, mild increases in total protein and nucleated cell counts; very rarely, serosanguineous
- Rectal palpation: adhesions are rarely palpable but their consequences are often felt (ie, distended small intestine)
- Reflux production: variable
- Transabdominal ultrasonography: occasionally reveals a fixed segment of intestine with adjacent hyperechoic material; however, most frequently just reveals the consequences of the adhesions (ie, small intestinal distension)

TREATMENT

THERAPEUTIC GOAL(S)

- Stabilize the patient.
- Facilitate passage of food past the area obstructed by the adhesion.
  - Frequently attempted medically with a low-residue diet.
  - Repeat exploratory laparotomy or laparoscopy if the patient is nonresponsive to medical management.

ACUTE GENERAL TREATMENT

- Medical management
  - Withhold feed and administer IV balanced polyionic fluid therapy.
  - Administer flunixin meglumine (1.1 mg/kg).
  - Decompress the stomach every 3 hours.
- If unresponsive, surgical intervention may be necessary.
  - Repeat exploratory celiotomy to break down adhesions and aggressive prevention of recurrence.
    - Atraumatic tissue handling
    - 1% carboxymethylcellulose gel application during bowel manipulations
    - Use of a bioresorbable hyaluronic acid–carboxymethylcellose membrane
    - Heparin (40 IU/kg) intraperitoneally, IV, or SC
    - Perioperative antibiotics and anti-inflammatory drugs
    - Dimethyl sulfoxide (200 mg/kg) in a 10% solution IV
    - Peritoneal lavage
  - Laparoscopic adhesiolysis and aggressive prevention of recurrence

CHRONIC TREATMENT

- Medical management
  - Low-residue diet (ie, no hay)
    - Grass diet only
    - Pelleted complete food diet only

POSSIBLE COMPLICATIONS

- Repeat adhesion formation
- Incisional infection
- Ileus
- Peritonitis
- Endotoxemia
- Reobstruction
- Jugular thrombophlebitis
- Diarrhea
- Pyrexia
- Recurrent colic

RECOMMENDED MONITORING

- Abdominal pain
- Incisional swelling, pain, or discharge
- Mentation
- Fecal output

PROGNOSIS AND OUTCOME

- Adhesions have been implicated as a cause of postoperative pain or colic in 22% of horses undergoing small-intestine surgery.
- The long-term survival rate after repeat celiotomy is poor.

PEARLS & CONSIDERATIONS

- One of the most common complications after colic surgery
- Second most common reason for repeat exploratory celiotomy in horses with colic
- More common after small intestinal surgery

ElibeVet.com

Adrenal Insufficiency, Relative

BASIC INFORMATION

DEFINITION

Relative adrenal insufficiency (RAI) is a condition in which the adrenal gland, notably the adrenal cortex, is unable to respond (ie, secrete cortisol) to an appropriate level given the stimulus. RAI is often observed in patients with critical illness such as sepsis, in which adrenal hypofunction is considered part of the multiple organ dysfunction complex.

SYNONYM(S)

- Adrenal exhaustion
- Adrenal hypofunction

SPECIES, AGE, SEX

Premature foals have been shown to have hypofunctional hypothalamic-pituitary-adrenal axis (HPAA) responses, possibly due to underdevelopment; however, foals with sepsis or severe stress may have RAI, with a reported incidence of up to 52%.

RISK FACTORS

- Critical illness such as systemic inflammatory response syndrome (SIRS), sepsis, septic shock, endotoxemia, and trauma
- Long-term administration of anabolic steroids
- Prematurity

ASSOCIATED CONDITIONS AND DISORDERS

- SIRS
- Sepsis
- Septic shock
- Chronic stress responses
- Prematurity

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Variable, based on the primary disease or disorder that causes RAI

PHYSICAL EXAM FINDINGS

- Referable to the primary illness: SIRS, sepsis, endotoxemia, or prematurity.
- Neurologic impairment, seizures, collapse, or other findings may be related to specific electrolyte abnormalities.

ETIOLOGY AND PATHOPHYSIOLOGY

- Prolonged or severe systemic illness leads to HPAA stimulation to yield increased cortisol concentrations.
- Diseases causing systemic inflammation and hypotension significantly increase HPAA responses.
- Excessive stimulation of the adrenal cortex (notably the zona fasciculata) results in an inability to secrete cortisol at an appropriate concentration for the stimulus (eg, adrenocorticotropin [ACTH])
- HPAA underdevelopment associated with neonatal prematurity may result in similar findings.
- In humans, subnormal cortisol responses have been associated with refractory hypotension and correlated with nonsurvival in certain patient populations (eg, septic shock).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Absolute adrenal insufficiency (true hypoadrenocorticism; Addison's disease), in which signs of mineralocorticoid deficiency exist, such as clinically relevant hyponatremia

INITIAL DATABASE

- Accurate diagnosis of the primary illness
  - Blood culture
  - Complete blood count
  - Serum chemistry
  - Fibrinogen concentration
  - Immunoglobulin G concentration in neonates
- Endogenous ACTH and cortisol concentrations
  - Highly variable values
  - An increased ACTH concentration with a concomitantly decreased or normal cortisol concentration may be suggestive of RAI
- Endogenous aldosterone concentration
  - Low concentrations are suggestive of mineralocorticoid deficiency, especially if concurrent with expected electrolyte derangements
- Hyponatremia, hyperkalemia, hypochloremia, and a sodium/potassium ratio <27 may be suggestive of mineralocorticoid deficiency
  - This is very unspecific because conditions such as uroperitoneum often have similar changes in electrolyte profiles

ADVANCED OR CONFIRMATORY TESTING

- ACTH stimulation test: Test of adrenocortical function
  - Administer exogenous ACTH (cosyntropin) and measure serial cortisol concentrations
  - In foals: 10 to 100 µg/51 kg body weight IV at time 0.
    - Serum cortisol measurements should be obtained at baseline and 30 minutes after injection.
    - A minimum twofold increase in cortisol concentration is expected.
    - Subnormal responses are diagnostic for RAI.
    - Reportedly, there is no difference in the 30-minute cortisol concentration response in normal foals with a 10 or 100 µg/51 kg dosing regimen.
  - Cosyntropin may also be dosed based on weight: 0.2 to 2 µg/kg IV.

TREATMENT

THERAPEUTIC GOAL(S)

- Limited information exists regarding the treatment of RAI in sick horses.
- Treating the primary disease is integral to a successful outcome (eg, in neonatal sepsis).
- Corticosteroid replacement is controversial due to lack of controlled studies.

ACUTE GENERAL TREATMENT

- Glucocorticoid treatment:
  - Prednisolone 0.5 to 1.0 mg/kg, q12–24h IV/PO, then lowered to every other day based on follow-up laboratory data (electrolyte concentrations).
  - If the RAI is reversible, gradual reduction in steroid administration is recommended over a period of weeks.
  - Follow-up ACTH stimulation testing should be performed at the end of therapy to assess adrenocortical function.
- Mineralocorticoid treatment:
  - Fludrocortisone administration may be beneficial.
  - Fludrocortisone effects have not been assessed extensively in horses.
  - Suggested dose rate based on case reports in horses and for the treatment of canine hypoadrenocortical crisis is 15 to 25 µg/kg/day as needed.
- Treatment indicated in life-threatening hyperkalemia
  - Calcium gluconate IV
  - IV sodium chloride (0.9% solution)
  - IV dextrose (2.5% to 5% solution)
  - Insulin
  - IV sodium bicarbonate
- Treatment of hyponatremia:
  - Hypertonic saline solutions (0.9%, 3%, 7.2%)
    - Aim to increase the serum sodium concentration by up to 15 mEq/L/day (0.5 mEq/L/h maximum)

ElibeVet.com

- Excessively fast sodium replacement has been reported to cause demyelinating central nervous system disorders in hyponatremic humans (central pontine myelinolysis)

CHRONIC TREATMENT

Ensure adequate sodium in the diet

RECOMMENDED MONITORING

- Serum electrolyte concentrations (sodium, potassium, chloride) should be monitored frequently (q6–12h), especially if the patient has received corticosteroids.
- ACTH stimulation testing should be reassessed at the end of corticosteroid therapy to confirm adequate adrenocortical function.
  - At least 12 to 24 hours after the last administration of prednisolone because it may interfere with test accuracy

PROGNOSIS AND OUTCOME

- RAI has been poorly described in horses.
- Based on preliminary work, foals with severe septicemia are more likely to have HPAA dysregulation, including RAI.
  - These foals are also more likely to die.
- RAI has been correlated to nonsurvival in critically ill humans, notably patients who do not respond to exogenous corticosteroid therapy.
- The prognosis in horses must be in part based on the primary illness (eg, sepsis or prematurity).

PEARLS & CONSIDERATIONS

- RAI is not well described in the equine literature.
- For the moment, treatment is largely empirical until further studies provide treatment guidelines for this condition in horses.
- RAI should be considered in critically ill horses with persistent catecholamine-resistant hypotension or unexplainable electrolyte derangements.

Aflatoxin Toxicosis

BASIC INFORMATION

DEFINITION

Aflatoxins are hepatotoxic mycotoxins (mold toxins) produced by various *Aspergillus* spp. and other fungi, most commonly *A. flavus* and *A. parasiticus*. Aflatoxin can contaminate a wide variety of nutritious feedstuffs, including but not limited to corn, peanuts, sorghum, wheat, rice, cottonseed, sweet potatoes, and potatoes. The four major forms of aflatoxin in feedstuffs are aflatoxin B1, B2, G1, and G2. Aflatoxicosis has been reported in numerous species, including humans, dogs, cattle, swine, poultry, and fish, but there have been relatively few cases reported in horses.

SYNONYM(S)

Synonyms for aflatoxin poisoning are aflatoxicosis, hepatitis X (dogs), and X disease (turkeys).

EPIDEMIOLOGY

SPECIES, AGE, SEX Neonates may be more sensitive.

RISK FACTORS A protein-deficient diet may enhance the hepatotoxic effects of aflatoxins. Dietary vitamin A, carotene, selenium, and antioxidants decrease the effects.

GEOGRAPHY AND SEASONALITY Preharvest contamination occurs in tropical and temperate climates. Contamination of stored grain occurs worldwide.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic aflatoxin poisoning is the most common form in large animals.
- Acute aflatoxicosis may occur if high concentrations of aflatoxins are present in the feed.

HISTORY, CHIEF COMPLAINT

- Affected horses usually have a history of grain in the diet, most commonly corn.
- Clinical signs of chronic aflatoxicosis may be subtle at first, including decreased weight gain or weight loss and poor haircoat. Signs may progress to anorexia, depression, icterus, and hepatic encephalopathy.
- Acute clinical aflatoxicosis is associated with anorexia, depression, diarrhea, gastrointestinal hemorrhage, and icterus.

PHYSICAL EXAM FINDINGS

- Chronic
  - General unthriftiness
  - Icterus
- Acute
  - Coagulopathy
  - Icterus

ETIOLOGY AND PATHOPHYSIOLOGY Aflatoxin is metabolized in the liver to an active compound that binds with cellular components such as nucleic acids, proteins, and subcellular organelles, disrupting cellular function.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other hepatotoxins cause similar clinical signs and lesions
  - Pyrrolizidine alkaloids
  - Carboxyatractyloside from *Xanthium* spp. (cockleburs)
  - *Lantana* spp.
  - Cyanobacterial toxins (microcystin)
  - Mushroom toxins (amanitin)
  - Phenolics and coal tar derivatives
  - Iron overdose
- Other causes
  - Theiler's disease
  - Inflammatory hepatitis

INITIAL DATABASE

Serum chemistry:

- Elevated gamma-glutamyl transpeptidase early with low doses
- Elevated alanine transaminase with higher doses
- Increased serum bilirubin

ElibeVet.com

- Activated prothrombin time may be increased

ADVANCED OR CONFIRMATORY TESTING

- Analysis for aflatoxin
  - Feed analysis
- Black-light analysis is used to check for the presence of *Aspergillus* spp. The absence of fluorescence does not guarantee that aflatoxin is absent nor does the presence of fluorescence guarantee the presence of aflatoxin.
- Commercially available bench-top enzyme-linked immunosorbent assays (ELISAs) for aflatoxin.
- Gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/mass spectrometry (LC/MS) are the definitive quantitative analysis for aflatoxin in tissues.
- GC/MS or LC/MS is used to detect aflatoxin in blood, liver, or milk.
- False-negative results are common.
- Pathology:
  - Hepatocellular degeneration and necrosis, megalocytosis, and hepatic fibrosis and bile duct proliferation have been reported on histology.
  - Hemorrhagic enteritis has been reported.
  - Cerebral edema has been reported.

TREATMENT

THERAPEUTIC GOAL(S)

- Early detoxification
- Symptomatic and supportive care
- Hepatoprotectants and supplement glutathione scavenging

ACUTE TREATMENT

- Early detoxification for large ingestions of feed highly contaminated by aflatoxin
  - Activated charcoal
- Symptomatic and supportive
  - Maintain blood volume and electrolyte balance
  - Vitamin K1 for coagulopathy
  - Gastroprotection
- Hepatoprotectants and supplement glutathione scavenging
  - *N*-acetylcysteine
  - *S*-adenosyl-L-methionine
  - Milk thistle

CHRONIC TREATMENT

Maintain the patient on a high-quality diet.

POSSIBLE COMPLICATIONS

Long-term liver damage may occur.

RECOMMENDED MONITORING

- Liver enzymes
- Bilirubin
- Activated prothrombin time

PROGNOSIS AND OUTCOME

The prognosis depends on the concentration of aflatoxin in the feed and the duration of exposure. Severe liver damage and death are possible outcomes.

PEARLS & CONSIDERATIONS

COMMENTS

- Toxic dose of aflatoxin:
  - Aflatoxin was lethal to ponies dosed with 2 mg/kg once.
  - Approximately 3.8 ppm in the diet was lethal to some ponies after 37 to 39 days.
  - Clinical signs have been reported with dietary aflatoxin concentrations of 500 ppb (0.50 ppm).
- Although the United States Food and Drug Administration (FDA), which regulates mycotoxins in foods and feeds, does not give a specific limit for the concentration of aflatoxin that may be present in horse feed, the limit is 20 ppb (0.02 ppm) for human and animal feeds that are not covered by other FDA recommendations.

PREVENTION

- Keep horses on a high-quality nutritionally balanced diet.
- Avoid feeding poor-quality or visibly moldy feeds.
- Screen feeds for aflatoxins.

CLIENT EDUCATION

- Horses with clinical aflatoxicosis typically have a guarded to poor prognosis depending on the concentration of aflatoxin in the feed and the amount ingested over time.
- It is often difficult to diagnose aflatoxicosis based on aflatoxin concentrations in the feed because:
  - Aflatoxin is not evenly distributed within the feed, and sampling error may occur.
  - The contaminated feed may be completely consumed before the clinical signs are apparent.
- It is difficult to diagnose aflatoxicosis from biologic (non-feed) samples because of the extremely low concentrations that remain in tissues. False-negative test results are common.
- It is best to prevent aflatoxicosis.

African Horse Sickness

BASIC INFORMATION

DEFINITION

- African horse sickness (AHS) is caused by a double-stranded, nonenveloped RNA virus that affects members of the family Equidae and is transmitted by midges (*Culicoides* spp.). Horses and mules are the most severely affected.
- There are nine distinct serotypes, with types 5 and 9 most commonly occurring outside of the endemic sub-Saharan Africa. Four major forms of the disease exist: peracute or pulmonary (95% mortality rate), subacute or cardiac (50% mortality rate), mixed (70% mortality rate), and horse sickness fever (recovery). The onset of disease in the severe forms is characterized by a high fever followed by respiratory failure with a frothy to serosanguineous nasal discharge or nondependent edema of the head and neck with petechiations of the conjunctiva. There is no effective treatment.
- A polyvalent vaccine exists that provides protection for all serotypes. Quarantine, constant monitoring, and vector control are necessary. This

ElibeVet.com

disease has not been documented in North America and is a World Organisation for Animal Health (OIE)–reportable disease.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Horses are most susceptible to infection, with a mortality rate of 70% to 95% depending on the form of the disease.
- Mules are slightly less susceptible, with a mortality rate of 50% to 70%.
- Donkeys and zebras develop subclinical disease.
- There does not appear to be an age predilection. Foals born to immune mares may receive passive immunity that disappears at age 4 to 6 months.
- There is no sex predilection.

GENETICS AND BREED PREDISPOSITION Horses indigenous to certain areas of North and West Africa appear to have acquired resistance to infection with AHS. There is no breed disposition.

CONTAGION AND ZOONOSIS The only known incident of humans contracting AHS occurred in a laboratory setting. AHS is not considered a zoonotic disease in the natural setting; however, veterinarians dealing with suspected cases of AHS should still follow universal precautions.

GEOGRAPHY AND SEASONALITY

- AHS is considered to be enzoonotic in eastern and central Africa, with yearly incursions of the disease into southern Africa. Documented and confirmed epidemics have occurred in North Africa, the Middle East, Turkey, Afghanistan, Pakistan, India, Spain, and Portugal. To date, the virus has never been documented in North America.
- Transmission
  - AHS is biologically transmitted by midges of the *Culicoides* genera. *Culicoides imicola* and *Culicoides bolitinos* appear to be the most important vectors in Africa. Other vectors, including ticks and mosquitoes, have been shown to transmit AHS under experimental conditions; however, they have never been shown to transmit the virus under natural conditions. Mechanical transmission of the virus may occur through biting flies and iatrogenic incidents. In the United States, *Culicoides sonorensis* and *Culicoides variipennis* (which are responsible for blue-tongue virus transmission) have been shown to transmit AHS under experimental conditions.
  - Transmission of AHS corresponds with peak vector activity. In Africa, this depends on climatic conditions, in which heavy rains followed by warm, dry periods favor the survival of *Culicoides* individuals. Cold weather and frosts kill *Culicoides* spp. and thus decrease or stop AHS transmission. This effect of climate on AHS transmission is especially evident in AHS epidemics, when the virus makes incursions into South Africa. The wet, warm months of February, March, and April have the highest case rates of AHS, with cases of AHS disappearing after the first frosts in April or May. Epidemics also occur when individuals having a high viral load are transported to countries with *Culicoides* vectors capable of transmitting the virus. Epidemics have also been reported with the windborne spread of infected vectors.
- Maintenance of AHS in the environment.
  - The exact mechanism of the maintenance of AHS in the environment is uncertain. The short incubation period accompanied by the high mortality rate in horses and mules make it unlikely that these animals can serve as effective reservoirs for maintaining the virus.
  - Continuous transmission between zebras and *Culicoides* midges was demonstrated in South Africa in Kruger National Park. Thus large populations of zebras and donkeys are likely to be one of the major reservoirs of AHS.
  - Dogs have been shown to be susceptible to AHS when fed raw horse meat infected with AHS. Other populations of animals have yet to be investigated for their possible role in the maintenance of AHS.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Pulmonary ("dunkop"): Peracute form
- Cardiac ("dikkop"): Subacute form
- Mixed: Most common form
- Horse sickness fever: Mildest form

HISTORY, CHIEF COMPLAINT Horses may present with a variety of clinical signs depending on the form of disease. These include a fever of 102° to 106° F, depression, supraorbital edema, and respiratory distress.

PHYSICAL EXAM FINDINGS

- Pulmonary/dunkop form: The peracute form of AHS appears in naive animals and is the most severe form of AHS, with a 95% mortality rate. The incubation period is 3 to 4 days. There is a sudden onset of a high fever (104°–106° F) with tachypnea (>50 beats/min) and dyspnea marked by expiratory distress and a heave line. Profuse sweating, coughing, and recumbency usually follow with a frothy to serosanguineous nasal discharge. The onset of dyspnea is usually followed by death within a few hours. The clinical course of this form of the disease lasts only a few days.
- Cardiac/dikkop form: The subacute form of AHS has a 50% mortality rate with an incubation period of 5 to 7 days. A fever (102°–106° F) that persists for 3 to 4 days first appears. After the fever begins to subside, supraorbital edema appears and is quickly followed by nondependent edema of the head and neck. Dyspnea and cyanosis may occur as a result of the edema. Signs of colic may be present. Petechiations (conjunctiva and ventral tongue) are a poor sign, and death usually follows. The clinical course of this form of the disease lasts 3 to 8 days.
- Mixed form: This is the most common form of AHS and has a 70% average mortality rate. A fever (102°–106° F) develops that persists for 1 to 4 days. Two courses of the disease may then develop. In the first, mild pulmonary signs are followed by edema and cardiac failure. In the second, edema and subclinical cardiac disease are followed by the sudden onset of dyspnea, nasal discharge, and death. The clinical course of this form of the disease lasts 3 to 6 days.
- Horse sickness fever: This is the mildest form of AHS and the form that usually appears in zebras and donkeys, with an incubation period of 5 to 9 days. There is a gradual increase in temperature to 104° F over 4 days and then a return to normal. Mild clinical signs of the cardiac and pulmonary forms may occur.

ETIOLOGY AND PATHOPHYSIOLOGY

- AHS is a double-stranded, nonenveloped RNA virus in the genus *Orbivirus*, family Reoviridae.
- Closely related to blue-tongue virus and equine encephalosis virus.
- Has seven structural (VP1-7) and three nonstructural (NS1-3) proteins.
  - VP2 is responsible for antigenic variation.
  - VP7 and NS3 are important in vaccination.
- Nine serotypes have been identified.
  - Most types are restricted to sub-Saharan Africa.
  - Types 4 and 9 are responsible for most outbreaks outside sub-Saharan Africa.
  - Types 5 and 9 are neurotropic.
  - Cross-protection occurs between serotypes.
- Initial infection occurs through the bite of an infected *Culicoides*.
  - Replication occurs in the local lymph nodes.
  - A primary viremia occurs, leading to the dissemination of the virus to

ElibeVet.com

target organs (lungs, spleen, lymphoid tissue, cecum, pharynx, choroid plexus).
    - Replication of AHS then occurs in the endothelial cells of the target organs, leading to edema and effusions.
    - A secondary viremia then occurs with fever and clinical signs.
- Horses have an average viremia of 4 to 8 days (≤21 days) with a $TCID_{50}$ of 10^5 PFU/mL.
- Zebras have an average viremia of 21 days (≤40 days) with a $TCID_{50}$ of 10^3 PFU/mL.
- Gross pathologic changes include:
    - Heavy, noncollapsible lungs
    - Yellow, gelatinous edema of the subcutaneous and intramuscular tissue
- Especially the nuchal ligament: Edema
- Lungs, supraorbital fossae, head, neck, thorax
    - Hydrothorax
    - Hydropericardium
    - Diffuse hemorrhage and petechiation
    - Lymphadenomegaly

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine encephalosis: Foreign animal disease not yet documented in North America
- Equine infectious anemia (EIA)
- *Streptococcus equi* subsp. *equi*: Strangles, bastard strangles, purpura hemorrhagica
- Piroplasmosis
- Equine viral arteritis
- Influenza
- Equine herpesviruses (EHV-1 and EHV-4)
- Bacterial pneumonia
- Pleuropneumonia
- Interstitial pneumonia
- Infectious heart disease: endocarditis, myocarditis, pericarditis
- Congestive heart failure

INITIAL DATABASE

- Complete blood count
    - Leukopenia
    - Thrombocytopenia
    - Increased packed cell volume
- Clotting tests
    - Increased fibrin degradation products
    - Prolonged prothrombin
    - Prolonged activated partial thromboplastin
    - Prolonged thrombin

ADVANCED OR CONFIRMATORY TESTING

- Viral isolation:
    - Cell culture
    - Intracerebral inoculation of suckling mice
- Serotyping of virus:
    - Virus neutralization
    - Complement fixation
    - Agar gel immunodiffusion
    - Indirect fluorescence antibody
    - Enzyme-linked immunosorbent assay (ELISA)
    - Polymerase chain reaction (RT-PCR)
- Antibody testing: ELISA
- Antigen testing:
    - ELISA
    - RT-PCR

TREATMENT

THERAPEUTIC GOAL(S)

Supportive care

ACUTE GENERAL TREATMENT

- Treatment should be aimed at making the horse comfortable with appropriate supportive care.
- It is extremely important that all affected equids are rested because exertion can lead to death. This rest should continue for at least 1 month after the cessation of clinical signs.

PROGNOSIS AND OUTCOME

- The prognosis for recovery from infection from AHS depends on the form that the equine contracts. In general, donkeys, horses, and mules from endemic areas have a much better prognosis for survival. Naive horses and mules have a moderate to poor prognosis depending on the form of AHS contracted.
- For the pulmonary or peracute form, there is a 5% chance of survival; for the cardiac or subacute form, there is a 50% chance of survival; and for the mixed form, there is a 30% chance of survival.

PEARLS & CONSIDERATIONS

COMMENTS

AHS is an OIE-reportable disease. Any suspect case in North America should be immediately reported to the United States Department of Agriculture (USDA).

PREVENTION

- Vaccination
    - Annually in endemic areas
    - Onderstepoort Laboratories (attenuated) in two components that should be administered 3 weeks apart
        - Trivalent: Serotypes 1, 3, and 4
        - Quadrivalent: Serotypes 2, 6, 7, and 8 (cross-protection for serotypes 5 and 9)
- Vector control
    - Stable 1 hour before dusk to 1 hour after dawn
    - Move only during daylight
    - Cover with day sheets
    - Apply insect repellant daily
    - Take rectal temperatures twice a day
    - Stable in insect-free stalls
- Decontamination:
    - Effective disinfectants: Virkon, acetic acid, bleach, formalin, β-propiolactone, acetyl-ethyleneimine derivatives
    - Susceptible to radiation
- Quarantine and import regulations by the USDA: All equids from AHSV endemic countries must have:
    - Resided in the country of interest for 60+ days
    - During this time found to be free of disease
    - Not been vaccinated in the 14 days before export
    - Not been on premises where AHSV has occurred in the 60 days preceding export
- Upon shipment to the United States, equines from countries with endemic AHSV must be quarantined for 60 days and watched for signs of illness.

ElibeVet.com

Aggressive Stallion Behavior

BASIC INFORMATION

DEFINITION

- Aggressive behavior is defined as the overt display of dangerous reactions that may endanger people or other animals.
- Aggressive behavior by the stallion toward itself is possible and is discussed under self-mutilation.

SYNONYM(S)

Unruly stallions, rowdy stallions

EPIDEMIOLOGY

RISK FACTORS

- Poor training or handling
- Housing conditions (proximity to other breeding stallions)
- Lack of exercise
- Conditions associated with high testosterone
- Proximity to other stallions or estrous mares

GEOGRAPHY AND SEASONALITY Aggressive behavior may be exacerbated during the breeding season.

ASSOCIATED CONDITIONS AND DISORDERS Cryptorchidism, interstitial cell tumors (increased testosterone secretion)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of recent introduction to the breeding shed
- History of abusive treatment
- Most common complaints:
  - Biting, kicking, or striking at the handler or mare
  - Rushing or charging the mare or dummy

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause is often multifactorial.
- The pathophysiology is often considered to involve either a high level of testosterone or a complex chain of behavioral responses to specific conditions.
- Most of these cases are exacerbated by inadequate training.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Progressively worsening or sudden development of aggressive behavior in stallions may reflect a painful condition associated with the genital tract such as abdominal or inguinal testicles, painful erection, or pelvic or back pain during breeding.

INITIAL DATABASE

- Detailed examination of the genital system.
- Measurement of serum testosterone levels may be helpful.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce the behavior through stallion and handler training.
- Reduce the urge to rush.
- Reduce the testosterone level.

ACUTE GENERAL TREATMENT

- Adequate training of the handler and stallion
  - Avoid explosive punishment if the stallion displays overt reactions, kicks, or rears.
  - Use calm estrous mares during training.
  - Work in several short sessions with the stallion.
  - Use appropriate negative reinforcement (verbal reprimands, shank chain pressure, occasional slaps on the shoulders).
  - Use positive reinforcement.
  - Keep terms, cues, and the environment consistent.
- Reduce the desire to rush.
  - Provide exercise.
  - Allow several breedings in rapid succession.
- Medical treatment is aimed at reducing testosterone or the libido and may be useful in nonbreeding stallions.
  - Immunization against gonadotropin-releasing hormone: Equity (Pfizer Animal Health; not available in the United States)
  - Progestogen: Altrenogest (0.088 mg/kg PO q24h)

POSSIBLE COMPLICATIONS

Stallions may become extremely dangerous if the situation is not handled properly.

RECOMMENDED MONITORING

Avoid changes in handlers and breeding routine.

PROGNOSIS AND OUTCOME

Very good in the majority of stallions

PEARLS & CONSIDERATIONS

COMMENTS

- Most of these problems are created by handlers.
- Knowledge of normal behavior of stallions in free mating as well as in-hand mating situations is paramount in understanding sexual behavioral alterations.
- Judicious use of disciplinary action is very important, particularly in stallions that are used for breeding and are still performing.

PREVENTION

Proper handling and socialization at a young age

CLIENT EDUCATION

- Stallion handling is a skill that requires a thorough understanding of stallion behavior and proper use of discipline.
- Avoid rough or excessive discipline of stallions during performance.
- Use judicious behavioral modification techniques to train stallions.

EDITOR: **JUAN C. SAMPER**

ElibeVet.com

Airway Obstruction, Recurrent

BASIC INFORMATION

DEFINITION

- A respiratory disease more frequently seen in middle-aged to older adult horses that is characterized clinically by recurrent episodes of airway obstruction when horses are exposed to organic dust or other particulate matter.
- Horses exhibit severe coughing and exaggerated respiratory effort that is more evident on expiration than inspiration. These attacks are initiated by an influx of neutrophils into the airways and by bronchoconstriction associated with excessive mucus and airway smooth muscle. At least in the initial stages, attacks of airway obstruction can be reversed by environmental remediation.

SYNONYMS

Chronic obstructive pulmonary disease (COPD), heaves, chronic bronchiolitis, bronchitis

EPIDEMIOLOGY

Middle-aged to older Equids

GENETICS AND BREED PREDISPOSITION There is evidence for a familial basis in Lipizaners and Warmbloods for recurrent airway obstruction (RAO), although the precise mode of inheritance is unknown.

RISK FACTORS Living in barns, exposure to organic dusts or moldy hay

GEOGRAPHY AND SEASONALITY

- Typically affects animals that have spent most of their lives in barns eating hay and housed in dusty environments.
- It is also seen in summer months when pastures are very dry or when there is excessive mold bloom in the pastures.

ASSOCIATED CONDITIONS AND DISORDERS Horses with RAO are predisposed to pulmonary hypertension.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Typically presents initially with a seasonal cough that worsens over a period of years.
- As the disease progresses, the cough is accompanied by tachypnea and evident respiratory distress.
- During an exacerbation of more severe disease, the horse will have flared nostrils and evident abdominal press seen more in expiration but also evident on inspiration.
- Hypertrophy of the expiratory muscles may result in a "heaves line."
- A marked nasal discharge is usually seen, ranging from serous to mucopurulent.
- Horses in advance stages of disease may be cachectic because their work of breathing exceeds their ability to eat.
- There is no history of fever.

PHYSICAL EXAM FINDINGS

- Physical examination findings usually are concordant with the above history. A moderate tachycardia may also be auscultated.
- Thoracic auscultation may reveal either loud bronchovesicular sounds or widely dispersed crackles and wheezes.
- In very severe cases, the lungs may be strangely silent because of the very small amount of airflow that the animal is able to achieve. In these cases, auscultation of the trachea is compatible with the presence of mucus.
- Lung fields are often enlarged because of air trapping, so percussion will reveal larger than normal lung fields.

ETIOLOGY AND PATHOPHYSIOLOGY

- RAO is akin to environmentally induced asthma in humans in that it is caused by chronic exposure to organic and inorganic dusts.
- Organic dusts are replete with endotoxin, β-glucans from mold, and various allergens. This exposure results in an outpouring of neutrophils into the horse's airways.
  - With acute exposure, there is endoscopically visible edema in the airways.
  - With chronic exposure, there is increased mucus production and poorer mucus clearance as well as airway wall remodeling, with smooth muscle hyperplasia and hypertrophy, peribronchial inflammation, and fibrosis. The combination of airway wall remodeling and increased responsiveness of the airway smooth muscle to various stimuli results in bronchoconstriction. It is unclear to what extent an allergic response is involved.
- Cytokine profiles in horses with RAO are not consistent, with some associated with a Th1 and others with a Th2 (allergic) response. The most likely explanation is that this is a very complex disease that develops differently in horses with differing genetic backgrounds and levels of exposure to particulates.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Septic bronchitis
- Pneumonia
- Chronic interstitial diseases
- Toxicoses, including inhaled toxins (silicosis, various gases) as well as systemically ingested substances such as perilla mint
- Neoplastic disease, including primary tumors of the respiratory tract or, more commonly, distant metastases

INITIAL DATABASE

- Complete blood count and serum chemistry profile usually demonstrate no abnormalities.
- Arterial blood gas analysis reveals hypoxemia during exacerbation. Depending on the severity of the disease, $PaCO_2$ may be normal or elevated. The abnormalities in blood gas will be commensurate with the severity of the disease.
- Airway sampling is best done by bronchoalveolar lavage. Normal horses have no more than 10% neutrophils in the bronchoalveolar (BAL) fluid, and the ratio of alveolar macrophages to lymphocytes is approximately 60:40.
  - Neutrophils commonly comprise 50% to 100% of the BAL fluid cytology. The neutrophils are generally nondegenerate, and there is no evidence of bacterial infection.
  - Mucus is often prominent and fibrillar. Large amounts of neutrophils are commonly trapped within the mucus.
  - Although a transtracheal aspirate may also be performed to evaluate the airways, it does not reliably reflect the lower airways.
- Lung function testing reveals increased pleural pressures, reflecting the elevated work of breathing, as well as increased pulmonary and respiratory resistance and dynamic compliance. Lung function testing is not necessary for making a diagnosis in an exacerbation of RAO.
  - Noninvasive methods of lung function testing, such as open plethysmography or forced oscillatory maneuvers, can be very useful in determining whether the horse has a normal response to bronchodilators.
  - In horses in remission, lung function testing is used in conjunction with histamine bronchoprovocation to probe the status of the small

ElibeVet.com

airways. In this procedure, small amounts of histamine are given while lung function is measured. Horses in remission are difficult to distinguish from normal horses on the basis of resting tests; however, horses in remission respond to much lower doses of histamine with a rapid increase in respiratory resistance.

ADVANCED OR CONFIRMATORY TESTING

- Radiography can be very helpful in determining whether disease is complicated (eg, whether there is coexisting bronchiolitis or pneumothorax caused by a ruptured bulla).
- Lung biopsy or bronchial biopsy reveals typical changes such as goblet cell and airway smooth muscle hyperplasia, as well as peribronchial fibrosis. Although a diagnostic sample is not always obtained with bronchial biopsy, it is associated with less risk than lung biopsy (eg, hemorrhage, pneumothorax).

TREATMENT

THERAPEUTIC GOALS

Treatment of RAO is three-pronged: effect bronchodilation, reduce inflammation, and remediate the environment.

ACUTE GENERAL TREATMENT

- The immediate goal of treatment in the face of RAO exacerbation is bronchodilation. This is best achieved by using a quickly acting β-adrenergic drug such as albuterol (5 puffs) via inhaler using a device such as the Aero-Hippus. If albuterol is not available, atropine may also be given IV (0.01–0.02 mg/kg); however, this treatment may induce ileus.
- Bronchodilation alone does not address the underlying problem, which is the reduction of inflammation. Therefore treatment with a corticosteroid should be initiated. Most horses in exacerbation require parenteral use of corticosteroids initially followed by inhaled corticosteroid therapy.
  - Multiple different glucocorticoids have been used for treatment of horses with RAO. The most commonly used are dexamethasone PO, IV, or IM (0.1 mg/kg) once daily for 5 to 7 days with a gradual reduction over 2 to 4 weeks and prednisolone (0.8 mg/kg) PO twice daily for 1 week, tapering gradually over 4 weeks.
  - The most commonly used inhaled glucocorticoids include fluticasone (Flovent 220) beginning with 9 to 12 puffs twice daily or QVAR (8 to 10 puffs twice daily) using the Aero-Hippus, with a gradual reduction over 2 to 3 weeks. A reasonable aim is to have the horse on an every other day treatment within 4 weeks. Inhaled glucocorticoids are expensive and not within the financial realm of all owners.

CHRONIC TREATMENT

Longer term goals involve reduction of inflammation through environmental remediation.

- This involves turnout in a nondusty paddock or if the horse cannot be turned out, reducing the dust in bedding and feed.
- Useful approaches include using a pelleted diet, ensiled hay (haylage), dengie (baked hay), or if this is not possible, soaking the hay for at least 1 hour.
- Although clean, bright straw has been shown to be low in organic dusts, it is very difficult to find.
- Pelleted bedding and shredded cardboard or paper are the lowest in dusts.
- Dust in the air is highest when there is a lot of human activity, especially during cleaning and feeding times, so ideally, horses are removed from the stable at that time.
- The first approach to dust is to dampen or sprinkle the aisleways with water before watering, and make sure that indoor and outdoor arenas are kept moist to reduce dust.

RECOMMENDED MONITORING

BAL and lung function testing 1 month after initiating treatment with corticosteroid is valuable in monitoring progress and response to drugs and environmental remediation.

PROGNOSIS AND OUTCOME

- Prognosis for uncomplicated RAO is good provided that vigorous efforts at environmental remediation are made and there is good compliance with the treatment plan.
- In long-standing disease, it is unlikely that chronic remodeling of the airways will ever be reversed; these horses may have respiratory compromise even in the face of appropriate management.

PEARLS & CONSIDERATIONS

Interstitial pneumonia of donkeys has recently been linked to asinine herpesvirus-2 and -5. The exact role of γ-herpesviridae in Equids is still unclear.

Algal Toxicosis

BASIC INFORMATION

DEFINITION

Acute intoxication of the liver (microcystin) or central nervous system (anatoxins) subsequent to algal toxin exposure

SYNONYM(S)

- Microcystin toxicosis
- Anatoxin-a toxicosis
- Blue-green algae intoxication
- Cyanobacteria toxicosis

EPIDEMIOLOGY

RISK FACTORS

- Algal bloom prevalence is increased with elevated water temperature and nutrient concentrations in the water.
- Steady winds that propel toxic blooms to shore allow ingestion by drinking animals.

ElibeVet.com

GEOGRAPHY AND SEASONALITY
More common in the summer and fall when water temperature is increased

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute hepatotoxicosis subsequent to microcystin exposure
- Acute onset of neurologic signs subsequent to anatoxin-a exposure
- Rapid onset of excessive salivation and neurologic signs subsequent to anatoxin-a(s) exposure

HISTORY, CHIEF COMPLAINT

- Microcystins: diarrhea and weakness within hours of exposure to water
- Anatoxin-a: rapid onset of muscle rigidity, muscle tremors, and convulsions within minutes to a few hours of exposure to water
- Anatoxin-a(s): rapid onset of excessive salivation, diarrhea, tremors, and convulsions within minutes of exposure to water

PHYSICAL EXAM FINDINGS

- Microcystins: microcystin intoxication should be suspected in cases of acute hepatotoxicosis with clinical signs of diarrhea, nasogastric reflux, weakness, pale mucous membranes, and shock. Although most animals die within a few hours of exposure, some animals may live for several hours and develop hyperkalemia, hypoglycemia, nervousness, recumbency, and convulsions. Animals that survive the acute intoxication may develop hepatogenous photosensitization.
- Anatoxin-a: clinical signs of anatoxin-a poisoning include a rapid onset of rigidity and muscle tremors followed by paralysis, cyanosis, and death. Death usually occurs within minutes to a few hours. In most cases, the animal is found dead.
- Anatoxin-a(s): animals poisoned with anatoxin-a(s) show a rapid onset of excessive salivation ("s" stands for salivation), lacrimation, diarrhea, and urination. Nicotinic overstimulation results in tremors, incoordination, convulsions, recumbency, and respiratory arrest. Animals often die within 30 minutes of exposure and thus are often found dead.

ETIOLOGY AND PATHOPHYSIOLOGY

- Microcystins are cyclic heptapeptides that inhibit protein phosphatases, which leads to hepatocyte necrosis. There are more than 80 different microcystins worldwide produced by various genera of cyanobacteria, such as *Microcystis*, *Anabaena*, *Planktothrix*, *Nostoc*, *Oscillatoria*, and *Anabaenopsis*.
- Anatoxin-a is a potent cholinergic agonist at nicotinic acetylcholine receptors in neurons and at the neuromuscular junctions. Anatoxin-a is produced worldwide by cyanobacteria genera such as *Anabaena*, *Plantkothrix*, *Oscillatoria*, *Microcystis*, *Aphanizomenon*, *Cylindorspermum*, and *Phormidium*.
- Anatoxin-a(s) is a naturally occurring irreversible acetylcholinesterase inhibitor produced by cyanobacteria species such as *Anabena flosaquae*, *Anabena lemmermannii*, and *Anabena spiroides*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Microcystins: other causes of acute liver failure such as iron, amanitins, aflatoxins, cocklebur, alsike clover, Theiler's disease, and Tyzzer's disease
- Anatoxin-a: cyanide, yew, oleander, poison hemlock, insecticides, ionophore antibiotics, intestinal compromise (eg, torsion)
- Anatoxin-a(s): organophosphorus and carbamate insecticides, slaframine

INITIAL DATABASE

- Microcystins: elevated serum gamma-glutamyl transpeptidase, aspartate aminotransferase, bile acids, alkaline phosphatase; hypoglycemia; hyperkalemia
- Anatoxin-a and a(s): no abnormalities

ADVANCED OR CONFIRMATORY TESTING

Confirmatory testing is needed to reach an accurate diagnosis of algal intoxication.

- Identification of the algae in the suspect water source or stomach contents. However, positive identification does not confirm intoxication because the toxicity of the cyanobacteria is strain specific, and morphologic observations alone cannot predict the hazard level.
- Detection of microcystins and anatoxin-a in water and gastric contents is provided by select veterinary toxicology laboratories.
- Detection of anatoxin-a(s) in water and gastric contents can also be provided by select laboratories. In addition, determination of blood acetylcholinesterase activity can aid in the diagnostic workup.

TREATMENT

THERAPEUTIC GOAL(S)

There is no specific antidote for algal toxins. Despite the evaluation of numerous treatment options, no specific therapy has been proven to be effective.

ACUTE GENERAL TREATMENT

- Provide symptomatic and supportive care to treat hypovolemia and electrolyte imbalances.
- Although no studies have evaluated the efficacy of specific decontamination procedures, administration of activated charcoal has been recommended.
- Microcystins: because microcystins can enhance oxidative stress, antioxidants such as vitamin E and selenium appear to be beneficial.
- Anatoxin-a: seizure control with benzodiazepine, phenobarbital, or pentobarbital.
- Anatoxin-a(s): atropine should be given. Determine its efficacy in animals with life-threatening clinical signs with an initial test dose. After the test dose, atropine can be given repeatedly until cessation of salivation.

CHRONIC TREATMENT

Protect from sun exposure if hepatogenous photosensitization develops subsequent to microcystin intoxication.

POSSIBLE COMPLICATIONS

In many cases, the rapid onset of acute intoxication does not allow timely therapeutic intervention, and mortality rates are high.

RECOMMENDED MONITORING

Close monitoring of serum electrolytes, liver function, body temperature, and central nervous system signs

PROGNOSIS AND OUTCOME

- Prognosis is poor. Animals with algal toxin intoxication are often found dead.
- Animals that survive acute microcystin intoxication may develop photosensitization.

PEARLS & CONSIDERATIONS

COMMENTS

- Algal toxin exposure in horses is rarely reported but may result in acute liver disease or neurologic signs. Mortality rates are high.
- Proper diagnostic workup of suspect blue-green algae poisoning cases is necessary to prevent additional exposures.
- Therapeutic measures are limited, so it is prudent to take measures for avoiding exposure to algal toxins.
- Worldwide, the frequency and intensity of harmful cyanobacterial blooms appear to be increasing, and it is likely

ElibeVet.com

that blue-green algae poisonings will become more common in animals as a result of accidental exposure.

PREVENTION

- Deny horses access to water with visible algal bloom.
- Reduce fertilizer run-off and applications in fields surrounding ponds used for drinking water.

CLIENT EDUCATION

- The increased incidence of blue-green algal blooms is partly a consequence of nutrient pollution.
- Inform clients that prognosis is poor for animals exposed to algal toxins.

Alopecia Areata

BASIC INFORMATION

DEFINITION

A cell-mediated autoimmune disorder resulting in round patches of hair loss

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION A hereditary factor has been suggested.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Acute or insidious onset of patches of hair loss

PHYSICAL EXAM FINDINGS

- Focal or multifocal, noninflammatory, well-circumscribed, annular areas of hair loss. Areas of hair regrowth may be lighter than normal.
- Thinning of the mane and tail.
- The animal is otherwise healthy.

ETIOLOGY AND PATHOPHYSIOLOGY

T-lymphocyte disruption of the hair matrix, root sheath, and epithelium of the hair follicles

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Dermatophytosis
- Dermatophilosis
- Anagen defluxion
- Occult sarcoid

ADVANCED OR CONFIRMATORY TESTING

Histopathologic examination of skin biopsy shows accumulation of lymphocytes around the hair bulbs, the presence of "miniature" hair follicles, and possibly defective keratinization (chronic lesions).

PROGNOSIS AND OUTCOME

Spontaneous recovery has been recorded.

Alphaviruses

BASIC INFORMATION

DEFINITION

The Togaviridae include the major causes of infectious arthropod-borne equine encephalitides and are divided into two main groups: the Alphaviridae—including Eastern equine encephalitis (EEE), Western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE)—and the Flaviviridae, including West Nile virus (WNV).

SYNONYM(S)

EEE, WEE, and VEE viruses are members of the *Alphavirus* genus of the family Togaviridae and were formerly referred to as Arbovirus group A of the Togaviridae.

EPIDEMIOLOGY

SPECIES, AGE, SEX Generally any age or breed and either sex. Disease is uncommon in suckling foals younger than 3 months.

RISK FACTORS

- Lack of protective vaccination. Widespread vaccination programs in North America have markedly reduced incidence of EEE and WEE.
- Disease is limited to the summer in temperate regions but is year-round in subtropical to tropical areas.

CONTAGION AND ZOONOSIS

- Although these viruses cause similar clinical syndromes in horses, the consequences of the infections they cause in humans differ.
- EEE is the most severe of the arboviral encephalitides, with case fatality rates of 50% to 70% and neurologic sequelae common in survivors.
- WEE virus appears to be less neuroinvasive but has pathology similar to EEE in patients with encephalitis.
- In adults, the VEE virus usually causes an acute, febrile, incapacitating disease with prolonged convalescence. In children, severe encephalitis may result from VEE.

GEOGRAPHY AND SEASONALITY

- As with most of the alphaviruses, EEE, WEE, and VEE are transmitted by mosquitoes and maintained in cycles with various vertebrate hosts. Environmental factors that affect the interactions of the relevant mosquito and reservoir host populations control the natural epidemiology of these viruses. Some overlap of geographic extent exists.

ElibeVet.com

- Outbreaks of EEE virus have occurred in most eastern states and in southeastern Canada but have been concentrated along the eastern and Gulf coasts.
- Outbreaks of WEE have been reported in the western and north-central United States, as well as Saskatchewan and Manitoba in Canada. Predominates west of the Mississippi River.
- VEE was originally reported in Venezuela, Colombia, Peru, and Ecuador before spreading to all of Central America and subsequently continuing north to Mexico and into Texas. Between active epizootics, it is not possible to isolate the equine virulent viruses with several attenuated, antigenically different VEE strains isolated instead. These enzootic strains can be differentiated among themselves and from the epizootic strains.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- EEE, WEE, and VEE present with similar clinical signs, including an inapparent, generalized febrile response.
- Encephalomyelitis may occur singly or in combination.
- Horses may present with colic or vague signs of diffuse brain involvement.

PHYSICAL EXAM FINDINGS

- Clinical signs not pathognomonic
- Fever associated with viremia in majority of infected horses
- Initial hyperexcitability, progressing to depression and recumbency
- Blindness
- Head pressing
- Ataxia
- Compulsive walking, circling
- Seizure activity
- Permanent neurologic deficits may occur in survivors
- Early neurologic signs reflect diffuse, multifocal cortical disease
- Mortality ranges from 75% to 90% for EEE, 19% to 50% for WEE, and 40% to 90% for VEE

ETIOLOGY AND PATHOPHYSIOLOGY

- Birds are the primary reservoir for EEE, WEE, and VEE. Transfer of infection depends on an interplay between migratory bird patterns and vector seasonal population fluctuations. EEE may be found year-round in the southeastern United States. Small rodents can harbor VEE.
- Virus replication occurs within arthropod vector (mosquitoes *Culex*, *Aedes*, *Anopheles*, and *Culiseta*).
- After inoculation into the equine host, local replication occurs in the subcutaneous tissue at the site of inoculation.
- Lymphatic spread to the spleen and liver.
- Short-lived viremia ensues in the majority of infected animals. Viremia of EEE and WEE is too low to infect vectors, so the horse is a dead-end host. However, VEE titers are sufficient to infect vectors.
- In a small number of infected horses, the blood-brain barrier is crossed and encephalomyelitis results.
- Infected EEE and WEE horses do not cause direct or indirect lateral spread.
- Widespread neuronal necrosis throughout the central nervous system, especially the cerebrum.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bacterial encephalomyelitis
- Hepatic encephalopathy
- Equine protozoal myeloencephalitis
- Rabies
- WNV
- Verminous encephalomyelitis
- Diffuse brain trauma

INITIAL DATABASE

- Cerebrospinal fluid: Neutrophilic pleocytosis, increased protein; may be xanthochromic
- Antibodies: Detection of IgM or IgG in serum. May already have high levels in acute sera, complicating diagnosis by a fourfold increase between acute and convalescent sera.

ADVANCED OR CONFIRMATORY TESTING

- Histology
  - EEE: Neutrophilic-endothelial cuffing
  - WEE: lymphocytic-plasmocytic
  - VEE: Lymphocytic-neutrophilic
- Gross pathology: Cerebral malacia, patchy hemorrhage, swelling
- Brain: Viral culture, antigen and antibody detection

TREATMENT

THERAPEUTIC GOAL(S)

Treatment for the alphavirus encephalitides is centered on the control of central nervous system inflammation and supportive therapies.

ACUTE GENERAL TREATMENT

- Antiinflammatories: Nonsteroidal antiinflammatory drugs are preferred over corticosteroids by some veterinarians.
- Dimethyl sulfoxide: 1 g/kg IV as 10% solution
- Seizure control: Benzodiazepines
- Intensive supportive therapies: IV fluids, nutrition, general nursing
- Antimicrobial therapy for secondary bacterial infections (if present)

CHRONIC TREATMENT

- Management of secondary complications: Recumbency, aspiration pneumonia, decubital ulcers
- Avoidance of self-trauma during encephalitic phase or as a result of residual deficits

POSSIBLE COMPLICATIONS

- Decubital ulceration
- Self-mutilation
- Aspiration pneumonia
- Residual neurologic deficits: Ataxia, depression

PROGNOSIS AND OUTCOME

- Unvaccinated horses are likely to succumb to infection.
- Prognosis is poor with the onset of encephalitic signs.
- Grave prognosis for EEE and VEE. Survival in EEE is reported with previous but insufficient vaccine exposure, resulting in a modified disease with slow progression and spinal cord or brainstem lesions.
- WEE survival is occasionally reported with permanent neurologic deficits (depressed mentation, spinal ataxia).

PEARLS & CONSIDERATIONS

COMMENTS

- Vaccinate horses in the face of outbreak: Antibody increase noted 3 days after vaccination
- If VEE vaccination is required, use trivalent vaccine because the response is poorer in horses previously vaccinated against EEE and WEE.

PREVENTION

- Inactivated vaccines are available and highly efficacious. The duration of immunity is short (4–6 months), which may be less than vector season; repeated vaccinations are therefore necessary. Four monthly vaccinations may be necessary in areas where disease is common.
- Vaccinate in early spring and summer. Time the program to precede the encephalitis season by several months.
- Vaccinate pregnant mares 1 month before foaling to boost colostral protection of the foal; antibody persists up to 6 months.
- Vaccination can begin at any age; must repeat after 6 months of age.
- Vector control: Removal of mosquito breeding areas (stagnant water).

EDITOR: **STEPHEN M. REED**

Amanitin Toxicosis

BASIC INFORMATION

DEFINITION

Acute hepatotoxicity subsequent to amanitin-containing mushroom exposure

SYNONYM(S)

- Amanita toxicosis
- Death cap intoxication
- Amatoxin poisoning
- Hepatotoxic mushroom poisoning
- Amanitin poisoning

EPIDEMIOLOGY

GEOGRAPHY AND SEASONALITY

Amanita phalloides mushrooms are found throughout North America, commonly in association with oaks and birch. The large fruiting bodies appear in the summer and fall. Local mycologic societies can provide detailed information on the occurrence of toxic mushrooms in certain regions.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Severe gastrointestinal (GI) signs such as colic and diarrhea
- Acute hepatotoxicosis
- Fulminant multiorgan failure

HISTORY, CHIEF COMPLAINT

- Colic and diarrhea within 24 hours of amanitin-containing mushroom exposure
- Lethargy, icterus, ataxia, seizures, and coma approximately 36 to 48 hours after exposure to amanitins

PHYSICAL EXAM FINDINGS

- The clinical course of amanitin exposure can be divided into four phases. Physical examination findings are different for each phase.
  - The initial phase is a latency period of approximately 8 to 12 hours without any clinical signs after ingestion of amanitin-containing mushrooms.
  - During the second phase (6 to 24 hours after mushroom ingestion), the animal develops severe GI signs such as colic and diarrhea.
  - The third phase is a period of several hours to a few days during which the animal appears to have recovered. During this phase, close monitoring of liver and kidney function is essential to prevent misdiagnosis.
  - The final stage begins approximately 36 to 84 hours after exposure to amanitins. In this stage, fulminant liver, renal, and multiorgan failure may occur, and affected animals may be icteric, lethargic, and ataxic and have seizures or coma. If large amounts of amanitin-containing mushrooms were ingested, it is feasible that the animal will die acutely within 24 hours and may simply be found dead.

ETIOLOGY AND PATHOPHYSIOLOGY

- Amanitins (α-, β-, γ-, and ε-amanitins) are bicyclic octapeptides and are found in three different mushroom genera: *Amanita*, *Galerina*, and *Lepiota* spp.
- The most toxic cylopeptide-containing mushrooms are *A. phalloides*, the ubiquitous "death cap" or "death angel," and *Galerina sulpices*. *A. phalloides* is found throughout North America, commonly in association with oaks and birch. *G. sulpices* is most commonly found in Europe.
- Amanitins inhibit nuclear RNA polymerase II, ultimately leading to decreased protein synthesis and cell death.
- Cells with a high metabolic rate, such as hepatocytes, crypt cells, and proximal convoluted tubules of the kidneys, are most commonly affected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of acute liver failure: iron, microcystins, aflatoxins, cocklebur, alsike clover, Theiler's disease, and Tyzzer's disease
- Other causes of gastroenteritis

INITIAL DATABASE

Approximately 24 hours after exposure: Elevated serum gamma-glutamyl transpeptidase, aspartate aminotransferase, bile acids, alkaline phosphatase, total bilirubin; hypoglycemia; prolonged prothrombin time, and partial thromboplastin time.

ADVANCED OR CONFIRMATORY TESTING

Confirmatory testing is needed to reach an accurate diagnosis of amanitin intoxication:

- Identification of mushroom pieces in gastric contents. Accurate mushroom identification requires consultation with an experienced mycologist and may include DNA sequencing.
- Detection of amanitins in the serum, urine, gastric contents, liver, or kidney: This testing is provided by select veterinary toxicology laboratories. In live symptomatic animals, urine is likely to be of superior diagnostic use to serum. Postmortem, the kidney contains higher concentrations than the liver and is considered the sample of choice.

TREATMENT

THERAPEUTIC GOAL(S)

- Close monitoring, fluid replacement, and supportive care are essential treatment components in amanitin poisoning.
- Even with supportive measures, the reported mortality rate from *Amanita* poisoning in humans is 20% to 40%. No data on horses are available, but amanitin intoxication requires prompt and aggressive treatment measures to improve prognosis.

ACUTE GENERAL TREATMENT

- Close monitoring and fluid replacement. There is no specific antidote for amanitins. Despite the evaluation of numerous treatment options, no specific therapy has proven to be effective.
- As part of vigorous supportive care, IV fluids, correction of hypoglycemia and electrolyte imbalances, vitamin K1, and plasma transfusions should be considered, depending on the severity of the clinical presentation.
- There is controversy about the efficacy of activated charcoal.
- Silibinin (the main component of milk thistle) may be beneficial, but controlled studies are lacking.

ElibeVet.com

- *N*-acetylcysteine, cimetidine, and ascorbic acid may be given as antioxidants.

CHRONIC TREATMENT

If the animal survives all four phases of amanitin intoxication, close monitoring of liver and kidney function is necessary.

POSSIBLE COMPLICATIONS

- In many cases, the rapid onset of severe hepatotoxicosis does not allow for timely therapeutic intervention.
- Amanitin-containing mushrooms may initially cause GI signs followed by an apparent recovery. Therefore any animal presenting with GI signs after a suspected or known history of mushroom ingestion must be evaluated carefully and treated promptly.

RECOMMENDED MONITORING

Close monitoring of serum electrolytes, liver and kidney function, body temperature, and central nervous system signs

PROGNOSIS AND OUTCOME

Prognosis is poor. Animals with amanitin intoxication are often presented when severe liver damage has already occurred.

PEARLS & CONSIDERATIONS

COMMENTS

- Hepatotoxic mushroom ingestion in horses is rarely reported but may result in severe liver disease.
- Proper diagnostic workup of suspect amanitin poisonings is necessary to prevent additional exposures and to rule out other causes of acute liver disease.
- Therapeutic measures are limited, so it is essential to take measures to avoid exposing horses to toxic mushrooms.

PREVENTION

Deny horses access to areas where toxic mushrooms grow.

CLIENT EDUCATION

Inform clients that the prognosis is poor for animals exposed to toxic mushrooms. Inform clients that an accurate diagnostic workup is needed to confirm suspected amanitin exposure. Advise clients to contact local mycologic societies for occurrence of toxic mushrooms to prevent exposures.

AUTHOR: **BIRGIT PUSCHNER**

EDITOR: **CYNTHIA L. GASKILL**

Aminoglycoside Toxicosis

BASIC INFORMATION

DEFINITION

The aminoglycosides are large molecules with numerous amino acid groups, making them basic polycations that are highly ionized at physiologic pHs. These physical properties are important in their known toxicities: nephrotoxicity, ototoxicity, and neuromuscular blockade.

EPIDEMIOLOGY

SPECIES, AGE, SEX All ages and sexes are affected, but neonates and geriatrics are more at risk because of their reduced renal function.

RISK FACTORS

- Prolonged aminoglycoside therapy (>7–10 days)
- Acidosis and electrolyte disturbances (hypokalemia, hyponatremia)
- Volume depletion (shock, endotoxemia)
- Concurrent therapy with nephrotoxic drug (eg, nonsteroidal antiinflammatory drugs [NSAIDs]) or diuretics
- Preexisting renal disease
- Elevated plasma trough concentrations

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Nonoliguric renal failure
- Hearing loss
- Neuromuscular blockade

PHYSICAL EXAM FINDINGS Usually related to the original disease for which the aminoglycoside was being administered

ETIOLOGY AND PATHOPHYSIOLOGY

Nephrotoxicity is caused by accumulation of the drug in the renal tubular epithelial cells.

- Aminoglycosides enter the renal tubule after filtration through the glomerulus.
- Cationic aminoglycoside molecules bind to anionic phospholipids on the proximal tubular cells.
- The aminoglycoside is taken into the cell by carrier-mediated pinocytosis and translocated into cytoplasmic vacuoles, which fuse with lysosomes.
- With additional pinocytosis, drug continues to accumulate within the lysosomes.
- The accumulated aminoglycoside interferes with normal lysosomal function, and the overloaded lysosomes eventually swell and rupture.
- Lysosomal enzymes, phospholipids, and the aminoglycoside are released into the cytosol of the proximal tubular cell, disrupting other organelles and causing cell death.
- Neomycin is the most nephrotoxic, and streptomycin and dihydrostreptomycin are the least nephrotoxic.
- Amikacin is often recommended in critical patients over gentamicin because it is considered less nephrotoxic.

Ototoxicity:

- Occurs by the same mechanisms as nephrotoxicity
  - Not typically diagnosed in horses because of failure to identify partial hearing losses
- Toxicity varies with the drug
  - Vestibular damage (balance): Streptomycin, gentamicin
  - Cochlear damage (hearing): Amikacin, kanamycin, neomycin
  - Both: Tobramycin

Neuromuscular blockade:

- Rapid IV administration causes bradycardia, reduced cardiac output, and hypotension through an effect on calcium metabolism. These effects are of minor significance.
- Paralysis of skeletal muscles
  - A rare effect
  - From blockade of acetylcholine at the nicotinic cholinergic receptor

ElibeVet.com

- Most often seen when anesthetic agents are administered concurrently

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

NSAID-induced and other drug-induced renal failure

INITIAL DATABASE

- Serum chemistries
  - Increased serum urea nitrogen and creatinine (Cr) confirm nephrotoxicity but are not seen for 7 days after significant renal damage has occurred.
- Urine gamma glutamyl transferase (GGT) and Cr
  - The urine GGT and urine GGT/urine Cr ratio increase.
  - The urine GGT/urine Cr ratio may increase to two to three times baseline within 3 days of a nephrotoxic dose.
- Urinalysis
  - Proteinuria is the next best indicator of nephrotoxicity after the urine GGT/urine Cr ratio and is easily determined in a practice setting with urine dipstick tests.
  - Hyposthenuria, polyuria, hematuria, and cylindruria (presence of casts in the urine) may also be seen.

ADVANCED OR CONFIRMATORY TESTING

Histopathology of renal biopsy or postmortem samples: lesions of acute tubular necrosis

TREATMENT

THERAPEUTIC GOAL(S)

Aminoglycoside nephrotoxicity is best prevented by appropriate dosing and a high-protein, high-calcium diet.

ACUTE GENERAL TREATMENT

- Discontinuation of aminoglycoside therapy
- Nephrotoxicity
  - Diuresis with balanced IV fluids and correction of metabolic acidosis and electrolyte abnormalities.
  - Although peritoneal dialysis is useful in lowering Cr and serum urea nitrogen, it may not be effective in significantly increasing the elimination of the accumulating aminoglycoside.
- Neuromuscular blockade
  - Prompt treatment with parenteral calcium chloride at 10 to 20 mg/kg IV or calcium gluconate at 30 to 60 mg/kg IV or neostigmine given slowly IV at 100 to 200 µg/kg to reverse dyspnea from muscle response depression.
  - Edrophonium at 0.5 mg/kg IV will also reverse neuromuscular blocking effects.

DRUG INTERACTIONS

- Aminoglycosides are inactivated if combined in vitro with other drugs because of pH incompatibilities.
- The aminoglycosides are synergistic against streptococci, *Pseudomonas* spp., and other gram-negative bacteria if combined with β-lactam antibiotics because of disruption of the bacterial cell wall by the β-lactam antibiotic.
- Halothane anesthesia causes significant changes in the pharmacokinetics of gentamicin in horses: total body clearance and volume of distribution decrease, and half-life of elimination increases. A longer gentamicin dosing interval after anesthesia may help correct the changes, but serious consideration should be given to choice of another antimicrobial.
- Neuromuscular blocking agents or drugs with neuromuscular blocking activity should not be used concurrently with aminoglycosides because they may increase the risk of neuromuscular blockade, particularly during anesthesia.
- Other nephrotoxic drugs and diuretics should be avoided when possible during aminoglycoside therapy.
- Concurrent administration of phenylbutazone with gentamicin decreases the elimination half-life of gentamicin by 23% and decreases the volume of distribution by 26%; the pharmacokinetics of phenylbutazone is not altered.

POSSIBLE COMPLICATIONS

- Chronic renal failure
- Death

RECOMMENDED MONITORING

- Individual horses differ widely in the serum concentrations produced from the same aminoglycoside dosage regimen.
  - There is a tendency to underdose neonatal patients, especially those that are receiving aggressive fluid therapy.
- Therapeutic drug monitoring may reduce toxicity and confirm therapeutic concentrations.
  - To allow for the distribution phase, blood sampling for the peak concentration is done at 0.5 to 1 hour after administration, and the trough sample is usually taken before the next dose.
  - The peak and trough concentrations can then be used to estimate the elimination half-life for the individual patient.
  - If using a once-daily regimen, a blood sample just before the next dose will be well below the recommended trough concentrations and may even be below the limit of detection of the assay. For these patients, an 8-hour postdose sample will provide a more accurate estimate of the elimination half-life.
  - Serum concentrations of drug should be 0.5 to 2.0 µg/mL before the next dose (gentamicin, tobramycin) or less than 6 µg/mL for amikacin.
  - An increase in the elimination half-life during therapy with increasing trough concentrations is a very sensitive indicator of early tubular insult.

PROGNOSIS AND OUTCOME

- Recovery depends on the total dose exposure and the amount of healthy renal tissue remaining to compensate.
- Progression to oliguric or anuric renal failure is infrequent, and most horses recover.

PEARLS & CONSIDERATIONS

COMMENTS

- Uptake and accumulation of aminoglycosides into renal tubular epithelium demonstrate saturable kinetics.
- Because nephrotoxicity is related to aminoglycoside accumulation in the renal proximal tubular cells, it is logical that peak concentrations are not related to toxicity and that longer dose intervals result in less total drug exposure to the renal brush border membrane.
- High-dose, once-daily dosing of aminoglycosides has now become common in human and veterinary medicine. This dosing regimen takes advantage of the concentration-dependent killing and long postantibiotic effect of these drugs, and avoids first exposure adaptive resistance and toxicity.

PREVENTION

- Calcium supplementation reduces the risk of nephrotoxicity.
- The risk of nephrotoxicity can also be decreased by feeding a high-protein, high-calcium diet such as alfalfa because protein and calcium cations compete with aminoglycoside cations

ElibVet.com

for binding to renal tubular epithelial cells. High dietary protein also increases the glomerular filtration rate and renal blood flow, reducing aminoglycoside accumulation.

EDITOR: **CYNTHIA M. GASKILL**

Amyloidosis

BASIC INFORMATION

DEFINITION

Progressive systemic or cutaneous disease resulting from excessive deposition of insoluble protein polymers known as amyloid in various organs, especially the kidneys. This leads to progressive organ failure.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- An uncommon disease that develops in older horses
- No sex or breed predilections

RISK FACTORS

- Visceral amyloidosis develops secondary to chronic infections, severe strongylid parasitism, or excessive immune stimulation. It is a significant problem in horses used in the commercial production of hyperimmune serum.
- Cutaneous amyloidosis is not associated with chronic inflammation but possibly with the presence of malignant histiocytic lymphoma.

ASSOCIATED CONDITIONS AND DISORDERS

- Renal failure
- Protein-losing nephropathy
- Specific organ failure depends on the location of amyloid deposits

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most visceral cases are detected incidentally at necropsy.
- Protein-losing nephropathy and renal failure secondary to deposition of amyloid within glomeruli present as nephritic syndrome with massive proteinuria.
- Rarely involves the upper respiratory tract, including the nasal cavity, pharynx, larynx, guttural pouch, and associated lymph nodes.
- Cutaneous disease is associated with development of tumorlike amyloid nodules; papules and plaques; and subcutaneous amyloid deposits present on the head, neck, and chest.

HISTORY, CHIEF COMPLAINT

- Disease of gradual insidious onset
- Secondary amyloidosis develops gradually in response to chronic inflammation in osteomyelitis, abscesses, traumatic pericarditis, or tuberculosis.
- Insidious signs of progressive liver and kidney failure
- Chronic weight loss leading to emaciation
- In renal failure, the animal is uremic and becomes comatose
- Amyloidosis of the gut wall may result in diarrhea
- Cutaneous amyloidosis is a nodular disease of the skin

PHYSICAL EXAM FINDINGS

- Visceral: Depends on the organs affected; may include mild splenomegaly or hepatomegaly, ascites or edema secondary to renal failure (see "Renal Failure, Chronic" in this section), or severe weight loss
- Cutaneous: Firm, nonpainful, nonpruritic swellings with normal overlying skin

ETIOLOGY AND PATHOPHYSIOLOGY

- Serum amyloid A is an acute-phase protein produced in large amounts in chronic inflammation.
- Misfolded serum amyloid A forms β-pleated sheets. β-pleated sheets are highly insoluble and are deposited in organs as AA amyloid.
- Deposition of AA amyloid in glomeruli leads to loss of glomerular function and progressive renal failure.
- Deposition of AA amyloid in the liver and spleen leads to organ enlargement.
- Very rarely, excessive immunoglobulin light chain production in myelomas or other monoclonal gammopathies may lead to deposition of AL amyloid. AL amyloid is a degradation product of immunoglobulin light chains.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Systemic

- Protein-losing nephropathy
- Nephritic syndrome
- Renal failure
- Pyelonephritis

Cutaneous

- Nodular necrobiosis
- Cutaneous lymphosarcoma

INITIAL DATABASE

- Hematology: Unremarkable
- Chemistry profile: Evidence of renal failure
- Urinalysis: Massive proteinuria if amyloid is deposited in glomeruli
- Imaging: Often unremarkable

TREATMENT

THERAPEUTIC GOAL(S)

- Visceral: Identification and removal of the underlying inflammatory cause
- Treatment of renal failure

ACUTE GENERAL TREATMENT

- Stabilization and treatment of any urinary crisis
- Treatment of protein-losing nephropathy
- Stop hyperimmunization

CHRONIC TREATMENT

- Management of concurrent inflammatory disease or neoplasm
- Maintenance of renal function
- Cutaneous: No effective treatment

RECOMMENDED MONITORING

Urine protein/creatinine ratio, urinalysis, serum albumin, and creatinine levels should be measured every 3 months after the patient is stabilized.

ElibeVet.com

PROGNOSIS AND OUTCOME

- Poor to bad
- Largely determined by the degree of renal damage
- Elimination of the source of inflammation will reduce the rate of disease progression and improve prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Some amyloidosis is present in all elderly horses. This may have no detectable effect on renal function.

PREVENTION

Prevent the development of persistent inflammatory foci such as abscesses and chronic osteomyelitis.

SUGGESTED READING

AUTHOR & EDITOR: **IAN TIZARD**

Anagen/Telogen Defluxion

BASIC INFORMATION

DEFINITION

- Telogen defluxion is hair loss associated with the telogen phase (resting phase) of hair growth.
- Anagen defluxion is the loss of hair during the anagen phase (active phase) of hair growth.

EPIDEMIOLOGY

RISK FACTORS

- Telogen defluxion: Stressors such as pregnancy, illness, and shock
- Anagen defluxion: Stressors such as antimitotic drugs, malnutrition, and metabolic and endocrine disorders

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Telogen defluxion: History of stressor
- Anagen defluxion: History of stressor, administration or antimitotic drug, malnutrition, or metabolic or endocrine disorder

PHYSICAL EXAM FINDINGS Acute hair loss

ETIOLOGY AND PATHOPHYSIOLOGY

- In telogen defluxion, there is a premature cessation of hair growth as a result of a stress, such as pregnancy, high fever, severe illness, or shock, that leads to synchronous shedding of telogen hairs 2 to 3 months later.
- Anagen defluxion is a result of similar stresses as telogen defluxion plus the use of antimitotic drugs, malnutrition, and endocrine and metabolic disorders that interfere with the anagen phase of hair growth. This interference leads to hair loss and breaking of anagen phase hairs at the epidermal surface.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Seasonal molting
- Dermatophilosis
- Dermatophytosis
- Sarcoidosis
- Pemphigus foliaceus
- Alopecia areata
- Mercurial poisoning
- Anhidrosis
- Selenium poisoning

ADVANCED OR CONFIRMATORY TESTING

- Microscopic examination of hairs is needed to confirm the diagnosis.
- Telogen hairs are characterized by a uniform shaft diameter; clubbed, non-pigmented root ends; and a lack of root sheaths.
- Anagen hairs are characterized by an irregular shaft diameter, deformity of the shaft, and ragged points or ends that easily break.

TREATMENT

ACUTE GENERAL TREATMENT

Resolves after removal or treatment of underlying cause

PROGNOSIS AND OUTCOME

Good

SUGGESTED READING

ElibeVet.com

Anaphylaxis

BASIC INFORMATION

DEFINITION

A life-threatening acute immediate hypersensitivity reaction occurring as a result of the rapid release of inflammatory mediators from mast cells. Affected horses may develop acute respiratory distress, cardiovascular collapse, and death.

SYNONYM(S)

- Anaphylactic shock
- Acute anaphylaxis
- Type I hypersensitivity

EPIDEMIOLOGY

RISK FACTORS

- Previous exposure and sensitization to antigens suspected to cause allergies increases the risk, but this is not always recognized.
- May be triggered by antigens in vaccines, hormones, antibiotics, or antiparasitic agents.
- IV penicillin may trigger acute anaphylaxis in horses.
- Geography and seasonality: Insect-related anaphylaxis may be a summer disease.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Anaphylactoid reactions: Under some circumstances, mast cell degranulation may occur in the absence of immunoglobulin E (IgE) antibodies and without prior sensitization. Thus these reactions do not require previous exposure to antigens.
- Anaphylactic reactions: Occur when an antigen (allergen) binds to IgE molecules located on the mast cell surface. These IgE molecules are induced by prior exposure to allergens.

HISTORY, CHIEF COMPLAINT

- Recent exposure to an inciting allergen
- Severe pruritus with urticaria
- Severe respiratory distress
- Excitement and ataxia
- Collapse
- Angioneurotic edema and laminitis may also develop

PHYSICAL EXAM FINDINGS

- Generalized wheals
- Weakness
- Poor pulse quality
- Tachycardia
- Severe dyspnea
- Collapse and coma

ETIOLOGY AND PATHOPHYSIOLOGY

Anaphylactic reactions

- Initial exposure to an allergen results in a Th2 response and the production of IgE antibodies. These antibodies bind to Fc receptors on the surface of mast cells and basophils.
- Subsequent exposure of the primed animal to the antigen results in antigen binding to the bound IgE and signaling to the mast cells and basophils, resulting in their rapid degranulation.
- Granules release the primary mediators, notably histamine and heparin.
- Degranulated cells synthesize secondary mediators, namely prostaglandins and leukotrienes, through the arachidonic acid cascade.
- Within a few hours, degranulated cells synthesize multiple cytokines, notably interleukin (IL)-4 and IL-13.
- The initial stages include acute hypotension combined with pulmonary arterial hypertension coinciding with histamine release. In a second phase, beginning about 3 minutes after exposure, venous blood pressure increases, coinciding with serotonin release. About 8 to 12 minutes after exposure, a third phase begins characterized by a reflex increase in blood pressure and alternating apnea and dyspnea. Subsequently, prostaglandin and leukotriene release lead to a phase of prolonged hypotension.
- The changes in vascular tone, increased vascular permeability, and bronchospasm lead to pulmonary congestion, edema, emphysema, and eventual death from hypoxia.

Anaphylactoid reactions

- Exposure to antigen leads to activation of the complement system, leading to the production of the peptides C3a and C5a.
- These peptides trigger mast cell and basophil degranulation and the release of mediator molecules.
- Mediator molecules, especially histamine, cause rapid smooth muscle contraction, especially in the respiratory and digestive tracts.
- Bronchoconstriction causes dyspnea, suffocation, collapse, and death.
- Severe rapid constriction of gastrointestinal smooth muscle leads to acute abdominal discomfort and colic.
- Heparin may prevent blood coagulation and lead to subsequent hemorrhage.
- Mast cell release of mediators within the skin may lead to localized swelling, urticaria, and pruritus.

DIAGNOSIS

- Diagnosis is based on history and physical examination findings.
- Anaphylaxis may cause severe dyspnea, distress, recumbency, and convulsions.
- Death may occur in less than 10 minutes but more commonly takes about 1 hour. Time is of the essence.

DIFFERENTIAL DIAGNOSIS

- Shock
- Pulmonary edema
- Heart disease
- Acute colic

INITIAL DATABASE

The complete blood count may show an increase in packed cell volume and neutropenia. Serum electrolytes may show high potassium.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove the offending allergen.
- Provide respiratory and cardiovascular support.
- Antagonize allergic mediators.

ACUTE GENERAL TREATMENT

- Initiate treatment immediately. Delay may be fatal.
- Epinephrine (0.1 mg/kg) to treat hypotension and bronchoconstriction. Give IM or one-fifth of the dose IV. This often works very rapidly, and the effect persists for 1 to 3 hours.
- Corticosteroids may potentiate the effects of epinephrine.
- Establish an airway in horses with upper airway obstruction or laryngeal edema.
- Give oxygen therapy.
- Bronchodilation if dyspnea persists after epinephrine administration: Aminophylline (15 mg/kg PO twice daily).

CHRONIC TREATMENT

- If the patient shows only mild signs of dyspnea or skin lesions, treatment may include:
  - Glucocorticoid therapy: Dexamethasone sodium phosphate
  - Antihistamine therapy (of questionable utility)

POSSIBLE COMPLICATION

Cardiac arrhythmias

ElibeVet.com

RECOMMENDED MONITORING

- Monitor frequently for 24 hours after reaction.
- Monitor heart rate, respiratory rate and effort, pulse rate and quality, and mucous membrane color.

PROGNOSIS AND OUTCOME

Immediate recognition and prompt epinephrine therapy are critical to success. Death may occur within minutes in severe cases.

PEARLS & CONSIDERATIONS

PREVENTION

- Administer all IV medications slowly.
- Be aware that many therapeutic agents, especially those containing proteins such as vaccines, may cause anaphylaxis.
- It is best not to administer potential allergens to patients with a history of allergic reactions to an agent.

CLIENT EDUCATION

After an animal is sensitized, allergen avoidance is the only sure method of prevention.

Anemia, Equine Infectious

BASIC INFORMATION

DEFINITION

Equine infectious anemia (EIA) A viral infection of Equids caused by a lentivirus and characterized by inapparent infections and occasional clinical disease with recurrent episodes of fever, lethargy, inappetence, thrombocytopenia, and anemia

SYNONYM(S)

- Swamp fever
- Coggins disease
- EIA

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No known age, gender, or breed predisposition
- Affects horses, ponies, donkeys, mules, and zebras

CONTAGION AND ZOONOSIS

- Spread by transfer of blood or body fluids
  - Most commonly transmitted by large biting horseflies and deerflies.
  - Stable flies may also be involved in transmission.
  - Insects are mechanical vectors, and the virus lives only a limited amount of time on vector mouthparts.
  - Iatrogenic infections are common through use of common needles or contaminated equipment.
  - A recent outbreak in Ireland suggests the possibility of direct or indirect horse-to-horse transmission without vectors or iatrogenic infection.
- Not zoonotic

GEOGRAPHY AND SEASONALITY

- Present worldwide
- Prevalence highest in regions with warm climates and large numbers of potential vector insects
- In the United States, most common in Gulf Coast states

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute disease causes fever, lethargy, and inappetence with mild thrombocytopenia.
- Inapparent infection with no recognizable clinical signs is most common.
- Chronic disease is associated with recurrent episodes of fever with weight loss, ventral edema, and petechial hemorrhages.

HISTORY, CHIEF COMPLAINT

- Fever, weight loss, petechial hemorrhages
- Inapparent carriers often identified at time of routine surveillance testing

PHYSICAL EXAM FINDINGS

- Acute disease: Fever, lethargy
- Inapparent carrier: Minimal recognizable clinical signs
- Chronic disease: Fever, ventral nonpainful pitting edema, petechial hemorrhages, poor body condition

ETIOLOGY AND PATHOPHYSIOLOGY

- EIA virus is a member of the lentivirus genus of the Retroviridae family.
- Establishes persistent, lifelong infection in Equids.
- The virus undergoes antigenic variation with resultant recurring episodes of fever and viremia.
- The immune system ultimately controls viral replication in most horses, resulting in inapparent carriers with minimal signs of disease.
- Uncontrolled viral replication results in signs of chronic disease.
- Anemia and thrombocytopenia probably result from immune- and non–immune-mediated peripheral destruction of erythrocytes and platelets as well as impaired bone marrow production of new cells.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Any chronic infectious or inflammatory disease
- Purpura hemorrhagica
- Equine viral arteritis
- African horse sickness

INITIAL DATABASE

- Acute disease: Thrombocytopenia most common; possibly mild anemia
- Inapparent carriers: Minimal abnormalities on routine bloodwork; possible mild hyperglobulinemia
- Chronic disease: Evidence of chronic infection, inflammation
  - Anemia
  - Leukocytosis caused by mature neutrophilia
  - Hyperfibrinogenemia
  - Hyperglobulinemia
  - Monocytosis
  - Thrombocytosis

ADVANCED OR CONFIRMATORY TESTING

- In the United States, all testing must be done at diagnostic laboratories approved by the U.S. Department of Agriculture (USDA).
- A positive serologic infection confirms infection in adult horses. Foals from

ElibeVet.com

seropositive mares may be seropositive from passive antibody transfer for up to 12 months.
- Serologic assays must be approved by the USDA for diagnosis.
  - Agar gel immunodiffusion (AGID or Coggins' test): Rare false-negative results
  - Enzyme-linked immunosorbent assay (ELISA): Occasional false-positive results
  - Western immunoblot: May be used as a confirmatory test for horses with equivocal AGID or ELISA results

TREATMENT

THERAPEUTIC GOAL(S)

- Supportive and symptomatic care may be considered during febrile, viremic episodes.
- Most seropositive, infected horses are euthanized.

ACUTE GENERAL TREATMENT

- No effective antiviral therapy is available.
- General, supportive care depending on the severity of clinical signs should be provided.

PROGNOSIS AND OUTCOME

- All seropositive horses are considered infected for life.
- Most seropositive horses show minimal clinical signs and may live a normal life span with the infection.
- In the United States, federal and state laws dictate the response to a positive serologic test.
  - Seropositive horses must be placed under quarantine within 24 hours after the positive test results are known.
  - The quarantine area must provide at least 200 yards of separation from all other Equids.
  - A confirmatory test is performed.
  - Seropositive reactor horses must be permanently identified using the National Uniform Tag code number assigned by the USDA to the state in which the reactor was tested followed by the letter A. This identification may take the form of a hot brand, chemical brand, freeze marking, or lip tattoo and must be applied by a USDA representative.
  - Reactor horses must be separated and removed from the herd by euthanasia, slaughter, or quarantine at the premises of origin.
  - Reactor horses may only move interstate under official permit to a federally inspected slaughter facility, to a federally approved diagnostic or research facility, or to return to the premises of origin.
  - After a reactor is detected in a herd and removed, testing for the disease must be performed on all horses on the premises and repeated until all remaining Equids on the premises test negative. These horses must be retested at 30- to 60-day intervals until no new cases are found.
  - Quarantine on the premises is released when test results for the entire herd have been negative at least 60 days after the reactor Equids have been removed.

PEARLS & CONSIDERATIONS

PREVENTION

- There is no effective vaccine to prevent EIA.
- The United States has an established federal and state prevention plan based on serosurveillance:
  - All Equids being moved interstate must have been tested for EIA with a negative result within 12 months before movement.
  - All Equids sold, traded, or donated within a state must have been tested negative for EIA no more than 12 months before a change in ownership and, preferably, no more than 60 to 90 days.
  - All Equids entering horse auctions or sales markets are required to have a negative test result before sale or the horse must be held in quarantine within the state until the test results are known.
- It is recommended that horse owners implement the following EIA control measures.
  - Test all horses at least every 12 months as part of a routine health program. More frequent testing may be indicated in some areas with a high incidence.
  - Owners of Equids entering exhibitions or competitive events should present proof to event officials of a negative EIA test result.
  - All new Equids introduced into a herd should have a negative EIA test result before entry or be isolated on the farm while test results are pending.
  - Vector control practices, including application of insecticides and repellants and environmental insect control, should be implemented.
  - Good hygiene and disinfection principles should be maintained to prevent iatrogenic infection of horses with contaminated needles, syringes, or equipment.

CLIENT EDUCATION

All horse owners should be advised of the importance of maintaining an EIA prevention program as described above and encouraged to test all horses at least annually.

Anemia, Immune-Mediated

BASIC INFORMATION

DEFINITION

Anemia resulting from a loss of erythrocytes caused by increased destruction by autoantibodies and complement.

SYNONYM(S)

- Autoimmune hemolytic anemia
- Immune-mediated hemolytic anemia (IMHA)

EPIDEMIOLOGY

- Acute anemia resulting from autoimmune attack by antibodies directed against erythrocyte membrane antigens.

ElibeVet.com

- May be triggered by infection with *Streptococcus fecalis*. In these cases, immunoglobulin M (IgM) cold agglutinins clump red blood cells (RBCs) from normal horses when chilled.
  - May occur in horses with lymphosarcoma and melanoma

ASSOCIATED CONDITIONS AND DISORDERS Thrombocytopenia (see "Thrombocytopenia, Immune-Mediated" in this section)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Pallor, weakness, depression, anorexia
- Anemia, lethargy, weakness
- Inappetence and anorexia
- Icterus
- Discolored urine (hemoglobinuria)

PHYSICAL EXAM FINDINGS

- Weakness and depression
- Pale mucous membranes
- Icterus
- Tachycardia
- Tachypnea or dyspnea
- Chronic anemia may result in cardiac dilation and development of a hemic murmur
- Pyrexia
- Splenomegaly
- Hemoglobinuria

ETIOLOGY AND PATHOPHYSIOLOGY

- Most cases are the result of apparently spontaneous production of anti-erythrocyte autoantibodies. These autoantibodies bind to erythrocytes and trigger their destruction.
- Some cases may be associated with infections or the presence of lymphoid neoplasia.
- Antibodies may target erythrocyte antigens directly (primary IMHA).
- Alternatively, antibodies may target modified erythrocyte membranes. These membranes may be modified by drugs or other infectious agents (secondary IMHA).
- Extravascular hemolysis may result in splenomegaly.
- Intravascular hemolysis may also occur.
- Liver and other organ damage may result from ischemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Blood loss for other reasons
- Bleeding disorder
- Bone marrow failure
- Anemia of chronic disease
- Hepatitis
- Biliary obstruction
- Hemolytic toxins

INITIAL DATABASE

- Complete blood count with packed cell volume (PCV), erythrocyte number, hemoglobin content, and RBC morphology. Reticulocyte counts are not usually informative.
- Check for autoagglutination, spherocytosis, polychromasia, anisocytosis, reticulocytosis, and increased erythrocyte fragility.
- Serum may be discolored because of hemoglobinemia.
- Serum chemistry profile with total protein, baseline bilirubin, serum electrolytes, and serum liver and kidney enzymes.
- Urinalysis as a measure of renal function.
- Coagulation panel.

ADVANCED OR CONFIRMATORY TESTING

Direct antibody test (Coomb's test) or flow cytometry

TREATMENT

THERAPEUTIC GOAL(S)

- Maintenance of oxygen-carrying capacity
- Prevention of additional RBC loss
- Replacement of lost RBCs
- Immunosuppression

ACUTE GENERAL TREATMENT

- Packed RBC transfusion if anemia is severe (tachycardia, tachypnea, weakness)
- Dexamethasone sodium phosphate solution (0.08 mg/kg) PO once daily. After a response is obtained, progressively decrease to 0.02 mg/kg/day.
- Alternatively, 1 mg/kg/day PO prednisolone
- IV crystalloids

CHRONIC TREATMENT

Continued immunosuppression with dexamethasone and tapering doses if hematocrit remains stable

POSSIBLE COMPLICATIONS

- Adverse drug side-effects.
- Steroid-induced laminitis.
- In extreme cases of anemia, irreversible renal damage may prevent complete recovery.

RECOMMENDED MONITORING

- During acute crisis, PCV should be assessed two to three times daily.
- After the patient is stabilized, PCV should be monitored weekly for at least 1 month.

PROGNOSIS AND OUTCOME

Animals generally respond well, so the prognosis is good; however, relapses are common.

PEARLS & CONSIDERATIONS

Clients should be counseled to watch for signs of relapse.

ElibEVet.com

Angular Limb Deformity

BASIC INFORMATION

DEFINITION

Angular limb deformities (ALDs) result in a limb deviation in the frontal plane either toward (varus) or away (valgus) from the body. They are often bilateral and are usually associated with growth centers, especially the epiphysis, but they can be diaphyseal. Not all ALDs are abnormal.

SYNONYM(S)

- Knock knees
- Cow hocks
- Toeing in or toeing out

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION

- Anecdotal evidence suggests ALD is genetic, but this is unproven.
- ALDs are most common in light-breed horses with fast growth rates such as Thoroughbreds and Quarter Horses, but they may occur in any breed.

RISK FACTORS

- Prematurity or dysmaturity, ligamentous laxity.
- For "windswept" foals, small uterine size in the mother and a lack of fetal activity are considered possible causes.

ASSOCIATED CONDITIONS AND DISORDERS Some degree of limb rotation is often associated with ALD. Inward rotation is usually associated with varus and outward rotation with valgus. Although most ALDs are bilaterally symmetrical, an uncommon manifestation of congenital ALD is windswept foals, in which paired limbs are deviated in one direction. Rarely, ALDs are the result of severe congenital developmental bone disorders.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The most common congenital ALD is carpal valgus followed by fetlock valgus and varus.
- Much rarer is tibial valgus followed by varus.

HISTORY, CHIEF COMPLAINT

- Congenital ALD may worsen during the first week of life because of the effects of gravity and asymmetric weight bearing.
- Severely affected foals may have difficulty nursing and ambulating.

PHYSICAL EXAM FINDINGS Uncomplicated ALD in a neonate should not result in lameness or periarticular swelling. If caused by epiphyseal or physeal dysplasia, the limb examination results are normal but the deviation cannot be corrected manually. If caused by epiphyseal ligamentous laxity, the deviation can be corrected manually.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most congenital ALDs are caused by some degree of immaturity of soft and hard tissues of limbs and possibly in utero positioning.
- The impact of genetics is more likely the result of breed influence for slender limbs and fast growth rather than an individual parent's impact.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Uncomplicated limb deviations
- ALD caused by severe laxity
- ALD caused by prematurity or dysmaturity
- Congenital limb malformation

INITIAL DATABASE

The limbs should be checked for ligamentous laxity and foot balance. Radiographs should be obtained of severe deviations or in foals in which cuboidal bone hypoplasia is suspected.

ADVANCED OR CONFIRMATORY TESTING

Computed tomography or magnetic resonance imaging can be used to characterize deviations in cross-sectional anatomy but is rarely necessary.

TREATMENT

THERAPEUTIC GOAL(S)

- Most ALDs improve as the foal matures, as long as there is no persistent uneven limb loading. Allowing appropriate exercise is the most important management strategy in the treatment of ALDs (Figure 1).
- Foals with severe ligamentous laxity should have splints or casts applied to properly align the limb and protect the lax ligaments from additional stretching. Coaptation will also protect bones from asymmetric loading that may result in added stretching and bone crushing (Figure 2).

ACUTE GENERAL TREATMENT

- Balance the foot.
- Provide enough exercise to promote musculoskeletal development but not enough to result in excessive asymmetric weight bearing and further

FIGURE 1 Six-week-old foal with significant bilateral carpal valgus deformity; right worse than left with outward rotation deviations. Full evaluation of these deviations requires radiography. (Courtesy Dr. Joanne Kramer.)

ElibeVet.com

FIGURE 2 Dorsopalmar radiograph of both forelimbs of the foal in Figure 1. Abnormalities apparent include greater than 20 degrees of carpal valgus and mild crushing of the lateral aspect of the epiphysis and the lateral styloid process of the right forelimb and approximately 10 degrees of carpal valgus in the left forelimb. (Courtesy Dr. Joanne Kramer.)

bone damage. Foals with hypoplastic carpal bones should have exercise limited to a large stall and may require external coaptation if immaturity is severe to protect the delicate cartilage model for the mature bone.
- For fetlock inward deviations, the addition of lateral hoof augmentation to promote central foot breakover and to limit lateral hoof wall wear can be curative if applied early enough.
- Foals with ligamentous laxity require splints or casts to protect the limb and require stall confinement.

CHRONIC TREATMENT

- Surgical therapy may be helpful later in life for some congenital ALDs.
- If maturation and exercise restriction are not sufficient to correct the limb deviation, either periosteal elevation (PE) or transphyseal bridging (TB) may be used to correct limb deviations. PE can be done at any age and may have some mild corrective effect. TB is done usually no sooner than 14 days of age because the bone must mature enough to hold the implants. The efficacy of both procedures relies on remaining growth potential in the growth plate, which is greater in younger foals. For distal metacarpal or metatarsal deformities, procedures should be done at less than 60 days. For distal radial deformities, correction can be obtained as late as 12 months, although moderate to severe deformities require earlier intervention.

POSSIBLE COMPLICATIONS

The most severe complication of ALD is permanent deformation of the bones of the limb, which will result in lifelong lameness and abnormal locomotion.

RECOMMENDED MONITORING

No specific monitoring besides visual examination is necessary for most foals with ALD. However, if limb deviations do not improve, radiographic examination is warranted.

PROGNOSIS AND OUTCOME

- The vast majority of carpal valgus in foals will correct as the foals mature. Fetlock and carpal varus deviations are more problematic and may require more aggressive intervention.
- Foals with hypoplastic bones or ligamentous laxity must be treated early and carefully to avoid permanent limb deformity.

PEARLS & CONSIDERATIONS

COMMENTS

ALDs are very common in young foals, and most self-correct. Intervention is only necessary in a small number of cases.

CLIENT EDUCATION

All foals should have a veterinary examination within 24 hours of birth to asses their overall health and determine appropriate passive transfer. Also important is a musculoskeletal examination to determine the foals' suitability for exercise.

Anthrax

BASIC INFORMATION

DEFINITION

Anthrax is an infectious disease caused by ingestion of spores of a bacterium that multiplies upon inoculation or ingestion and secretes lethal toxins. A spore is a refractile or stainable structure of a microorganism formed as a hypobiotic stage in the organism's life cycle that allows survival in environmental extremes. The vegetative form is a structure of a microorganism that develops when environmental conditions allow asexual reproduction or multiplication.

ElibeVet.com

SYNONYM(S)

Wool sorter's disease, carbon fever, splenic fever

EPIDEMIOLOGY

SPECIES, AGE, SEX No predilection. Susceptibility to disease is greatest for cattle followed by sheep and then horses and goats. Pigs frequently develop clinical anthrax after exposure to *Bacillus anthracis* but are the only species that may spontaneously recover (many still die).

RISK FACTORS Geography, soil, water conditions

CONTAGION AND ZOONOSIS

- The zoonotic risk of *B. anthracis* cannot be minimized, and the occupational risk of infection of veterinarians is very high compared with the risk of intentional human-to-human transmission. Personal protection when handling anthrax-suspected animals should be complete, including gloves, boots, protective suits, and respiratory and eye protection. This protection must be maintained throughout all environmental and equipment decontamination processes. Complete bathing is recommended after handling any tissues or animals.
- In some situations, prophylactic antibiotic therapy is recommended if exposure is thought to be high or inadvertent through improper attention to personal protection. Animal hide, hair, and wool can contain spores, and people at occupational risk should seek immediate medical attention if skin or respiratory signs occur.

GEOGRAPHY AND SEASONALITY

- Climatic stressors allow reliable prediction of anthrax outbreaks. With climatic change, outbreaks of anthrax occur in infection cycles. A harbinger of infection or primary infection cycle occurs with the sudden death of one or two animals that have been recently introduced into an area. These infected carcasses contaminate the soil with *B. anthracis*. The secondary infection cycle involves multiple animals that develop anthrax after exposure to contaminated soil or carcasses from the primary infection cycle.
- Anthrax in local cattle is usually observed within the same time period.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cutaneous
- Respiratory
- Septicemic
- Sudden death

HISTORY, CHIEF COMPLAINT Sudden death in an appropriate geographic location

PHYSICAL EXAM FINDINGS

- Although not as frequently diagnosed with *B. anthracis* infection as cattle, horses do develop disease and die from anthrax. After an incubation period of about 3 to 7 days (can be as short as 1 day or as long as 7 days), horses usually develop the acute form of anthrax, although sudden death may occur. Initial clinical signs frequently include colic with presenting signs that may resemble those of acute enteritis. These horses rapidly progress to high fever with dyspnea. Subcutaneous edema of the ventral neck, thorax, and abdomen may be seen, especially with mediastinal involvement. Ventral edema involving the prepuce and mammary gland is postulated to be secondary to local transmission from insects.
- If an animal dies of disease consistent with anthrax in an endemic area, it is best not to open the carcass. Not only is this important for human safety, but it is also exceptionally important for long-term control by minimizing environmental contamination. Collection of blood in a closed system or a splenic aspirate obtained percutaneously is recommended to facilitate confirmation of the diagnosis. Blood clots poorly in affected animals, so a sample may be obtained for an extended time after death.
- Postmortem analysis is not recommended. The pathologic hallmark of anthrax is the absence of rigor mortis, with passage of blood from body orifices. Petechiae and ecchymoses are widespread, with large quantities of blood-stained serous fluid within body cavities. Severe mediastinal edema, enteritis, and splenomegaly are common. In particular, the spleen has a "blackberry jam" appearance.

ETIOLOGY AND PATHOPHYSIOLOGY

- *B. anthracis* infection
- Evasion of the immune system, rapid vegetative proliferation, and elaboration of toxin are critical steps in the pathogenesis of anthrax.
- The mammalian incubation period is 1 to 7 days for respiratory and gastrointestinal anthrax.
- Ingestion is likely the primary route of inoculation, with a break in the mucous membranes important.
- There is an initial round of primary replication in the regional lymph nodes.
- The organism enters the bloodstream through lymphatic drainage, with resultant bacteremia, septicemia, toxemia, and dissemination to all major organs.
- Anthrax toxin has three components: Protective antigen (PA), lethal factor (LF), and edema factor (EF).
  - PA molecule binds to the cell surface and is the target of antiserum.
  - LF mediates the fatal effect of *B. anthracis*.
  - EF causes extravasation of intercellular fluids into subcutaneous and peritoneal compartments and interstitial spaces.
  - A combination of PA and LF must be present for lethality.
  - Complexing of EF and PA produces edema.
  - When all three toxin components are present, the organism causes necrosis of cells with edema and is lethal.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Sudden death
- Sepsis
- Systemic inflammatory response syndrome (SIRS) or endotoxemia

INITIAL DATABASE

- With sudden death or a short course of fatal disease in suspect cases, a blood smear is safest.
- New methylene blue stain shows chains of large, square, gram-positive rods.

ADVANCED OR CONFIRMATORY TESTING

- If a sample for culture is obtained, initial identification of *B. anthracis* is through the basic microbiologic features discussed.
- Much safer for laboratory personnel is the inoculation of guinea pigs for lethality or fluorescent antibody testing of smears of froth, blood, or splenic aspirate.
- Serologic and molecular-based techniques are important for identification of the specific strain of *B. anthracis*.
- Strain typing to determine the origin of exposure in humans is a priority when bioterrorism is suspected.
- Molecular-based techniques have been developed for environmental monitoring and likely pose an alternative to inadvertent culture of body fluids.

TREATMENT

THERAPEUTIC GOAL(S)

Prevent death

ACUTE GENERAL TREATMENT

- Anthrax is rapidly fatal in horses, and it is unlikely that there would be an opportunity for therapy of an animal showing clinical signs at diagnosis.

ElibeVet.com

- Careful examination of other exposed animals for disease should be performed. Close monitoring of any exposed horses may result in timely administration of antimicrobial agents.
- Antimicrobials recommended for prevention and treatment of anthrax include penicillin, tetracyclines, and fluoroquinolones.
- Recent outbreaks in humans support the use of fluoroquinolones as a first-line antimicrobial in suspected *B. anthracis* infection.
- IV administration is highly recommended. Single or short-duration administration of prophylactic antibiotics is recommended for exposed humans and is an option for horses.
- Supportive care is essential and consists of cardiovascular support in the form of fluid and oncotic therapy. Intranasal oxygen may alleviate signs of dyspnea.

RECOMMENDED MONITORING

- Limit access to body fluids.
- Limit access to hemolymphatic system.
- Do not perform a necropsy.

PROGNOSIS AND OUTCOME

Extremely poor

PEARLS & CONSIDERATIONS

PREVENTION

- Vaccines are available for the prevention of anthrax in cattle in some countries outside the United States.
- Cattle vaccines in horses are not recommended in the guidelines of the American Association of Equine Practitioners. Injection site reactions and severe edema after vaccination have been described.
- If *B. anthracis* is identified or suspected in horses, implement methods to prevent additional disease in horses and to minimize risk of human disease.
- Animals should have all external debris removed by thorough bathing with soap and water.
  - May use a 0.5% hypochlorite solution.
  - Move animals away from sites that have been exposed to anthrax-laden carcasses.
  - The World Health Organization recommends incineration of closed carcasses as the best method of disposal.
  - Ensure complete incineration, including the ventral parts of the carcass.
  - The soil from the site can be burned separately from the carcass or actually torched.

CLIENT EDUCATION

- Education regarding veterinarian evaluation of animals that die inexplicably and suddenly
- Education on zoonoses for persons living in endemic areas

SUGGESTED READING

American Veterinary Medical Association: *Anthrax Facts*. Available at http://www.avma.org/public_health/biosecurity/anthrax_facts.asp.

EDITORS: **DEBRA C. SELLON** and **MAUREEN T. LONG**

Aortic Aneurysm

BASIC INFORMATION

DEFINITION

Localized abnormal dilation of the aorta that can be congenital or acquired. May occur at the aortic sinus or in the thoracic or abdominal aorta.

EPIDEMIOLOGY

SPECIES, AGE, SEX More common in males than females

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Intact aneurysm: May not cause clinical signs.
- Ruptured aneurysms: Clinical signs vary depending on the location (intracardiac, thoracic, or abdominal).

HISTORY, CHIEF COMPLAINT

- Depends on the location and etiopathology:
  - Sinus of Valsalva: Condition is asymptomatic until the aneurysm ruptures (see "Aortocardiac Fistula" in this section)
  - Intrathoracic: Signs of right-sided congestive heart failure, recumbency, shortness of breath, distress, collapse, cardiovascular collapse, or sudden death
  - Intraabdominal: Colic, lameness, or sudden death

PHYSICAL EXAM FINDINGS

- Intact aneurysm: may be found incidentally; may or may not have a murmur
- Clinical signs depend on the site of rupture:
  - Intracardiac
    - Acute onset of right-sided heart failure: Ventral edema, jugular vein distension, jugular pulses, congested mucous membranes, decreased capillary refill time, weak arterial pulses
    - Ventricular arrhythmias: Result of disruption of the conduction system
    - Sudden death
  - Intrathoracic
    - Signs of right-sided heart failure: Ventral edema, jugular vein distension, jugular pulses, congested mucous membranes, decreased capillary refill time, weak arterial pulses
    - Sudden death
  - Intraabdominal
    - Hindlimb lameness and colic
    - Sudden death

ETIOLOGY AND PATHOPHYSIOLOGY

- Sinus of Valsalva aneurysms are congenital defects in the media of the wall of the aorta at the right sinus of Valsalva.
- The pathogenesis of equine aortic aneurysms is unknown.
  - Damage to the aortic wall (degeneration of the media followed by degeneration of the elastic tissue) secondary to septic thrombosis, parasitic migration, trauma, arteriosclerosis, bacterial or mycotic infections, cystic or laminar medial necrosis, or a dissecting aneurysm have all been suggested.
- Tears in the aorta may occur at any level.
  - Intracardiac rupture produces an aortocardiac fistula.
  - Rupture within the pericardium produces acute cardiac tamponade and sudden death.
  - Rupture of the extrapericardial aorta leads to fatal hemorrhage or a systemic-to-pulmonary shunt.

ElibeVet.com

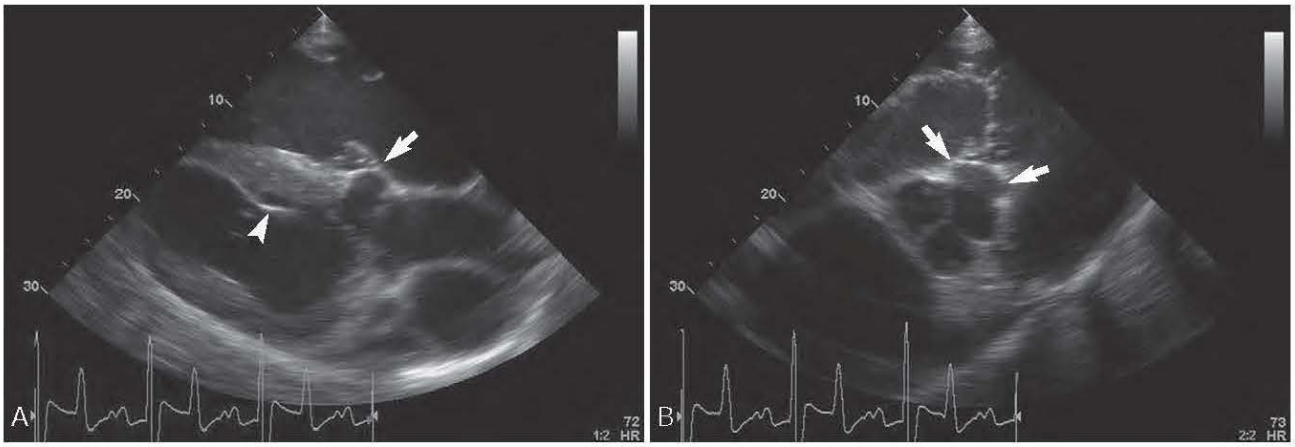

FIGURE 1 Right parasternal echocardiograms of the left ventricular outflow tract. **A,** Long-axis view. Note the thin membranous sac protruding from the sinus of Valsalva into the right atrium (*arrow*) and the dissection of blood along the left ventricular side of the interventricular septum (*arrowhead*). **B,** Short-axis view. Note the thin membranous sac protruding from the sinus of Valsalva into the right atrium (*arrows*).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Heart failure from other causes
- Abdominal pain

INITIAL DATABASE

Radiology: May detect enlargement of a dilated aortic aneurysm in the aortic arch

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography: Used to detect sinus of Valsalva aneurysm, which is visualized as a thin membranous sac protruding from the sinus of Valsalva at the junction of the membranous septum and the aortic root (Figure 1). Aneurysms of the ascending aorta may be detected with echocardiography.
- Transesophageal echocardiography: May detect aneurysms in the aortic arch and descending aorta.
- Aneurysms in the thoracic or abdominal aorta are usually a postmortem diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- There is no treatment for intact aneurysms; horses are not safe to ride.

ACUTE GENERAL TREATMENT

Only symptomatic treatment for intracardiac rupture of a sinus of Valsalva aneurysm (see "Aortocardiac Fistula" in this section)

RECOMMENDED MONITORING

Horses with documented aortic aneurysms should have their attitude, appetite, and vital signs (heart rate and rhythm, respiratory rate and rhythm, and pulse quality) regularly monitored by their owners. In addition, these horses should be periodically auscultated for the presence of new murmurs or a change in character of existing murmurs. Any changes should prompt a complete cardiac workup, including echocardiography and electrocardiography, by a veterinarian.

PROGNOSIS AND OUTCOME

- Extremely grave
- Grave prognosis after identification of an aneurysm because of the high risk of sudden death
- Grave prognosis after rupture of the aneurysm
  - If the aorta ruptures into the thoracic or abdominal cavities, death occurs from rapid hypovolemic shock.
  - If the aorta ruptures into the pericardial sac, hemopericardium, cardiac tamponade, and death occur.
- Horses with intact aneurysms may live for years; however, they are not safe to use as performance horses because of risk of rupture and sudden death.

PEARLS & CONSIDERATIONS

A horse with an aortic aneurysm, regardless of the location, should not be used for riding because of the high risk of sudden death.

ElibeVet.com

Aortic/Pulmonic Regurgitation, Acquired

BASIC INFORMATION

DEFINITION

- Aortic regurgitation is common in older horses, and the aortic valve is the most common valve diagnosed with pathologic changes (usually nodular or general fibrous thickening of the valve leaflets).
- Pulmonic regurgitation is extremely rarely diagnosed by auscultation; it seldom results in an audible murmur because the pressure difference between the pulmonary circulation and the right ventricle in diastole is too low to produce significant turbulence that will cause a murmur. In addition, only rarely are clinical signs associated with pulmonic regurgitation in horses. Therefore most pulmonic regurgitation is of no relevance for clinicians unless it is severe or associated with bacterial endocarditis. This entry focuses primarily on aortic regurgitation.
- For both the pulmonic and the aortic valve, mild regurgitation detected by Doppler echocardiography occurs in a high proportion of Standardbred and Thoroughbred racehorses (Figure 1). Training-induced myocardial hypertrophy is the most likely reason for this minor regurgitation.

SYNONYM(S)

- Aortic or pulmonic insufficiency
- Aortic or pulmonic valve disease
- Semilunar valve insufficiency or regurgitation

EPIDEMIOLOGY

SPECIES, AGE, SEX Aortic regurgitation occurs commonly in older horses.

GENETICS AND BREED PREDISPOSITION There is no genetic predisposition, but the prevalence of very mild regurgitation is higher in Standardbreds and Thoroughbreds compared with the general horse population.

RISK FACTORS Aortic regurgitation: fenestrations of the aortic valves, membranous ventricular septal defect (VSD), and endocarditis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Aortic regurgitation incidentally diagnosed in clinically normal horses (eg, during a pre-purchase examination)
- Aortic regurgitation causing clinical signs of heart failure, ataxia, or collapse during strenuous exercise in severe cases

HISTORY, CHIEF COMPLAINT

- Aortic regurgitation seldom causes reduced performance or other clinical changes that the owner will notice.
- However, if more severe, exercise intolerance may be reported.

PHYSICAL EXAM FINDINGS

- Diastolic cardiac murmur with the point of maximal intensity (PMI) over the aortic valve at the basal area of the left hemithorax: Because the aortic valve is located centrally in the heart, the murmur is often also heard over the right hemithorax and may radiate over the entire thorax. The murmur is often holosystolic or pansystolic with a decrescendo musical quality and is relatively easy to diagnose in these cases. A fenestration or vibrating portion of the leaflet is usually responsible for the musical quality, which is easily heard. However, the murmur may be harsh or blowing, and if the heart sounds are engulfed by the murmur, it may be difficult to differentiate from a systolic murmur. In these cases, simultaneous palpation of the peripheral pulse is helpful. The intensity of the murmur does not always correlate with the severity of the disease.
- Depending on the severity, one or more of the following signs may also be observed:
  - Systolic murmur on the left hemithorax over the mitral valve area is indicative of mitral regurgitation.
  - Palpation of the facial artery may reveal a bounding ("water hammer") pulse caused by a large difference between the systolic and the low diastolic pressure. This indicates more hemodynamically significant disease with an enlarged left ventricle.
  - Cardiac arrhythmias
  - Rarely, signs of heart failure may be observed, including one or more of the following: resting tachycardia and tachypnea, distension of the jugular veins, dependent edema, increased respiratory sounds caused by pulmonary edema, prolonged capillary refill time, or weight loss.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most commonly, valvular changes arise because of normal progressive degeneration from aging. The condition is likely to deteriorate with time, but the rate of progression in individual horses is impossible to predict. For older horses, however, this seldom results in clinical signs of poor performance, and the eventual cause of death or euthanasia is seldom because of cardiac disease.
- When aortic regurgitation is diagnosed in younger horses (<10 years), it indicates premature aortic valve disease that may be caused by either complicating factors predisposing to development of aortic regurgitation or valvular malformations. In these situations, a VSD is often present and the right coronary cusp of the aortic valve prolapses into the septal defect, leading to aortic regurgitation. Because the aortic valve seals the septal defect, the

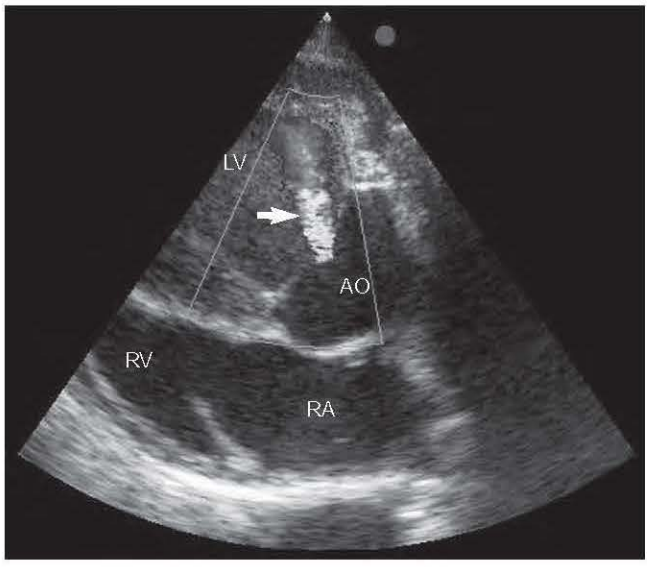

FIGURE 1 Long-axis color-flow Doppler echocardiogram of the aorta obtained from the left cardiac window showing mild aortic regurgitation (*arrow*). *AO,* Aorta; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

ElibeVet.com

typical murmur associated with a VSD may not be heard.
- Progression of aortic regurgitation leads to volume overload of the left ventricle and dilation and eccentric ventricular hypertrophy with a subsequent increasing myocardial oxygen demand. Blood supply for the myocardium is delivered during diastole via the coronary arteries just above the aortic valve, and as a result of the rapid decrease of diastolic blood pressure, coronary perfusion is reduced. Ischemia of the ventricles may lead to potentially fatal ventricular arrhythmias.
- Secondary to volume overload of the left ventricle, dilation of the mitral valve annulus may occur, leading to mitral valve regurgitation. If this becomes severe, pulmonary hypertension and right heart failure may develop.
- The aortic valve, along with the mitral valve, is the most common location of endocarditis (see "Endocarditis, Infective" in this section); however, the disease is not commonly encountered.
- Murmurs of aortic, mitral, and tricuspid regurgitation are often detected in Standardbred and Thoroughbred racehorses. These murmurs may develop in response to training, and their prevalence increases with age and training. However, the regurgitations are generally mild, the severity remains unchanged over time, and no negative effect on racing performance has been documented.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Functional murmur (flow murmur, ejection murmur). The rapid filling of the ventricles may result in an early diastolic filling murmur, especially in young horses, and has been described as a "2-year-old squeak." These are of no clinical significance.
- Endocarditis

INITIAL DATABASE

- Definitive diagnosis of aortic or pulmonic regurgitation requires echocardiographic examination with the regurgitant jet visualized with Doppler echocardiography (see Figure 1).
- The severity of the disease must be assessed by echocardiography. Nodular thickening of the valve is not necessarily related to severity. The most important echocardiographic variables to measure are degree of left ventricular dilation, contractility of the left ventricle, and severity of mitral regurgitation. If mitral regurgitation is severe, left atrial enlargement is important to note. The size and severity of the regurgitant jet can be estimated by Doppler echocardiography.
- Electrocardiography (ECG) at rest and during exercise is recommended if the horse is used for riding purposes.
- Complete blood count and serum biochemistry are usually unremarkable.

ADVANCED OR CONFIRMATORY TESTING

- Direct or indirect blood pressure measurements should be performed.
- Cardiac output monitoring provides information on the effect of regurgitation and cardiac function on hemodynamic status.

TREATMENT

THERAPEUTIC GOAL(S)

- In most equine patients with aortic or pulmonic valve disease, specific therapy is not indicated, and management is aimed at periodic monitoring of the disease progression and cardiac function and providing client information. Because there is a potential risk of developing arrhythmias in association with significant aortic regurgitation, serial echocardiography and exercising ECG are indicated.
- Heart failure rarely develops because of aortic regurgitation, but if it does, supportive therapy may be considered. In general, because of the poor prognosis, treatment of horses in heart failure is often not considered. But for some valuable breeding horses or horses in which the owner has sentimental attachment, treatment can be tried.

ACUTE GENERAL TREATMENT

Supportive treatment of patients in heart failure includes diuretics to reduce congestion (furosemide 1–2 mg/kg IV q12h) in combination with a vasodilator such as an angiotensin-converting enzyme (ACE) inhibitor (enalapril 0.5 mg/kg IV q24h or quinapril 0.25 mg/kg PO q24h). ACE inhibitors have not been extensively studied in horses, although quinapril has been shown to be effective in horses with mitral regurgitation. If severe tachycardia is present, rate control with digoxin can be used at a dose of 0.0022 mg/kg IV q12h or 0.011 mg/kg PO q24h. For more detail on treatment regimens, see "Cardiac Failure" in this section.

CHRONIC TREATMENT

Similar to acute treatment, with drugs and dosages tailored to the individual. Oral treatment regimens are preferred, if possible (see "Cardiac Failure" in this section).

POSSIBLE COMPLICATIONS

- Reoccurrence of heart failure or no effect of treatment
- Ventricular arrhythmia
- Atrial fibrillation
- Sudden cardiac death

RECOMMENDED MONITORING

- Clinical examination findings such as attitude, appetite, weight, respiratory rate and effort, heart rate, and exercise tolerance should be monitored by the owner regularly. Any changes should prompt a veterinary reexamination.
- Periodic echocardiography to assess progression of regurgitation or heart failure.
- Periodic exercising ECG to determine safety for use as a riding horse.

PROGNOSIS AND OUTCOME

- In older horses, the prognosis is generally good because progression occurs gradually over several years, and the condition rarely affects performance or life span.
- For young and middle-aged horses, the prognosis is more difficult to determine, but if no volume overload or mitral regurgitation is present and the progression during subsequent examinations is slow, the prognosis is considered good.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- Regular echocardiographic monitoring and exercising ECG are recommended for horses with aortic regurgitation that are used for riding purposes; the horse should be retired from work when severe left ventricular dilation develops or ventricular arrhythmias occur during exercise.
- Most insurance companies insert a proviso in case of aortic valve regurgitation in young horses. In addition, resale may be considered more risky than for horses without regurgitation. Therefore the sale prices are often reduced in horses with valvular regurgitation greater than mild.

AUTHOR: **RIKKE BUHL**

EDITOR: **MARY M. DURANDO**

Aortocardiac Fistula

BASIC INFORMATION

DEFINITION

An aortocardiac fistula is a defect in the wall of the aorta at the right aortic sinus. The defect can take the form of a tract dissecting through the aortic ring to the right ventricle (RV), right atrium (RA), or interventricular septum (IVS), or it may occur from aneurysmal dilation of the right aortic sinus (or more rarely in the noncoronary portion of the sinus) rupturing in the RA or RV or creating tracts dissecting through the myocardial septum.

SYNONYM(S)

- Aortic root rupture
- Ruptured aortic sinus aneurysm
- Tear of the aortic root

EPIDEMIOLOGY

SPECIES, AGE, SEX More common in middle-aged and older stallions, although it may affect geldings and mares as well

DISEASE FORMS/SUBTYPES

- Acute rupture
  - Sudden death
  - Distress, ventricular tachycardia, and right-sided murmur
- Subacute or chronic: Right-sided continuous murmur
  - Fistula opening in the RV or RA: Severe RA and RV volume overload leading to right-sided heart failure
  - Fistula dissecting down into the IVS: Form subendocardial tract along the septum that may rupture into RV, LV, or both, causing RV or LV volume overload

HISTORY, CHIEF COMPLAINT

- Acute distress sometimes mistaken for abdominal pain: Restlessness, sweating, and recumbency
- Exercise intolerance
- A murmur detected during routine examination
- Sudden death

PHYSICAL EXAM FINDINGS

- Extreme distress
- Right-sided, loud, continuous murmur
- Tachycardia
- Rapid, weak arterial pulses with pulse deficits
- Bounding arterial pulses
- Jugular venous pulses
- Tachypnea

ETIOLOGY AND PATHOPHYSIOLOGY

- May be congenital or acquired
  - A congenital sinus of Valsalva aneurysm is the underlying defect that precedes aortic rupture in some cases. The defect is believed to be an absence of the tunica media of the aorta in the area of the right sinus of Valsalva (see "Aortic Aneurysm" in this section).
  - May be an acquired lesion caused by increased intraaortic pressure that occurs during strenuous exercise such as racing or breeding in stallions that could be coupled with preexisting degeneration of the aortic media.
  - Degenerative aortic medionecrosis may predispose to aortic ring rupture.
- Aortic rupture into the right side of the heart usually causes severe right heart overload, leading to right heart failure.
- Aortic rupture dissecting through the ventricular septum causes widespread damage to the cardiac conduction system, resulting in rhythm disturbances (usually monomorphic ventricular tachycardia).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Abdominal pain
- Other congenital or acquired cardiac anomalies

INITIAL DATABASE

- Auscultation: Tachycardia and loud right-sided continuous murmur
- Electrocardiography: Sustained monomorphic ventricular tachycardia with heart rate (HR) of 120 to 240 beats/min in horses presented soon after rupture

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography: Defect in the aortic wall usually affecting the right aortic sinus or ruptured aneurysmal dilation of the aortic wall at this site. The ruptured aneurysm is visualized as a thin membrane fluttering into the RA or RV as blood shunts through the defect (Figure 1). Fistulas may extend to the RV, RA, or LV or dissect along the septal myocardium, appearing as anechoic blood between the septal endocardium and myocardium (Figure 2). The ventricles may appear enlarged from biventricular volume overload.
- Color-flow, pulsed, and continuous-wave Doppler echocardiography: High-velocity continuous blood flow through the aortocardiac fistula into the RA or RV
- Contrast echocardiography: Negative contrast jet from the left side into the right cardiac chambers that otherwise appears echogenic after the injection of the contrast solution into the jugular vein

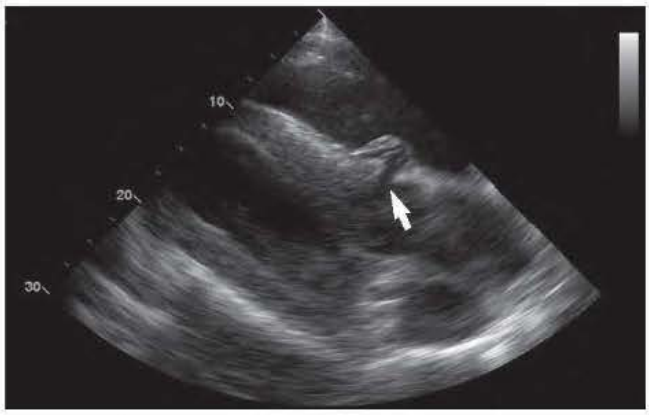

FIGURE 1 Right parasternal long-axis echocardiogram of the left ventricular outflow tract. Note the defect in the wall of the aorta at the right aortic sinus (*arrow*) that appears as a tract dissecting through the aortic ring to the right ventricle.

ElibEVet.com

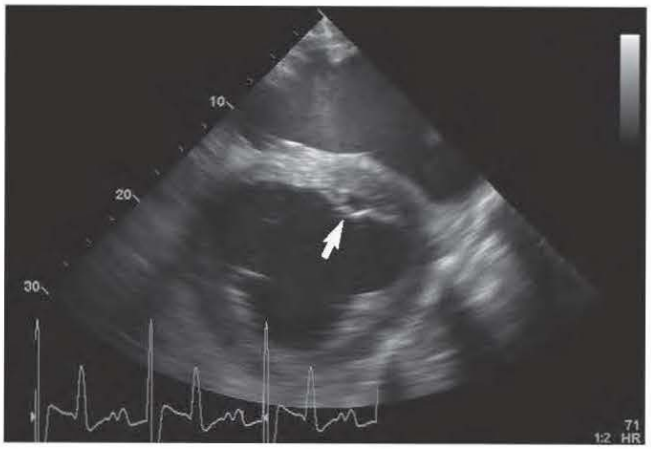

FIGURE 2 Right parasternal short-axis echocardiogram of the left ventricle. Note the dissection of blood between the endocardium (*arrow*) and myocardium along the left ventricular side of the interventricular septum.

TREATMENT

THERAPEUTIC GOAL(S)

- Stabilize the patient in the acute phase.
- Treatment is only symptomatic.

ACUTE GENERAL TREATMENT

Antiarrhythmic drugs to treat ventricular tachycardia when present (sometimes it resolves spontaneously): Treat if the HR is greater than 100 to 120 beats/min, clinical signs of cardiovascular collapse are present, or multiform or R on T phenomenon is present (see "Antiarrhythmic Drugs" in Section VI).

CHRONIC TREATMENT

- No specific treatment
- If heart failure develops (for detailed therapy recommendations, see "Cardiac Failure" in this section):
  - Diuretic therapy, such as furosemide: 1–2 mg/kg as needed IM or IV
  - Digoxin: 0.011–0.0175 mg/kg PO q12h
  - Angiotensin-converting enzyme inhibitor therapy such as enalapril: 0.5 mg/kg PO q12h
  - Hydralazine: 0.5–1.5 mg/kg PO q12h

POSSIBLE COMPLICATIONS

- RV and LV overload and myocardial dysfunction or failure leading to development of congestive heart failure
- Sudden death from cardiac arrhythmias
- Aortic regurgitation from loss of aortic root support from the aneurysm or after the aneurismal rupture, leading to further LV volume overload

RECOMMENDED MONITORING

- Acute event
  - Clinical signs pertaining to the cardiovascular system (HR, respiratory rate, arterial pulse quality, jugular pulses, or distension)
  - Telemetric electrocardiography to monitor heart rhythm
- Chronic monitoring
  - HR and rhythm, respiratory rate and effort, change in existing murmurs, attitude, and appetite should be monitored by owner. Any changes could signify a deterioration of status and should prompt a veterinary reexamination.
  - Periodic echocardiography (every 6–12 months) to monitor for progression of disease or sooner if any of the above clinical signs any noted.

PROGNOSIS AND OUTCOME

- Guarded to grave prognosis
  - Death usually occurs acutely or soon after vessel rupture.
  - Some horses survive the acute event. The majority of these survive weeks to months (depending on the site and size of the rupture), although some horses survive for years after the acute rupture without developing congestive heart failure.
- The prognosis for performance is poor because these horses are not safe to ride or use.

PEARLS & CONSIDERATIONS

COMMENTS

- Aortic root rupture should be suspected in any horse presenting with acute distress; tachycardia with a HR greater than 80 beats/min; and a loud, continuous heart murmur.
- Horses with aortocardiac fistulas are not safe to ride for any kind of performance because they have a high risk of sudden death.

CLIENT EDUCATION

- Regular cardiac auscultation should be performed in middle-aged stallions, and if a continuous heart murmur is detected, a cardiac examination should be performed.
- Horses with aortocardiac fistulas are unsafe to use because of a high risk of sudden death.

ElibeVet.com

Aortoiliac Thrombosis

BASIC INFORMATION

DEFINITION

Total or partial occlusion of the terminal portion of the aorta or the internal or external iliac arteries by masses of well-organized and vascularized fibrous tissue containing hemorrhagic, necrotic, and sometimes calcified areas with large thrombi around them. Often these masses also affect the popliteal and femoral arteries or other branches of the iliac arteries.

SYNONYM(S)

- Vascular obstruction of the hindlimbs
- Aortoiliac obstruction
- Aortoiliac-femoral thrombosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All ages reported
- Both sexes (although there is greater incidence of clinical disease in males because collateral circulation is thought to be more efficient in females)

GENETICS AND BREED PREDISPOSITION

- A hereditary predisposition has been suggested in one report, but there is little evidence to support it.
- Light breeds appear to be more commonly affected than heavy breeds.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Clinical signs vary depending on the size, location of the thrombus, and amount of occlusion of the blood vessel.

HISTORY, CHIEF COMPLAINT

- Poor performance
- Chronic progressive hindlimb lameness that worsens with exercise
- Sexual dysfunction in stallions
- May be subclinical in nonathletic horses

PHYSICAL EXAM FINDINGS

- Lameness that becomes evident during exercise, is aggravated by work, and resolves after a brief rest
- May show weakness in the pelvic limbs, ataxia, collapse after strenuous work in advanced cases, reluctance to put a hind leg down, or tendency to cow-kick after exercise
- Absence of sweating in the affected limb with profuse sweating of the remainder of the body and respiratory distress after exercise
- May have reduced skin temperature of the affected distal hind limb after exercise
- May have reduced pulse in the femoral or plantar digital arteries after exercise
- May have prolonged medial saphenous vein filling time in the affected limb shortly after work; the veins in the affected leg are indistinct
- May have gluteal atrophy on the affected side
- Failure to ejaculate in stallions

ETIOLOGY AND PATHOPHYSIOLOGY

- Unknown
- Possible causes:
  - Organization of thromboembolisms caused by migrating forms of *Strongylus vulgaris* with incorporation of the thrombi into the arterial wall and centripetal development of progressive thrombosis
  - Damage to the arterial endothelium at points of turbulence or branching leading to plaque formation and overlying thrombosis
  - Spontaneous degenerative vascular disease at the aortic quadrification that may result in thrombosis and thromboembolism
  - Secondary to coagulopathies
  - Secondary to bacterial infection
  - Direct trauma attributable to falling or parturition

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Postexercise myopathy
- Cervical vertebral malformation
- Spinal or pelvic trauma (back disorders)
- Musculoskeletal lameness

INITIAL DATABASE

- Plasma and serum muscle enzymes are usually normal before and after exercise, although creatine kinase may be increased in severe cases with marked muscle damage.
- Rectal palpation: May feel a firm area of the aorta or iliac arteries with reduced pulsations and enlargement of the iliac arteries. The rectal examination may also be unremarkable.

ADVANCED OR CONFIRMATORY TESTING

- Transrectal ultrasound examination: Heterogeneous mass in the terminal aorta or iliac arteries (or both) (Figure 1)
- Arteriography: Invasive and technically difficult; unnecessary since the advent of rectal ultrasonography
- Nuclear angiography: Marked reduction or absence of blood flow through the affected iliac arteries

TREATMENT

THERAPEUTIC GOAL(S)

- Improve collateral circulation
- Prevent additional thrombus formation
- Encourage thrombolysis
- Provide analgesia

ACUTE GENERAL TREATMENT

- No drugs are effective to eliminate a formed thrombus; treatment is based on pain relief and antiinflammatory drugs, platelet inhibitors, antihelmintics, fibrinolytic agents, and anticoagulant drugs. Some of the medical treatments reported include phenylbutazone, aspirin, isoxsuprine, IV sodium gluconate, and ivermectin.
- Intraluminal arterial thrombectomy for total or partial removal of the thrombus may improve clinical signs if a portion of the thrombus is removed; however, recurrence is high.

FIGURE 1 Transverse ultrasound of the terminal aorta using a rectal approach. A large heterogeneous mass is seen within the lumen of the aorta (*arrows*).

ElibEVet.com

CHRONIC TREATMENT

Continued exercise to encourage and maintain collateral circulation

POSSIBLE COMPLICATIONS

- Progressive lameness unresponsive to analgesia.
- Acute thrombosis of one of the external iliac arteries may result in necrosis of the muscles in the affected limb.
- Progressive occlusion of the major arterial branches and embolism of the peripheral hind limb vessels that may cause initial mild lameness or large areas of muscle ischemia.
- Death from spontaneous rupture of an ischemic rectum has been reported.
- Reduced fertility in stallions.
- Death.

PROGNOSIS AND OUTCOME

- Guarded to poor, particularly in cases with bilateral involvement. No treatment consistently improves outcome. Successful treatment is based on development of collateral circulation.
- Poor prognosis for return to previous levels of athletic performance.

PEARLS & CONSIDERATIONS

- Rectal ultrasonography is the best diagnostic technique for a definitive diagnosis of this disorder.
- The severity of clinical signs depends on the degree of vascular occlusion. Complete vascular occlusion of the arteries may result in death caused by ischemic necrosis.
- Serum muscle enzymes, neurologic examination, and diagnostic regional anesthesia may rule out other disorders.
- Any improvement in clinical signs is most likely attributable to development of effective collateral circulation.

EDITOR: **MARY M. DURANDO**

Arsenic Toxicosis

BASIC INFORMATION

DEFINITION

Arsenic toxicosis is the syndrome caused by exposure to injurious amounts of inorganic arsenic (trivalent arsenic, pentavalent arsenate) or organic arsenic (aliphatic, aromatic, and phenylarsenic compounds). Exposure can be by ingestion or by dermal contact. Possible sources of arsenic include older formulation of some insecticides, rodenticides, herbicides, fungicides, and defoliants or desiccants; ashes from arsenic-treated lumber; contaminated water and soil sources; and feed additives for poultry and swine. Arsenic can also be found in mine tailings and ores, old paints and other industrial chemicals, and some drugs. Arsenic is naturally found in soil, rocks, and some water sources.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Debilitated animals and young animals are more sensitive.
- The phenylarsonic feed additives are less likely to be a problem in horses and cause problems mainly in swine and pigs.

RISK FACTORS

- Access to old barns or sheds that may contain older pesticides or chemicals
- Access to dump or burn piles containing burned lumber
- Proximity to mining and manufacturing operations that may contribute to ground and water contamination

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Peracute or acute toxicosis: Single toxic dose
- Subacute toxicosis: Lower repeated doses over a longer period
- Phenylarsonic toxicosis: Mainly seen in swine and poultry, not horses

HISTORY, CHIEF COMPLAINT

- Exposure to arsenic-containing product
- Peracute death (no premonitory clinical signs)
- Acute: Severe gastrointestinal (GI) signs, colic, ataxia, recumbency, shock, and death
- Subacute: Persistent watery diarrhea and signs of renal dysfunction
- Phenylarsonics: Peripheral neuropathy with low mortality rate

PHYSICAL EXAM FINDINGS Acute toxicosis:

- High morbidity and mortality rates
- Drooling
- Trembling
- GI pain or stasis
- Colic (sudden onset)
- Diarrhea (green to black and severe)
- Dehydration
- Weak pulse
- Recumbency

Subacute toxicosis:

- Persistent GI signs (watery diarrhea)
- Depression
- Anorexia

Signs associated with severe shock:

- Dehydration
- Oliguria, polyuria, anuria
- Weakness
- Ataxia
- Metabolic acidosis
- Hyperemic mucous membranes
- Tachycardia

ETIOLOGY AND PATHOPHYSIOLOGY

- Arsenic reacts with sulfhydryl groups in cells. As a result, sulfhydryl enzyme systems essential to cellular metabolism are impaired. The net effect is the blocking of fat and carbohydrate metabolism and cellular respiration.
- Tissues most affected are those rich in oxidative enzymes (GI tract, endothelium, lung, kidney, liver, and epidermis).
- Disruption of capillary integrity is the effect on the GI tract, resulting in necrosis and hemorrhagic enteritis.
- Endothelial damage with fluid loss into interstitium, hypovolemia, hypotension, and pulmonary edema.

ElibEVet.com

- Hepatic and renal damage from direct effect of arsenic or secondary to hypovolemia and organ hypoperfusion.
- Toxicity varies with physical form, solubility, and valence.
- Inorganic arsenic (eg, arsenic trioxide) is more toxic than organic forms (eg, arsanilic acid).
- Trivalent arsenic (arsenite) is more toxic than pentavalent forms (arsenate).
- Highly soluble forms (arsenic acid) are more toxic than insoluble forms.
- Single lethal dose of sodium arsenite = 1 to 25 mg/kg of body weight
- Arsenic trioxide is three to 10 times less toxic than sodium arsenite.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other heavy metal toxicosis (eg, lead, mercury)
- Poisonous plants
- Salmonellosis
- Caustic agents
- Zinc phosphide toxicosis

INITIAL DATABASE

If the horse survives the acute phase:

- Azotemia
- Hypokalemia
- Hyponatremia
- Hypochloremia
- Hyperglycemia
- Hyperbilirubinemia
- Increased glutamate dehydrogenase and lactate dehydrogenase

ADVANCED OR CONFIRMATORY TESTING

- Normal renal and hepatic arsenic concentrations are less than 1 ppm; definitive diagnosis of arsenic toxicosis is based on liver and kidney arsenic concentrations greater than 10 ppm (wet weight).
- Antemortem urine arsenic concentrations greater than 10 mg/L indicate excessive exposure.
- Postmortem lesions include generalized or localized redness, edema, and necrosis of gastric and intestinal mucosa with massive accumulation of fluid in dilated and atonic intestine.
- Organic arsenicals target the nervous system with edema and necrosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Control life-threatening signs.
- Prevent systemic absorption.
- Provide chelation therapy.
- Manage GI effects.

ACUTE GENERAL TREATMENT

- Provide decontamination with activated charcoal if no clinical signs are present.
- Provide aggressive fluid therapy.
- Administer sodium thiosulfate orally to bind unabsorbed arsenic.
- Administer arsenic chelators such as dimercaprol or D-penicillamine (marginally useful).
- Provide other sources of sulfhydryl groups (cysteine, acetylcysteine).
- Give antibiotics for secondary bacterial infection.
- Monitor renal and hepatic function.

CHRONIC TREATMENT

- Provide general supportive care
- Manage renal insufficiency as needed
- Provide supportive care for possible hepatic dysfunction

POSSIBLE COMPLICATIONS

Renal failure

RECOMMENDED MONITORING

- Hydration and electrolyte status
- Hematocrit, total solids
- Acid-base status
- Biochemical profile, especially renal values

PROGNOSIS AND OUTCOME

Most horses die within 12 to 24 hours of ingestion of lethal doses.

PEARLS & CONSIDERATIONS

COMMENTS

- Toxicosis is less common now because of decreased use of arsenic-containing products, but occasional cases are still seen.
- Horses with extensive damage to the GI mucosa are unlikely to recover fully.
- The destruction of crypt cells may prevent regeneration of the mucosa needed for proper absorption of nutrients.

PREVENTION

- Avoid arsenic-containing products where horses are kept.
- Ensure ashes from arsenic-treated wood are not disposed of where horses are kept.

Arteritis, Equine Viral

BASIC INFORMATION

DEFINITION

Equine viral arteritis (EVA) is a contagious arterivirus disease of horses named for the characteristic vascular lesions that develop.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Disease of horses, but antibodies have been found in donkeys
- Disease depends on age and sex
- Inapparent infection, especially in mares
- Persistent infection only in stallions (testosterone dependent)

GENETICS AND BREED PREDISPOSITION

- Seroprevalence varies by country, breed, and age. EVA is endemic in Standardbreds (75%–80% seropositive) but has a low prevalence in Thoroughbreds, with a 1% to 5% seropositive rate. Many European Warmblood stallions are seropositive.
- Genetic differences conferring resistance to infection may be a factor but have not been proven.

RISK FACTORS

- Stallions may be inapparent carriers and can shed virus in the semen for years. Cooled or frozen serum can still retain infective virus.

ElibeVet.com

- Infected mares and/or vaccinated mares bred to infected stallions can become infected and shed the virus.

CONTAGION AND ZOONOSIS

- EVA is an arterivirus in the family of Arteriviridae. The first Bucyrus strain was isolated in 1953. Virulence is variable in terms of clinical disease and abortion of viral isolates, but all strains are neutralized by polyclonal antiserum from the highly virulent Bucyrus strain.
- There is no known zoonotic potential.

GEOGRAPHY AND SEASONALITY

Worldwide except for Iceland and Japan

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Anorexia, depression, edema (ventral limbs, preputial [male], mammary [mare]), abortion storms, urticaria.
- Most infections are subclinical or inapparent.

PHYSICAL EXAM FINDINGS

- Variable clinical signs (depend on age, condition of horse, viral strain, environmental conditions)
- Usually inapparent infection, particularly in mares
- Systemic disease: Fever (105°–106° F), anorexia, depression, edema (ventrum, periorbital, distal limbs, prepuce, mammary), urticaria, conjunctivitis, rhinitis, cough/dyspnea
- Less common: Icterus, photophobia, corneal opacity, abdominal pain, diarrhea, ataxia, petechiation, lymphadenopathy
- Abortion (3–10 months' gestation) with no premonitory signs
- Neonates: Fulminant severe interstitial pneumonia or fibrinonecrotic enteritis
- Stallions: Temporary subfertility, decreased libido, decreased sperm motility, concentration, and morphology up to 7 weeks
- Stallions with persistent infection: No change in semen quality after acute recovery

ETIOLOGY AND PATHOPHYSIOLOGY

- Transmission is primarily by inhalation of aerosolized virus from respiratory secretions and contact with venereal secretions, urine, or exposure to aborted fetus or placenta. Indirect transmission of the virus with fomites is possible.
- Incubation is 3 to 14 days; the virus then spreads to the lungs and bronchial lymph nodes.
- The circulatory system spreads it through rest of body, with infection and replication of virus occurring in the endothelial cells.
- Increased vascular permeability, hemorrhage, and edema with degeneration and necrosis of the tunica media of small arteries (>1 mm).
- Mares remain infective for up to 2 weeks after infection, with shedding of the virus in nasal secretions.
- Transplacental infection of the fetus is possible if the mare is infected in late pregnancy.
- Virus is not isolated from horses after 28 days except for stallions.
- Persistent infection in stallions
  - Unknown mechanism, testosterone dependent
  - Virus lives in the accessory sex glands of stallions, with the highest titers found in the ampulla of the vas deferens
  - Variable duration
    - Short term: A few weeks after acute infection
    - Intermediate: 3 to 7 months
    - Long term (30%–35% of stallions): Lifelong, continual shedders or may spontaneously stop shedding

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine herpesvirus-1 and -4
- Influenza
- Equine rhinitis A and B viruses
- Equine adenovirus
- Equine infectious anemia
- Purpura hemorrhagica
- Urticaria
- Leptospirosis
- African horse sickness
- Hoary alyssum toxicosis

INITIAL DATABASE

- Leukopenia
- Thrombocytopenia

ADVANCED OR CONFIRMATORY TESTING

- Virus isolation using whole blood (ethylenediamine tetraacetic acid or citrate only; heparin will inhibit the virus), nasopharyngeal or conjunctival swabs, placental or fetal tissues/fluid, vaginal secretions, semen.
  - Virus cannot be isolated after 28 days of infection except in semen or carrier stallions.
  - Virus is detected in the nasopharynx (2–14 days), buffy coat (2–19 days), or serum or plasma (7–9 days).
- Paired (acute and convalescent) serology using serum taken 3 to 4 weeks apart with four-fold increase; this is the gold standard set by the World Organisation for Animal Health.
- Antigen detection: Immunohistochemistry.
- Polymerase chain reaction (PCR) (real-time PCR, nested) is still being validated and standardized.
- Diagnosis of carrier stallions: (1) Test breed to two seronegative mares and monitor for seroconversion; (2) isolate virus from sperm-rich fraction of semen.

TREATMENT

THERAPEUTIC GOAL(S)

- Symptomatic and supportive care to maintain general health and well-being.
- Decrease distal edema.
- Prevent or treat secondary bacterial infections.

ACUTE GENERAL TREATMENT

- Symptomatic treatment (rest, antipyretics) as for other viral respiratory infections
- Symptomatic treatment for distal edema (diuretics, support wraps)
- No effective treatment for foals with EVA-induced interstitial pneumonia or enteritis; antibiotics for secondary bacterial infection
- Only way to eliminate persistent infection in stallions is by castration

PROGNOSIS AND OUTCOME

- Majority of EVA infections are subclinical or inapparent. Mortality is rare in adult horses.
- Fatal interstitial pneumonia may occur in neonates.

PEARLS & CONSIDERATIONS

COMMENTS

EVA is an important disease in terms of its economic impact on the equine industry from abortion losses, export restrictions of seropositive horses, and performance-related losses.

PREVENTION

- No domestic program for EVA prevention or control exists, but the U.S. Department of Agriculture and Animal and Plant Health Inspection Services have guidelines and standards outlining preventative vaccination and control measures.
- Modified live virus vaccine is available in the United States.
- Vaccinate foals before puberty (at 6 months of age), then annually.
- Vaccinate seronegative stallions 28 days before breeding season and isolate after vaccination. Stallions should be screened before primary

ElibeVet.com

immunization. Neutralization titer of 1:4 or greater is positive for EVA.
- Nonvaccinated seropositive stallions should be tested for virus shedding by virus isolation every 12 months or by test breeding with two seronegative mares monitored for seroconversion at 14 and 28 days after breeding.
- Pony/outrider horses or any horses with potential contact with multiple horses should be vaccinated annually for EVA.
- Carrier stallions and confirmed semen shedders should be isolated, collected separately, and bred to mares that are seropositive or vaccinated at least 3 weeks before breeding.
- Mares bred to shedding stallions or inseminated with infective semen should be isolated for 3 weeks from seronegative or nonvaccinated horses. Mares should be vaccinated 3 weeks before breeding to shedding stallions.

CLIENT EDUCATION

- The increasing number of outbreaks and apparent global dissemination of EVA likely reflect the rapid national and international movement of horses for competition and breeding as well as increased recognition of the importance of EVA infection.
- Prevention of outbreaks of EVA relies on raising the awareness of the disease in owners, identification of persistently infected stallions, and institution of management practices (eg, vaccines, biosecurity).
- If an outbreak of EVA is suspected:
  - Notify the state veterinarian.
  - Institute quarantine of premises by isolating affected and in-contact horses, stopping traffic movement on and off the farm, vaccinating at-risk horses, and stopping breeding activity.
  - Confirm diagnosis of EVA with laboratory testing.
  - Properly disinfect affected premises.
  - End the quarantine when no more clinical cases of EVA or serologic evidence of infection is observed for 3 consecutive weeks.

AUTHOR: **KATHY K. SEINO**

EDITORS: **MAUREEN T. LONG** and **DEBRA C. SELLON**

Arytenoid Chondritis and Chondropathy

BASIC INFORMATION

DEFINITION

A progressive, acute or chronic, predominately infectious process resulting in exercise intolerance or upper airway noise caused by thickening of the arytenoid cartilage, the surrounding soft tissue, or both

SYNONYM(S)

- Arytenoid granuloma is a granulating mass and may be a component of the lesion.
- *Arytenoid chondroma* is a term used previously for granuloma.
- Neoplasia is uncommon and not part of this disease.

EPIDEMIOLOGY

SPECIES, AGE, SEX
- Racing breeds during active training
- Former race horses, including broodmares
- A milder, predominately self-limiting form observed in yearlings
- Less frequently affects horses of any breed or occupation

RISK FACTORS
- Mucosal surface trauma caused by contact of arytenoid cartilages during exercise
  - Laryngeal hemiplegia
  - Enlargement of the opposite arytenoid cartilage
- Mucosal disruption has been experimentally demonstrated to cause the disease

CONTAGION AND ZOONOSIS Not considered contagious

GEOGRAPHY AND SEASONALITY
- The incidence can be variably higher from particular regions or racetracks within a region.
  - Racing surface, air quality, and training methods must be considered.
  - Arytenoid chondritis is very uncommon where racing is predominately on turf.

ASSOCIATED CONDITIONS AND DISORDERS
- May be observed concurrently with laryngeal hemiplegia, presumably because of mucosal surface trauma from collapse of the paretic cartilage.
- Either or both cartilages may be affected.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Acute or chronic progression of:
  - Arytenoid mucosal ulceration
  - Arytenoid axial surface granulation
  - Arytenoid full- or partial-thickness intracartilaginous septic tracts
  - Intracartilaginous or pericartilaginous abscessation: The arytenoid cartilage may be axially displaced by abaxial extracartilaginous abscessation, producing airway obstruction without actual invasion of the arytenoid cartilage.
  - Arytenoid cartilage enlargement or distortion

HISTORY, CHIEF COMPLAINT
- Variable exercise intolerance
- Variable upper respiratory noise
- Occasionally presents as a respiratory emergency caused by airway obstruction at rest because of abscessation or granulation tissue masses
- Often becomes more severe in nonathletes because it remains undetected until the obstruction is complete

PHYSICAL EXAM FINDINGS
- Generally outwardly normal horse
- Physical examination usually normal; possible exceptions:
  - Upper airway inspiratory stertor at rest in severe cases; however, with persistent stenosis, the stertor is audible on expiration as well.
  - Dysphagia is uncommon but may be associated with severe perilaryngeal or pharyngeal inflammation.

ETIOLOGY AND PATHOPHYSIOLOGY
- Most often presumed to be mucosal disruption leading to deeper infection or inflammation, causing thickening of the arytenoid cartilage or swelling of the surrounding tissue.
- Arytenoid abduction is mechanically prevented by cartilage distortion or adjacent soft tissue swelling.
- Arytenoid distortion or axial compression of the arytenoid may be observed without a visible mucosal disruption.
- Hematogenous seeding of infection must be considered a possibility,

ElibeVet.com

although a previously undetected mucosal lesion could have healed.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Laryngeal hemiplegia
  - There should be no thickening or mucosal lesion with left laryngeal hemiplegia
  - May occur concurrently
- Retropharyngeal abscess
- Ventricular mucocele
- Has been observed after ventricular ablation without resection
- Neoplasia

INITIAL DATABASE

- External laryngeal palpation is most commonly normal.
- Arytenoid chondritis may occur concurrently with laryngeal hemiplegia, so cricoarytenoideus dorsalis muscle atrophy may be palpable.

ADVANCED OR CONFIRMATORY TESTING

- Nasopharyngeal endoscopy provides the diagnosis for almost all cases.
  - Affected arytenoid cartilage(s) will be thickened with or without mucosal swelling. Both may be subtle.
  - There is often a contact (kissing) lesion on the contralateral cartilage from contact with the enlarged cartilage or a granulation tissue mass from the affected cartilage (Figure 1). Arytenoid chondritis may be bilateral.
  - Retroflexion of the scope within the trachea allows detection of thickening of the caudal arytenoid body or changes in mobility, particularly during swallowing.
- Ultrasonography may demonstrate:
  - Cartilage thickening or abscessation
  - Extracartilaginous abscess or mucocele
- Magnetic resonance imaging: Demonstrative but not likely to be necessary

FIGURE 1 Left arytenoid chondropathy. The right arytenoid is fully abducted, but the left is not. The left corniculate is abnormally shaped and has a mucosal lesion on its medial surface. All are consistent with a left arytenoid chondropathy.

TREATMENT

THERAPEUTIC GOAL(S)

- Restoration of normal upper airway function
- Restoration of an airway to save the life of the horse

ACUTE GENERAL TREATMENT

- Provide an airway for emergency situations.
  - Tracheotomy
  - More likely during warm weather or when the horse is stressed
- Medical therapy may be successful in horses without arytenoid deformity or airway compromise.
  - Broad-spectrum or specific antibacterial therapy: Duration, 10 to 30 days depending on severity and chronicity
  - Local and systemic antiinflammatory therapy
    - Topical antiinflammatory throat spray
    - Systemic nonsteroidal antiinflammatory drug therapy
    - Systemic steroid therapy unless acute infection is too active
- Horses with permanent arytenoid deformity or adjacent thickening that compromises the airway must undergo a partial arytenoidectomy (removing all but the muscular process of the arytenoid cartilage).
  - Acute inflammation should be relieved with medical therapy as much as possible before surgery. The applicable procedure or the need for any surgery at all may change after medical therapy.
  - Successful partial arytenoidectomy can be performed with or without mucosal closure.
- Horses with less-affected arytenoid cartilages or resolvable adjacent soft tissue lesions may undergo successful (standing) debridement of the affected areas accompanied by medical therapy.
  - The lesion is accessed through a trocar placed in the cricothyroid membrane and performed with a laser and conventional instruments. Culture of the lesion is recommended.
  - Debridement may lead to drainage of arytenoid or adjacent abscesses, thereby rapidly reducing the deformity.
  - Case selection is critical for success because the potential for arytenoid abduction must be present after the inflammation has resolved.
    - Evaluation of cartilage morphology and mobility can be improved by digital palpation through a standing laryngotomy.
    - The caudal margin, mid-body through the lateral ventricle and rostral body abaxial and caudal to the corniculate process should be palpated.
- Horses with only surface granulomas may respond favorably to standing removal of the mass followed by local and systemic antiinflammatory and antibacterial therapy.
- The author's opinion is that all but the most obviously superficial lesions should be probed for deeper tracts that may be debrided or drained before permanent arytenoid deformity occurs.

POSSIBLE COMPLICATIONS

- Partial arytenoidectomy may be followed by a variable degree of aspiration of food into the trachea, causing mild or serious aspiration pneumonia, although this seems to be less common.
- Horses undergoing bilateral partial arytenoidectomy do not commonly remain functional athletes.
- The most serious complication of arytenoid debridement is failure to restore function and a subsequent need for partial arytenoidectomy.

PROGNOSIS AND OUTCOME

- Partial arytenoidectomy has been reported in the older literature to fail to return horses to their previous athletic ability.
- More recent experience and reports have been more favorable.
- Success of arytenoid debridement in appropriate cases has been quite favorable.

PEARLS & CONSIDERATIONS

COMMENTS

- When the arytenoid cartilage is affected in an area containing a medullary cavity, the axial and abaxial laminae of the cartilage may be split apart. The axial lamina may separate during partial arytenoidectomy, leaving an incomplete removal. The surgeon should watch for this situation.

ElibVet.com

- Subtotal arytenoidectomy (leaving the corniculate and muscular process) has been reported in older literature but has been shown to be insufficient for return to substantial athletic performance.

Ascariasis

BASIC INFORMATION

DEFINITION

Mange caused by a variety of mites, including the chorioptic (leg mange) and psoroptic families

SYNONYM(S)

Mange

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Chorioptic mange typically affects draft breeds with heavy feathering in their legs but may occasionally affect light breeds with thin hair coats. Psoroptic mange typically affects young horses of any breed.

RISK FACTORS

Young, stabled horses are at increased risk of being affected by psoroptic mange. When introduced into a new barn, they can transmit the disease to older horses. Horses affected by chorioptic mange can be asymptomatic carriers.

CONTAGION AND ZOONOSIS Neither psoroptic nor chorioptic mange is considered a zoonotic disease. Both psoroptic and chorioptic mange are reportable diseases in the United States.

GEOGRAPHY AND SEASONALITY Both chorioptic and psoroptic mange are more frequently seen in the cooler months of the year. Psoroptic mange has been eradicated from horses in the United States but is still present in other areas.

ASSOCIATED CONDITIONS AND DISORDERS Psoroptic mange has been associated with tail rubbing and otic irritation, which may lead to head shaking. Chorioptic mange may cause weight loss, irritability, and decreased exercise tolerance.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Psoroptic and chorioptic mange

HISTORY, CHIEF COMPLAINT

- Psoroptic mange is characterized by severe pruritus, head shaking, and tail rubbing. Papules, crusts, and alopecia are frequently seen at the base of the mane, tail, ears, and submandibular area, and it may then spread to the rest of the body.
- Chorioptic mange lesions are typically seen in the pastern area, but in severe cases, the infection may spread to the ventral abdomen or even become generalized. Pruritus in chorioptic mange is variable, and severe thickening of the skin with secondary bacterial infection may result from self-trauma.

PHYSICAL EXAM FINDINGS Moderate to severe pruritic dermatitis in the ears, mane, body, and tail head ("rat tail" appearance), head shaking, and irritability are characteristic of psoroptic mange. Irritation, moderate pruritus with significant discomfort of the legs characterized by foot stamping and biting at the lower legs, patchy alopecia, and scaling are also common in chorioptic mange.

ETIOLOGY AND PATHOPHYSIOLOGY

- Mites *Psoroptes equi* and *Chorioptes equi*, both of which are relatively host specific, live on the surface of the epidermis.
- Both *P. equi* and *C. equi* normally have a 2-week lifespan.
- If there are favorable conditions of temperature, moisture, and humidity in the environment, *P. equi* can live away from its host for up to 3 weeks, but *C. equi* can live away from its host for just a few days.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Dermatophilosis
- Dermatophytosis
- Trombiculidiasis
- Lice infestation
- *Culicoides* hypersensitivity
- Parasitic dermatitis
- Pastern dermatitis

INITIAL DATABASE

- *P. equi*: Demonstration of mites in skin scrapings and ear swabs from affected animals; round, elongated bodies with segmented pedicles
- *C. equi*: Demonstration of mites in skin scrapings from the pastern area and plantar or palmar area of the cannon bone

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate both eggs and adults of the parasites
- Decrease the risk of contamination of other animals in the barn

ACUTE GENERAL TREATMENT

- Psoroptic mange: Topical insecticides, including deltamethrin, coumaphos, diazinon, malathion, toxaphene, and lime sulphur, should be used. Ivermectin has also been used, but it does not always eliminate live mites from all animals. The contaminated environment also needs to be treated to prevent infection of other animals. It is important to continue treatment for at least 1 month.
- *C. equi*: Lime sulfur or fipronil applied once a week for at least 1 month is recommended. Lesions should be clipped and scabs removed before the affected areas are scrubbed with insecticidal shampoo or powder. Oral ivermectin given twice at 2-week intervals may be effective.

CHRONIC TREATMENT

Ascariasis may be difficult to eradicate after it becomes established in a stable.

ElibeVet.com

PROGNOSIS AND OUTCOME

- If diagnosed and appropriately treated early in the course of the disease, the prognosis is favorable.
- After it has been established in the barn, the disease may be difficult to eradicate.

PEARLS & CONSIDERATIONS

Not zoonotic diseases, but reportable

Ascites

BASIC INFORMATION

DEFINITION

Accumulation of peritoneal fluid (transudative effusion) in the peritoneal cavity

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Abdominal distension
- Inappetence, mild colic, and lethargy are frequently reported.

PHYSICAL EXAM FINDINGS

- Ventral abdominal or distal limb edema is often present.
- Other clinical signs are variable and depend on the cause of ascites.
  - Poor body condition and signs of abdominal pain are often present if ascites occurs with abdominal neoplasia.
  - Jugular vein distension and pulsation, exercise intolerance, tachycardia, and a heart murmur may be present if right heart failure is the inciting cause.
- Rectal examination may be abnormal, with organ enlargement, intestinal distension, or palpable masses if intraabdominal neoplasia is the cause.

ETIOLOGY AND PATHOPHYSIOLOGY

- Abdominal neoplasia may result in obstruction of abdominal lymphatics or production of excess peritoneal fluid (especially with mesothelioma) and may result in ascites.
- Right-sided heart failure causes congestion of the venous circulation and increases capillary hydrostatic pressure, resulting in a transudative abdominal effusion.
- Hypoproteinemia may result from protein-losing enteropathy or protein-losing nephropathy, causing a decrease in colloid oncotic pressure that results in loss of fluid from the vascular space.
- However, clinically apparent ascites is uncommonly seen with right heart failure or hypoproteinemia in horses because of the large capacity of the equine peritoneal cavity.
- Also, in contrast to other species, ascites rarely accompanies hepatic disease in horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hydroallantois or hydramnios (in a broodmare)
- Chronic peritonitis
- Uroperitoneum
- Hemoperitoneum

INITIAL DATABASE

- Complete blood count: Variable; may be normal or may show evidence of chronic inflammation (mild anemia, leukocytosis, hyperfibrinogenemia) or abnormal leukocyte distribution or morphology if neoplasia is the inciting cause.
- Serum biochemistry profile: Variable; may be normal or hypoproteinemia or hypoalbuminemia may be present.
- Urinalysis: Should be performed in hypoproteinemic patients to rule out protein-losing nephropathy. Significant proteinuria should warrant further evaluation for glomerular disease.
- Transabdominal ultrasonography.
  - A large amount of hypoechoic free peritoneal fluid is visible in the ventral abdomen.
  - Evidence of intestinal disease (eg, inflammatory bowel disease causing protein-losing enteropathy) or intraabdominal neoplasia with intestinal thickening or intraabdominal masses may be apparent.
- Peritoneal fluid analysis.
  - Fluid is typically clear and watery but is occasionally cloudy or red-tinged if abdominal neoplasia is the cause.
  - The nucleated cell count and total protein concentration are usually within reference intervals (<10,000 cells/μL and 1.5 mg/dL, respectively). Occasionally, the fluid is more consistent with a modified transudate (ie, mildly increased cell count and total protein concentration) in neoplastic disease.
  - Cytologic evaluation of the peritoneal fluid may be within normal limits or neoplastic cells may be seen.
  - Measurement of peritoneal fluid creatinine concentration may be performed to help rule out uroperitoneum. In ascites, peritoneal fluid creatinine is comparable to or lower than plasma creatinine.
- Cardiac ultrasonography should be performed if clinical evidence of right heart failure is present or if an alternative cause of ascites cannot be identified.

TREATMENT

THERAPEUTIC GOAL(S)

- Manage or treat primary disease if possible.
- Remove accumulated fluid.

ACUTE GENERAL TREATMENT

- Management of primary disease
  - Right heart failure may be managed with diuretics and positive inotropes (see "Cardiac Failure" in this section).
  - Plasma transfusion or administration of synthetic colloids may be indicated in hypoproteinemic patients.
  - Specific therapy for disseminated abdominal neoplasia resulting in ascites is usually palliative in horses. Dexamethasone (0.05–0.10 mg/kg IV or IM q24h) may result in transient clinical improvement in some neoplasias, especially lymphosarcoma.
- Drainage of accumulated peritoneal fluid
  - Not indicated unless large volume accumulation and associated clinical signs (abdominal pain, colic) are present.

ElibeVet.com

FIGURE 1 Drainage of peritoneal fluid with a chest drain from the abdomen of a yearling with ascites secondary to neoplasia.

- May be performed with a teat cannula as for an abdominocentesis or chest drain, but fluid removal should be done slowly and an equivalent volume of IV fluids administered simultaneously to avoid hypovolemic shock.

PROGNOSIS AND OUTCOME

Guarded to poor because the inciting causes of ascites in horses are usually difficult to impossible to treat.

PEARLS & CONSIDERATIONS

Because ascites is uncommon in horses, it is vital to rule out uroperitoneum in horses with abdominal distension and a large volume of free hypoechoic peritoneal fluid. The concurrent presence of azotemia or electrolyte derangements, such as hyponatremia or hyperkalemia, should warrant a comprehensive evaluation of the urogenital tract.

EDITOR: **TIM MAIR**

Atonic/Hypotonic Bladder

BASIC INFORMATION

DEFINITION

Dysuria or incontinence caused by sensory and motor deficits of the nervous system

SYNONYM(S)

Atonic or paralytic bladder, lower motor neuron bladder, spastic bladder, upper motor neuron bladder

EPIDEMIOLOGY

RISK FACTORS

- Feeding or exposure to sorghum or sudan grass
- Illicit tail blocking

CONTAGION AND ZOONOSIS Infectious agents incriminated include equine herpesvirus-1 (EHV-1), *Sarcocystis neurona*, and *Neospora hughesi*.

ASSOCIATED CONDITIONS AND DISORDERS

- Affected animals have a history or suspicion of a congenital disorder, spinal cord trauma, sacral trauma, or evidence of a concurrent inflammatory or degenerative neurologic disorder.
- Sabulous urolithiasis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Upper motor neuron or spastic bladder: Lack of descending inhibition, turgid bladder, increased urethral sphincter tone, periodic uncontrolled high-pressure urine production, and incomplete bladder emptying. The bladder is difficult to express by transrectal compression. The urethra is difficult to catheterize because of increased tone.
- Lower motor neuron or paralytic bladder: Loss of sensory fibers signaling bladder wall stretching that normally initiates urination. Detrusor muscle innervation and contractility are lost. The bladder fills to capacity and then passively overflows. The bladder is easily compressed per rectum, allowing urine voiding.
- Automatic bladder: Spinal cord damage cranial to the sacrum. Bladder filling and uncontrolled reflex emptying caused by loss of upper motor neuron influence. Higher sensation of bladder fill is lost, and emptying is incomplete.

HISTORY, CHIEF COMPLAINT

- Urinary incontinence
- May have concurrent neurologic disease

PHYSICAL EXAM FINDINGS

- Urine scalding over the perineum and between the hind legs.
- Frequent attempts to urinate or uncontrolled voiding.
- Perineal analgesia, loss of tail tone, loss of anal tone, fecal incontinence.
- Abnormalities of pelvic limb gait and regional muscle wasting may occur.
- Signs referable to more widespread neurologic dysfunction may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Sympathetic, parasympathetic, and somatic branches of the central nervous system are required to coordinate bladder function.
  - Sympathetic innervation: Hypogastric nerve (L1–L4) via the caudal mesenteric ganglion. Postganglionic fibers innervate the bladder wall (β_2 receptors) and proximal urethra (α_1 with some α_2 receptors).
  - Parasympathetic innervation: The pelvic nerve (sacral segments) innervates the detrusor smooth muscle.
  - Somatic innervation: The pudendal nerve (S1–S2) supplies the striated musculature of the urethra.

ElibEVet.com

- Normal bladder function consists of bladder filling, urine storage, and evacuation. Extrapolation from other species is used to model bladder function in horses.
  - During bladder filling, tone increases in the external (pudendal nerve) and internal (sympathetic) urethral sphincters to hold urine. The detrusor muscle relaxes because of α-receptor–mediated inhibition of pelvic nerve afferent input and smooth muscle β_2-receptor stimulation caused by stretch receptors in the bladder wall acting on pelvic nerve afferents stimulating the hypogastric nerve. This allows an increased volume of urine storage in the bladder without a corresponding increase in pressure.
  - Evacuation of the bladder results from pelvic nerve afferent impulses transmitted to higher (intracranial) control centers in response to detrusor muscle stretch. Detrusor contraction is initiated by pelvic nerve impulses, spreading throughout the smooth muscle of the bladder and allowing coordinated contraction. Inhibition of pudendal and hypogastric nerve input also occurs, allowing more complete detrusor muscle contraction and urethral sphincter relaxation. Bladder emptying ceases when stretch receptors sense the bladder is no longer full. Pudendal and hypogastric nerve activity is then no longer inhibited, allowing detrusor muscle relaxation and increased urethral sphincter tone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Congenital anomaly: Ectopic ureter
- Cystolithiasis
- Cystitis
- Sabulous urolithiasis
- Nonneurogenic or myogenic bladder: Degenerative detrusor muscle changes
- Idiopathic incontinence of geldings
- Parturient urethral trauma of mares: Physical trauma to the pelvic urethra and pelvic nerves
- Musculoskeletal disorders: Pain preventing posturing to urinate

INITIAL DATABASE

- Complete blood count with fibrinogen concentration
- Serum chemistries
- Rectal palpation: Bladder size and tone, ease of manual expression
- Transrectal ultrasonography: Bladder size and content
- Urethral catheterization: May be difficult with increased urethral tone (upper motor neuron bladder)
- Cystoscopy, urethroscopy: To rule out nonneurogenic problems

ADVANCED OR CONFIRMATORY TESTING

- Suspected meningitis: Cerebrospinal fluid analysis ± culture
- Suspected viral infection: EHV-1 polymerase chain reaction, serology
- Suspected pelvic or sacral fracture (pain, compressive myelopathy): Radiography, scintigraphy, ultrasonography
- Suspected degenerative conditions (equine degenerative myelopathy, equine motor neuron disease): Vitamin E levels, muscle or peripheral nerve biopsy

TREATMENT

THERAPEUTIC GOAL(S)

- Management of primary neurologic disorder
- Management of bladder distension and urolithiasis
- Management of urine scalding from chronic overflow
- Management of cystitis and ascending infection of kidneys, if present

ACUTE GENERAL TREATMENT

- Drainage of urine by catheterization
- Appropriate antimicrobial therapy if cystitis is present
- Management of secondary complications: Urine scald
- Management of concurrent neurologic or musculoskeletal disorders

CHRONIC TREATMENT

- Long-term bladder catheterization
- Long-term antimicrobial or antiinflammatory therapy for appropriate cases
- Management of underlying neurologic or musculoskeletal disorder may be necessary
- Prevention and treatment of dermatitis secondary to urine scald

PROGNOSIS AND OUTCOME

- Prognosis is favorable for horses with incontinence occurring during the onset of acute neurologic disease that responds to treatment, provided bladder atony and distension are managed effectively and quickly.
- Prognosis is poor for horses with urinary incontinence resulting from chronic bladder dysfunction caused by a persistence of underlying neurologic factors or onset of sabulous urolithiasis.
- Chronically overdistended bladders are unlikely to respond to treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Prognosis depends on the anatomic location of any neurogenic cause of dysfunction.
- Treatment options are limited and similar, regardless of the origin of the problem.
- Secondary changes (cystitis, detrusor muscle degeneration) may be irreversible in advanced cases.

CLIENT EDUCATION

Neurologic bladder dysfunction may not resolve and requires long-term management.

EDITOR: **BRYAN M. WALDRIDGE**

ElibeVet.com

Atrial Fibrillation

BASIC INFORMATION

DEFINITION

Supraventricular arrhythmia characterized by very rapid and chaotic, self-sustaining atrial electrical activity with an irregularly irregular ventricular response.

SYNONYM(S)

Auricular fibrillation

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Large breeds are more susceptible than small breeds.
- Rarely occurs in ponies unless severe cardiac pathology is present.

RISK FACTORS

- Underlying cardiovascular pathology leading to:
  - Atrial dilation: Chronic valvular regurgitation (eg, mitral regurgitation), congenital heart disease (eg, ventricular septal defect)
  - Structural lesions of the atrial myocardium (eg, fibrosis caused by heart failure or pressure overload)
- Frequent occurrence of atrial premature beats (eg, caused by electrolyte disturbances, structural lesions, viral disease, myocardial stretch [exercise])
- Electrolyte disturbances
- High vagal tone (leads to dispersion in refractoriness of the atrial myocardium)

ASSOCIATED CONDITIONS AND DISORDERS

- Epistaxis during vigorous exercise
- Occasionally associated with ventricular ectopy

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Regarding etiology:
  - Primary or "lone" atrial fibrillation (AF): No underlying cardiac pathology. This form is much more common in horses than in other species.
  - Secondary AF: Underlying cardiac or noncardiac disease.
- Regarding duration:
  - Persistent (sustained) AF: Can only convert to sinus rhythm with treatment (most frequently in horses).
  - Paroxysmal AF (terminates spontaneously). Occasionally seen in racehorses (Thoroughbreds, Standardbreds) during (sub)maximal exercise. Within minutes, hours, or days, spontaneous conversion to sinus rhythm occurs.

HISTORY, CHIEF COMPLAINT

- Obvious signs of performance loss in horses working at maximal speed: Pulling up during race with signs of respiratory distress, ataxia, or even collapse
- Less pronounced signs of decreased performance in jumping and dressage horses or horses working at lower levels
- May be an incidental finding in pleasure horses, breeding horses, or horses at rest
- Epistaxis during exercise
- Signs of heart failure in horses with severe underlying cardiac disease and secondary AF

PHYSICAL EXAM FINDINGS

- Irregular pulse with pulse deficits
- Auscultation
  - Irregularly irregular rhythm
  - No atrial sound; loud first heart sound
  - Normal heart rate at rest or tachycardia in case of cardiac failure
- Signs of underlying cardiac disease
  - Cardiac murmur
  - Signs of heart failure (edema, jugular pulsation, tachypnea, weight loss)

ETIOLOGY AND PATHOPHYSIOLOGY

- Mechanism
  - During AF, depolarization waves spread continuously and in a rapid and chaotic manner over the atrial myocardium (usually 350–450/min). These depolarization waves originate from reentry or from rapidly firing foci and result in a continuous source of electrical activity independent of the sinoatrial node.
  - During AF, a (reversible) loss of atrial contractile function occurs.
  - At rest and when no severe underlying cardiac disease is present, high vagal tone causes the atrioventricular (AV) node to block most of the electrical pulses, thereby maintaining a normal heart rate. Conduction toward the ventricle occurs randomly resulting in an irregularly irregular cardiac rhythm.
  - Decreases in vagal tone (stress, exercise, heart failure, colic) results in an exacerbated increase in heart rate.
- Etiology
  - To be sustained, AF depends on a trigger to start the arrhythmia (atrial premature beat or rapidly firing focus) and a substrate to maintain it (atrial myocardium). Factors in favor of AF are:
    - A high trigger burden, that is, a high number of atrial premature beats: induced by stretch (eg, high atrial pressure during exercise), myocardial lesions, or electrolyte disturbances.
    - A suitable substrate, that is, the atrial myocardium: large atrial size, high vagal tone, short refractoriness of the myocardium and structural lesions.
  - In general, once initiated, AF rapidly (hours to days) becomes permanent, that is, it will never convert to sinus rhythm without therapy. In particular, during the first weeks to months the arrhythmia becomes increasingly stable.
  - Occasionally paroxysmal AF occurs during exercise, most commonly in racehorses. A potential cause is a high trigger burden during (sub) maximal exercise, while the myocardium is not suited to maintain the arrhythmia for a prolonged period (due to its size, electrophysiologic properties). Spontaneous conversion generally occurs within the first 72 hours.
- Impact:
  - In horses with lone AF:
    - At rest: no impairment of cardiac function (long diastolic time renders ventricular filling sufficient).
    - During exercise: impaired cardiac function occurs because of impaired ventricular filling as a result of (1) an absent atrial contractile function and (2) a disproportionate increase in heart rate. Some horses may present with epistaxis because of effects on pulmonary vascular pressures.
  - In horses with severe underlying cardiac disease: exacerbation of clinical signs because of a further decrease in cardiac function.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Second-degree AV block: regularly irregular on auscultation with presence of the atrial sound (S4).
- Frequently and irregularly occurring atrial and/or ventricular premature beats.

INITIAL DATABASE

- AF may be strongly suspected on auscultation: an irregularly irregular

ElibEVet.com

rhythm, a loud first heart sound, and absence of the atrial sound.
- Final diagnosis is made with an electrocardiogram (ECG) by the typical characteristics (Figures 1 and 2):
  - No P waves
  - Presence of f (fibrillation) waves. Changes between coarse (clearly undulating baseline) and fine (minor deflections of the baseline) fibrillation waves frequently occur on the same ECG.
  - Irregular RR interval (less obvious at high heart rates)
  - QRS morphology is normal but often shows minor alterations because of superposition with the f waves. The T wave may change after short RR intervals.
- Assess for signs of underlying cardiac disease such as a cardiac murmur, ventral edema, jugular pulsations, and tachycardia.

ADVANCED OR CONFIRMATORY TESTING

- Cardiac ultrasonography is essential to distinguish between lone and secondary AF (eg, atrial dilation, valvular regurgitation, congenital heart disease, congestive heart failure).
- Electrolyte imbalance (serum and fractional excretions) especially for recent-onset AF.
- Myocardial markers (cardiac troponin I) when myocardial damage is suspected.
- ECG (long-term telemetric or 24-hour Holter monitoring) to monitor for concurrent ventricular premature beats (Figure 3).

TREATMENT

- Do not treat for the first 72 hours after onset of AF because spontaneous conversion may occur (especially in racehorses).
- Check electrolyte status before treatment.

THERAPEUTIC GOAL(S)

- Lone AF: Medical or electrical conversion to sinus rhythm; no treatment in horses at rest.
- Secondary AF: Medical therapy to improve cardiac function, reduce ventricular response rate (furosemide, digoxin, angiotensin-converting enzyme inhibitors). Cardioversion should not be attempted in horses with heart failure.

ACUTE GENERAL TREATMENT

- Medical treatment: Perform in a quiet environment and have IV access available. Continuous ECG monitoring is necessary.
  - Quinidine sulphate via nasogastric tube: 22 mg/kg q2h until:
    - Conversion to sinus rhythm: Terminate treatment.

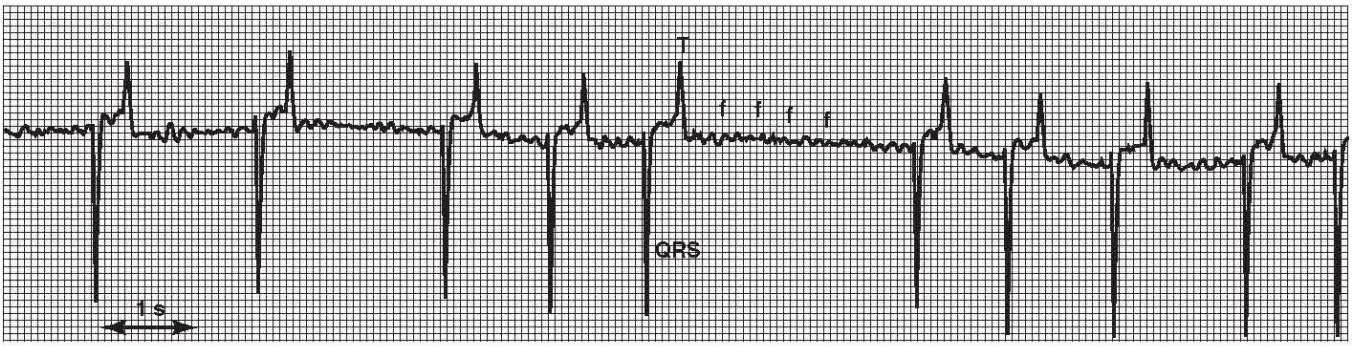

FIGURE 1 Atrial fibrillation (AF). During AF, P waves are absent and replaced by (coarse and fine) fibrillation waves (f waves). QRS complexes have a normal morphology, but RR intervals are irregularly irregular.

FIGURE 2 Transvenous electrical cardioversion (TVEC). Surface electrocardiogram during TVEC of a horse with atrial fibrillation (AF) of 10 weeks' duration. A 150-J biphasic shock (*arrow*), synchronized with the R wave (*arrowheads*), converts AF (f waves) instantaneously to sinus rhythm (P waves).

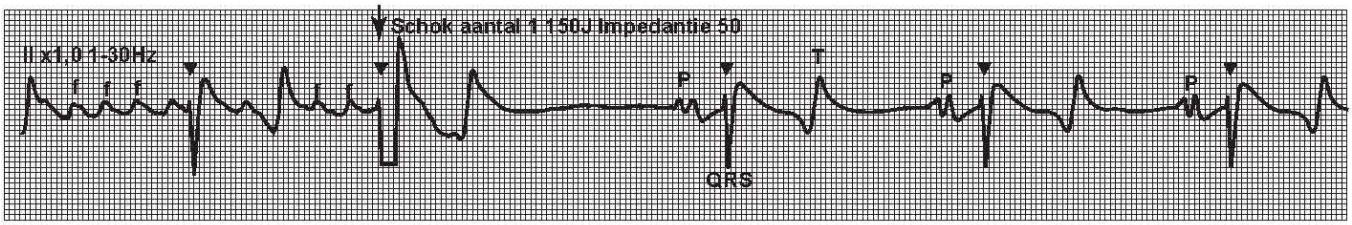

FIGURE 3 Atrial fibrillation with ventricular tachycardia. During exercise, rhythm remains irregular, although differences in RR intervals are smaller and less obvious because of the high heart rate. The horse presents with a run of wide QRS complexes (*arrows*) and shows the R-on-T phenomenon. The abnormal QRS complexes are caused by ventricular ectopy or aberrant conduction.

ElibeVet.com

- Maximal daily dose of 132 mg/kg: Continue the same treatment for the second (or third) day.
- Mild toxic signs occur such as tachycardia below 100 beats/min, depression, anorexia, nasal edema, mild discomfort: Increase the interval between treatments (q3–4h) or administer q6h (half-life of quinidine).
- Severe toxic signs such as a ventricular rate in excess of 100 beats/min, QRS duration increased by 25%, colic, diarrhea, laminitis, hypotension, collapse: Terminate quinidine treatment.
  - Administer isotonic sodium bicarbonate (1 mEq/kg IV) to increase protein binding.
  - If tachycardia is supraventricular: Digoxin (2.2 µg/kg IV) (because of protein binding, the risk for adverse effects might be increased) or propranolol (0.03 mg/kg IV) or if no severe signs of hypotension are present, an IV α_2-agonist (eg, detomidine 5.0–7.5 µg/kg). Diltiazem may prove useful for ventricular rate control but has not been proven in horses with AF.
  - If tachycardia is ventricular: Magnesium sulphate IV (4 mg/kg q2min up to a total of 50 mg/kg). Treat life-threatening ventricular tachycardia with lidocaine IV (0.25–0.5 mg/kg q5min to a total dose of 2–4 mg/kg) or procainamide (1 mg/kg/min IV; maximal dose, 20 mg/kg).
  - In case of hypotension: Crystalloids and phenylephrine IV (0.1–0.2 g/kg/min up to 0.01 mg/kg)
- If quinidine plasma levels can be monitored: Therapeutic plasma concentration is 2 to 5 µg/mL.
- If cardioversion is not achieved, a second treatment might be attempted after 1 week. Combine treatment with digoxin if treatment failure occurred because of tachycardia.

- Quinidine gluconate IV: 1.0 to 1.5 mg/kg q10min until conversion, toxic side effects occur, or a total dose of 12 mg/kg
  - Particularly useful for recent-onset AF
  - Increased risk of side effects
- Amiodarone IV: 5 mg/kg administered over 1 hour followed by continuous infusion of 0.83 to 1.90 mg/kg/min over 1 to 3 days
  - Side effects include diarrhea and hindlimb weakness.
  - Lower efficacy than oral quinidine sulphate.
  - Especially useful in horses when therapeutic quinidine levels cannot be achieved because of toxic side effects.
- Flecainide IV at 0.2 mg/kg/min over 10 minutes. Should not be used because of low efficacy and high risk for life-threatening ventricular arrhythmias.

- Transvenous electrical cardioversion
  - Requires general anesthesia, specialized equipment, and expertise
  - A biphasic synchronized direct-current shock is delivered via two transvenously inserted cardioversion catheters (with a large surface area electrode).
    - Preparation in the standing horse
      - Check and correct electrolyte disorders.
      - Insert and position catheters under ultrasonographic guidance.
        - Position one cardioversion catheter in the left branch of the pulmonary artery.
        - Position one cardioversion catheter in the right atrium.
      - An additional pacing catheter may be inserted into the right ventricular apex.
      - Administration of an antiarrhythmic drug may decrease the risk for immediate recurrence of AF after cardioversion.
    - After induction of general anesthesia
      - Take precautions to avoid injury because of the horse's limb movement during shock delivery.
      - Avoid any direct or indirect (urine, table) contact between individuals and the horse during shock delivery.
      - Check catheter position by ultrasongraphy or radiography and correct if necessary.
      - Connect both catheters and a surface ECG (avoid alcohol as a coupling agent!) to the defibrillator.
      - Carefully check R-wave detection by the defibrillator. In case of T-wave detection, always reposition surface electrodes to avoid T-wave detection. There is no unique electrode position that avoids T-wave detection.
      - Deliver biphasic synchronized shocks (simultaneous with the R wave of the surface ECG) at incremental energy levels (125–360 J with 50-J steps). Cardioversion usually occurs between 150 and 250 J (see Figure 3).
      - In case of temporary asystole, ventricular pacing is performed via the right ventricular pacing electrode.
      - In case of conversion failure, cardioversion catheters should be repositioned to repeat the cardioversion procedure. Simultaneous administration of antiarrhythmic drugs (eg, IV amiodarone) may increase the success rate.
      - After successful cardioversion, wait for 10 minutes before gentle retraction of the catheters. Atrial premature beats might easily reinduce AF.

DRUG INTERACTIONS

Quinidine and digoxin are both highly protein bound with narrow therapeutic windows. Their concurrent use increases effective plasma levels of both drugs, increasing the risk of adverse effects.

POSSIBLE COMPLICATIONS

- Quinidine sulphate complications
  - Laminitis, diarrhea, hypotension, collapse, sudden death (ventricular proarrhythmia).
  - Permanent venous access and permanent ECG monitoring should be available during treatment.
- Amiodarone complications
  - Hindlimb weakness, weight shifting, and diarrhea.
  - Terminate amiodarone treatment; treat with 6000 IU of vitamin E PO.
  - Symptoms of weight shifting resolve within a few hours.
  - Diarrhea may last for about 1 to 10 days. Treat with supportive therapy.
- Transvenous electrical cardioversion complications
  - Related to anesthesia
  - Related to catheterization (premature beats, embolism, and thrombosis)
  - Related to shock delivery
    - T wave on the surface ECG is detected as an R wave. Shock delivery on a T wave holds a very high risk for induction of ventricular fibrillation (fatal). Reposition surface electrodes (no standard location) so that the T wave is no longer detected by the defibrillator.
    - Atrial or ventricular ectopy: Minimize risk by shock synchronization with R wave and by using lowest energy levels.
    - Temporary asystole: Perform temporary right ventricular pacing via the temporary pacing catheter (inserted before induction of anesthesia).

ElibeVet.com

- Myocardial damage: Keep applied energy to a minimum.
- Related to catheter withdrawal: Atrial or ventricular premature beats, which might result in immediate recurrence of AF.
  - Wait for 10 minutes after cardioversion before withdrawing catheters.
  - Simultaneous use of antiarrhythmic drugs during electrical cardioversion reduces the risk for immediate recurrence or may lower the cardioversion threshold.

RECOMMENDED MONITORING

- In case of successful cardioversion
  - Wait at least 5 days after cardioversion to perform 24-hour ECG monitoring.
    - Presence of frequently occurring atrial premature beats might increase the risk for AF recurrence.
    - Presence of ventricular premature beats
  - Rest period:
    - (Sub)acute AF (days to weeks): May rest similar to the duration of AF
    - If AF duration is more than 2 months: May rest for 1 to 2 months
  - Check heart rhythm before returning to work.
  - Teach the owner to palpate apex beat or auscultate with a stethoscope. Check every 3 to 6 months or when recurrence is suspected.
- In case of cardioversion failure
  - Horse at rest: No further monitoring unless underlying cardiac disease is present.
  - Horses intended for exercise: An exercise ECG during a thorough exercise test, compatible with the level of work the horse will be used for, is strongly recommended. Horses presenting with extremely high ventricular rates with abnormal QRS morphology (R-on-T) should not be used for intense work because of an increased risk for collapse or sudden death and an inability to perform that work level.
  - Horses with AF cannot perform strenuous exercise such as racing.

PROGNOSIS AND OUTCOME

- Lone AF: Good prognosis if sinus rhythm can be restored, particularly if present for a short duration before conversion attempts. Horses return to previous level of performance when sinus rhythm is restored. The recurrence rate of AF is approximately 15% to 20%.
- Lone AF with concurrent ventricular ectopy: Guarded as long as ventricular premature beats persist.
- Secondary AF: Poor prognosis; depends on the underlying cardiac disease.

PEARLS & CONSIDERATIONS

COMMENTS

- Inform owners about the possible risk of the treatment, especially medical treatment (all antiarrhythmic drugs have the potential to be proarrhythmic).
- AF is very well tolerated when horses are not put into work and may be well tolerated if the work is not strenuous.
- Paroxysmal AF may be difficult to discover when it only occurs during maximal exercise. ECG monitoring during exercise is necessary and may show extremely high rates (commonly >250 beats/min). At such high rates, the irregularity in RR interval becomes difficult to detect.

PREVENTION

There is no prevention for AF. However, there may be some benefit to being extremely cautious if using diuretics in racehorses that have had a prior episode of AF because electrolyte disturbances arising from diuretic use may potentiate AF.

CLIENT EDUCATION

For successfully converted horses, the owner should be trained how to palpate the apex beat or auscultate with a stethoscope. A change in exercise tolerance should also prompt a recheck evaluation by a veterinarian.

Atrial Flutter

BASIC INFORMATION

DEFINITION

Supraventricular arrhythmia characterized by rapid, regular atrial depolarizations that are caused by a self-sustaining, single-circuit reentry mechanism. The atrial rate is approximately 180 to 250 contractions per minute with an irregular ventricular response.

SYNONYM(S)

Auricular flutter

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Large breeds are more susceptible than small breeds.
- Rarely occurs in ponies.

ElibeVet.com

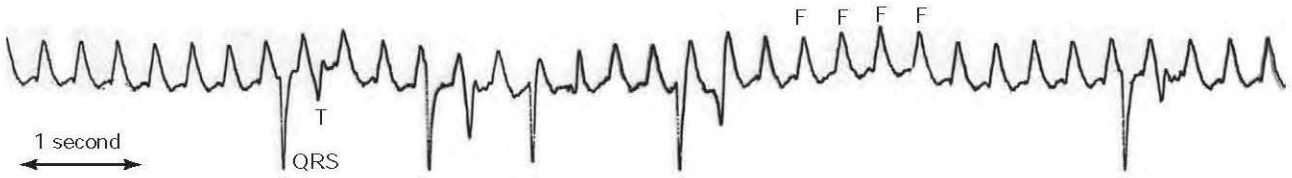

FIGURE 1 Atrial flutter is characterized by continuous, rapid, regular, sawtooth flutter waves (F waves). The ventricular rate at rest is normal, but the ventricular rhythm is irregular. Slight changes in QRS and T-wave morphology occur because of superposition of the flutter waves.

RISK FACTORS
- Similar to atrial fibrillation (AF)
- Underlying cardiovascular pathology leading to atrial dilation or atrial myocardial structural lesions
- Atrial premature contractions
- Electrolyte disturbances
- High vagal tone

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Spontaneous, sustained atrial flutter occurs on rare occasions in horses. In most animals, the arrhythmia quickly turns into AF.
- Atrial flutter is frequently encountered during quinidine treatment in horses, as an intermediate rhythm between AF and sinus rhythm.

HISTORY, CHIEF COMPLAINT
- Performance loss
- Occurs during quinidine treatment

PHYSICAL EXAM FINDINGS
- Irregular pulse
- Auscultation
  - Irregular rhythm (normal rate at rest)
  - Rapid atrial sounds rarely detected

ETIOLOGY AND PATHOPHYSIOLOGY
- A single-circuit reentry is induced by atrial premature beats and results in a regular, rapid atrial rate independent of the sinus node.
- Irregular conduction of the atrial impulses through the atrioventricular (AV) node results in an irregular ventricular response.
- Chronic atrial flutter leads to a loss of atrial contractile function caused by tachycardiomyopathy.
- Generally, no or only mild underlying cardiac pathology is present. Horses with severe cardiac disease generally do not develop atrial flutter but rather AF.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Atrial tachycardia: Generally produces a slower or irregular atrial rate (or both). However, regular atrial tachycardia at a high rate may be impossible to differentiate from atrial flutter.
- AF: Fibrillation waves are found on the surface electrocardiogram (ECG).
- Advanced second-degree AV block: At rest, P waves occur at a rate of 24 to 120/min; isoelectric segments are present; normal QRS morphology with (ir)regular RR intervals.
- Third-degree AV block: At rest, the surface ECG presents P waves (24–120/min); isoelectric segments are present; normal or abnormal QRS morphology with (ir)regular RR intervals.

INITIAL DATABASE
- Auscultation: Irregularly irregular rhythm
- ECG:
  - Typical sawtooth flutter waves replace the P waves and isoelectric segments
  - Irregular RR intervals
  - QRS morphology is supraventricular but shows small alterations because of superposition with the flutter waves
- Evaluate for signs of underlying cardiac disease

ADVANCED OR CONFIRMATORY TESTING
- Cardiac ultrasonography
- Electrolyte status
- Myocardial markers

TREATMENT

THERAPEUTIC GOAL(S)
Conversion of sustained atrial flutter to sinus rhythm

ACUTE GENERAL TREATMENT
- Similar treatment as for AF.
- Atrial burst pacing in standing horses has been described.
  - A temporary pacing catheter is placed in the right atrium and connected to a pacing device.
  - Burst pacing (pulses of 5.0–7.5 V and 0.5–1.0 ms) at a rate slightly faster than the flutter rate is performed to entrain and terminate the reentry mechanism.

RECOMMENDED MONITORING
Similar to AF

PROGNOSIS AND OUTCOME

Good prognosis if sinus rhythm is restored

SUGGESTED READING

ElibVet.com

Atrial Premature Complexes and Atrial Tachycardia

BASIC INFORMATION

DEFINITION

- Atrial premature complex (APC): A premature depolarization that originates from the atrial myocardium, resulting in a P′ wave on the surface electrocardiogram (ECG) (Figure 1).
- Atrial tachycardia (AT): Three or more consecutive atrial premature beats, usually with regular P′P′ intervals.
- Depending on their prematurity, the premature beats may or may not be conducted to the ventricles.

SYNONYM(S)

- Atrial premature contractions
- Atrial premature beats
- Atrial premature depolarizations
- Atrial extrasystoles
- Atrial ectopy

EPIDEMIOLOGY

RISK FACTORS

- Atrial dilation
- Atrial myocardial disease
- Electrolyte and metabolic disturbances
- Hypoxia, anemia
- Fever
- High sympathetic tone or administration of sympathomimetics

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Isolated atrial premature contractions versus AT
- Paroxysmal (short, self-terminating bout) versus sustained (continuous) AT

HISTORY, CHIEF COMPLAINT

- Usually no complaints; incidental finding during auscultation or ECG
- Occasionally, poor performance
- Complaints related to underlying disease (eg, respiratory or gastrointestinal disease, atrial dilation caused by mitral regurgitation)
- Drug administration
- Previous episodes of atrial fibrillation (paroxysmal AF or successfully converted AF)

PHYSICAL EXAM FINDINGS

- APCs
  - Generally result in an irregular cardiac rhythm on auscultation; the intensity of the first heart sound is usually normal or decreased.
  - Nonconducted, interlaced APCs may produce a soft atrial sound or may not be heard on auscultation at all.
- AT
  - May result in a fast but regular ventricular response when 1:1 or 2:1 atrioventricular conduction occurs
  - May result in an irregular ventricular response because of irregular atrioventricular conduction
- Pulse deficits or weak pulses may be palpated.
- Signs of underlying disease that produces hypoxia, electrolyte imbalance, atrial dilation (eg, heart murmur, heart failure)

ETIOLOGY AND PATHOPHYSIOLOGY

- Atrial dilation
- Atrial myocardial lesions
- Electrolyte and metabolic disturbances
- Hypoxia, anemia
- Fever
- Drug administration (halothane, dobutamine)
- Endocarditis, pericarditis
- Iatrogenic during cardiac catheterization
- An electrical impulse is generated in the atrial myocardium and depolarizes both atria.
- Hemodynamic effects of isolated APCs, especially nonconducted APCs, are minimal. Frequent occurrence of conducted APCs, bouts of AT, or sustained AT reduce cardiac output and affect performance.
- APCs may increase, decrease, or disappear altogether during exercise.

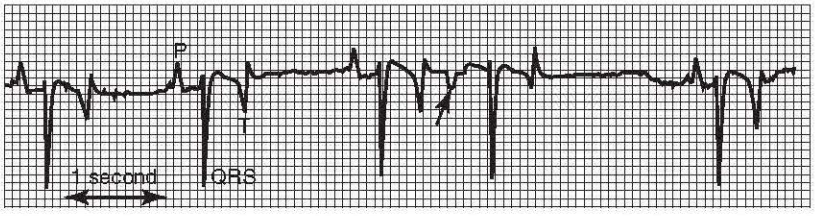

FIGURE 1 An atrial premature contraction presents as a P′ wave that occurs too early. In this case, the P′ wave has a different morphology. The QRS complex that follows has a normal morphology and duration.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Sinus tachycardia: Regularly occurring P waves (>50–60/min) because of stress, exercise, pain, drugs, or underlying disease.
- Atrial flutter: Regularly occurring sawtooth flutter waves at about 180 to 250/min.
- Atrial fibrillation: Fibrillation waves replace P waves.
- Ventricular premature contractions (VPCs): Depending on the prematurity of a VPC, the intensity of the first heart sound may be normal or reduced (indistinguishable from APC) or increased (in contrast to an APC). ECG is needed for the final diagnosis.
- Ventricular tachycardia: (Ir)regular RR intervals, QRS complexes with abnormal duration and morphology, and not associated with a preceding P wave

INITIAL DATABASE

- Ambulatory ECG
  - APC:
    - P′ occurs earlier than expected (premature) but may be buried in the preceding QRS or T.
    - P′ morphology may be normal or abnormal.
    - If conducted to the ventricles, QRS morphology is normal; T-wave morphology might change with a shortened RR interval (for a short RR interval, the T wave becomes opposite to the QRS complex).
    - The P′Q interval may be slightly different.
    - P′ is:
      - Usually followed by a noncompensatory pause (the RR interval of three consecutive sinus complexes [normal–normal–normal] is longer than that of the normal–premature–normal complexes because of resetting of the sinus node by the APC).
      - Occasionally followed by a compensatory pause (the RR interval of three consecutive sinus complexes is equal to that of the normal–premature–normal complexes because resetting of the sinus node did not occur)
      - Occasionally interlaced (P′ is not conducted to the ventri-

ElibVet.com

cles, does not reset the sinus node, and therefore does not disturb the underlying rhythm)
  - AT:
    - Three or more consecutive APCs, usually with a fairly regular P′P′ interval, and a rate of ±50 to 160/min.
    - P′ waves that conduct to the ventricles result in a normal QRS morphology (abnormal QRS morphology caused by bundle branch block is probably rare in horses).
    - Paroxysmal (self-terminating) or sustained.
    - Intermittent conduction (2:1 or 3:1) or irregular conduction results in a normal or moderately elevated ventricular rate or an irregular ventricular rate.
    - When every P′ is conducted (1:1 conduction), the ventricular rate is high and regular. Because of their high vagal tone, horses rarely present with a high (>120 beats/min) ventricular response rate and 1:1 conduction at rest except when sympathetic tone is increased (stress, exercise, hypotension, heart failure, hypoxia).
- Exercise ECG is needed (unless the condition of the horse precludes an exercise test) to look at the response of APC or AT during exercise and to find out if paroxysmal atrial fibrillation develops during (sub)maximal exercise.
- Echocardiography to identify atrial structural lesions or predisposing cardiac disease.
- Electrolyte status (serum, fractional excretion).
- Complete blood cell count and biochemistry to look for underlying disease.

ADVANCED OR CONFIRMATORY TESTING

- Arterial blood gas analysis.
- Vitamin E and selenium levels.
- Myocardial markers (cardiac troponin I, CK-MB).
- Long-term ambulatory ECG recordings (24-hour Holter monitor) should be made to monitor the frequency of APC or AT.
- Repeated monitoring of electrolyte status to look for a correlation with the arrhythmia.
- Right atrial myocardial biopsies may be taken, especially when generalized myocardial disease is suspected (not commonly performed in horses).

TREATMENT

THERAPEUTIC GOAL(S)

- No treatment in case of occasional and asymptomatic APCs
- Rest
- Treatment of underlying, predisposing disorders
- Antiinflammatory drugs in case of suspected myocardial disease

ACUTE GENERAL TREATMENT

- No treatment is required if APCs are infrequent and asymptomatic and disappear during exercise.
- Treat electrolyte imbalances.
- Terminate drug administration (eg, dobutamine).
- If APCs occur only during exercise or if APCs are frequent at rest and exercise and there is exercise intolerance, rest for 4 to 8 weeks. If no response, the rest period can be combined with prednisolone therapy when there is no indication of infection (1 mg/kg PO SID for 1 week; 0.5 mg/kg PO SID for 1 week; 0.5 mg/kg SID every other day for 1 week).
- If AT with normal ventricular rate: Rest for 4 to 8 weeks (may be combined with steroids)
- If AT with persistent high ventricular response rate at rest (rare): Treat with propranolol, diltiazem, or digoxin.
- Repeated resting ECGs, 24-hour Holter monitoring, and exercise ECG need to be performed before the horse returns to full exercise.

RECOMMENDED MONITORING

Telemetric ECG monitoring during treatment with propranolol, diltiazem, or digoxin (rarely indicated)

PROGNOSIS AND OUTCOME

- APCs and AT are a possible trigger for induction of atrial fibrillation, although the exact prevalence is unknown.
- Horses with occasional and asymptomatic APCs have a fairly good prognosis.
- Occasional APCs at rest that disappear during exercise are not likely to be associated with poor performance and carry a fairly good prognosis.
- If APCs occur frequently during exercise, APCs are frequent at rest and exercise, or the APCs are related to paroxysmal AF during exercise:
  - Prognosis is guarded until repeated ECG monitoring shows improvement of the condition.
  - Prognosis is guarded in case of myocardial disease (fibrosis, calcification, neoplasia), endocarditis, and pericarditis.
- Prognosis depends on the underlying cause (hypoxia, anemia, renal disorders).

PEARLS & CONSIDERATIONS

APCs or AT represent a risk factor for development of sustained or paroxysmal atrial fibrillation (generally during [sub]maximal exercise).

Atrioventricular Block, First Degree

BASIC INFORMATION

DEFINITION

Delayed conduction of the supraventricular impulse at the level of the atrioventricular (AV) node, resulting in a prolonged PQ interval.

SYNONYM(S)

First-degree AV block, first-degree heart block

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION More common in horses than in ponies

ElibVet.com

FIGURE 1 First-degree atrioventricular (AV) block. During first-degree AV block, conduction of the atrial impulse (P wave) through the AV node is delayed, resulting in an increased PQ interval (>500 ms).

RISK FACTORS
- High vagal tone
- Drug administration (eg, α_2 agonists, digoxin)

ASSOCIATED CONDITIONS AND DISORDERS Other vagally induced arrhythmias such as sinus arrhythmia, sinus block, second-degree AV block

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT
- Usually no complaints
- Drug administration

PHYSICAL EXAM FINDINGS Auscultation: Normal or slow heart rate. The atrial sound is clearly separated from the first heart sound.

ETIOLOGY AND PATHOPHYSIOLOGY
- High vagal tone
- Drug administration (eg, α_2 agonists such as detomidine or xylazine or calcium channel blockers such as verapamil or digoxin)
- Electrolyte disorders

DIAGNOSIS

INITIAL DATABASE

- Electrocardiography (Figure 1):
  - Prolonged PQ interval (>500 ms). The duration of the PQ interval often increases and decreases.
  - Normal P wave and QRS morphology.
  - P wave is followed by QRS complex.
  - Disappears upon decreased vagal tone (eg, stress, physical activity, atropine administration).

ADVANCED OR CONFIRMATORY TESTING

Ultrasound: The M-mode of the mitral valve often shows a presystolic opening.

SUGGESTED READING

Holmes JR: Cardiac rhythm irregularities in the horse. *Equine Pract* 2:15–25, 1980.

AUTHOR: **GUNTHER VAN LOON**

EDITOR: **MARY M. DURANDO**

Atrioventricular Block, Second Degree

BASIC INFORMATION

DEFINITION

The supraventricular impulse is intermittently blocked at the level of the atrioventricular (AV) node, resulting in a "missed" ventricular beat. At rest, this arrhythmia occurs in about 45% of healthy horses.

SYNONYM(S)

- Second-degree AV block
- Second-degree heart block
- The term *high-grade* or *high-degree AV block* is used for both advanced second- and third-degree AV block.

EPIDEMIOLOGY

RISK FACTORS
- High vagal tone
- Drug administration (eg, α_2 agonists)

ASSOCIATED CONDITIONS AND DISORDERS Other vagally induced arrhythmias such as sinus arrhythmia, sinus block, first-degree AV block

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Physiologic second-degree AV block (most common arrhythmia in healthy horses)
  - Mobitz type I (Wenckebach): The PQ interval progressively prolongs until a P wave is blocked. Variations in pp intervals are often present.
  - Mobitz type II: Constant PQ interval with an intermittently blocked P wave.
- Advanced (high-grade or high-degree) second-degree AV block (pathologic): Three or more consecutive P waves are blocked, resulting in a large difference between atrial and ventricular rate. AV conduction is still present.

HISTORY, CHIEF COMPLAINT
- Usually no complaints
- Drug administration
- For advanced second-degree AV block: Exercise intolerance, weakness, and occasionally syncope

PHYSICAL EXAM FINDINGS
- Heart rate normal or decreased
- Pulse deficit (missing pulse)
- Auscultation
  - A dropped beat: Beat-to-beat interval is double the preceding intervals.
  - An atrial sound (S4) is often heard during the pause.
  - The irregularity often appears at regular intervals (eg, every 4 or 5 beats).
  - The irregularity abolishes with stress, exercise, or vagolytic agents.
- In case of advanced second-degree AV block: Slow or normal heart rate. Weakness or exercise intolerance may be present. Multiple dropped beats in a row that may not disappear with exercise or vagolytic agents may occur.

ElibeVet.com

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused by high vagal tone: This is a regulatory mechanism at rest whereby a beat-to-beat increase in blood pressure leads to a blocked beat to maintain a stable blood pressure.
- Drug administration: α_2 agonists (detomidine, xylazine) or calcium channel blockers (verapamil).
- Electrolyte imbalance.
- Toxicity (digitalis, injection of iron preparations).
- Structural lesions of the AV node (degeneration, inflammation, fibrosis). In these cases, advanced second-degree AV block may progress to third-degree AV block.
- Immediately after delivery of an intracardiac direct current electrical shock (eg, treatment of atrial fibrillation [AF]), advanced second-degree AV block may occur temporarily.
- Idiopathic.
- Second-degree AV block does not produce any clinical signs unless it results in a very slow heart rate (ie, advanced second-degree AV block).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Sinus block: Missing beat without a P wave
- Sinus arrest: Longer pause without the presence of a P wave
- AF: Irregularly irregular RR intervals, absence of P waves, presence of fibrillation waves
- Third-degree AV block: No relationship between P waves and QRS complexes; QRS morphology often abnormal; RR intervals often irregular

INITIAL DATABASE

- Auscultation: A dropped beat with the presence of an atrial sound (this cannot always be heard)
- Electrocardiography (ECG)
  - Intermittently, the P wave is blocked at the AV node and therefore not followed by a QRS complex (Figure 1).
  - In between the blocked beats, the underlying rhythm is regular.
  - The PQ interval can progressively prolong until it is blocked (Mobitz I) or can be fixed (Mobitz II).
  - QRS complexes are preceded by a P wave, have a normal (or slightly prolonged) PQ interval, and have a normal morphology.
  - Advanced second-degree AV block: Three or more consecutively blocked P waves (Figure 2).
- ECG during stress or exercise or after administration of vagolytic drugs (eg, atropine or glycopyrrolate):
  - The arrhythmia is usually physiologic and disappears.
  - Persistence of the arrhythmia is pathologic.
- Electrolyte status

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography to look for structural lesions:
  - It is normal to detect a brief regurgitant flow at the AV valves after a blocked P wave.
  - It is normal to detect a small amount of regurgitation at the semilunar valves at the end of diastole after a blocked P wave.
- Myocardial markers (eg, cardiac troponins)

TREATMENT

THERAPEUTIC GOAL(S)

- No treatment is required for physiologic second-degree AV block
- Advanced second-degree AV block
  - Reduce inflammation
  - Increase heart rate

ACUTE GENERAL TREATMENT

- Physiologic second-degree AV block: No treatment is required.
- Advanced second-degree AV block:
  - Complete rest
  - Correction of electrolyte status
  - Antiinflammatory treatment. Corticosteroids are generally used (if no infection is present): Dexamethasone (0.05–0.2 mg/kg IV followed by longer term oral prednisolone)
  - Signs of weakness or syncope
    - Vagolytic drugs such as atropine or glycopyrrolate at 0.001 to 0.01 mg/kg to determine if an increase in AV node conduction can occur (treatment may induce colic)
    - Isoproterenol at 0.05 to 0.2 µg/kg/min: Should be used with care because it may induce ventricular tachyarrhythmias
    - Temporary pacing or permanent pacemaker implantation

CHRONIC TREATMENT

- Advanced second-degree AV block
  - Prolonged oral prednisolone treatment
  - Response to medical treatment to increase heart rate often unrewarding

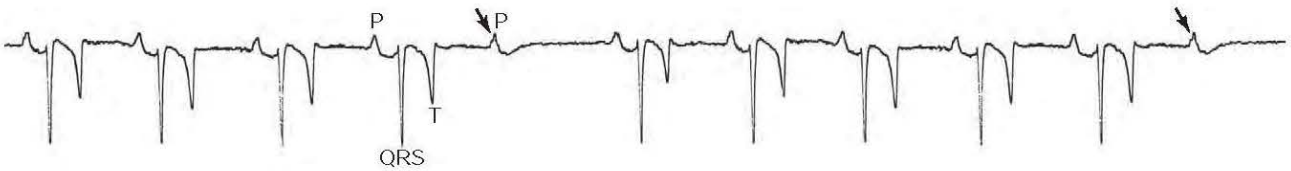

FIGURE 1 Second-degree atrioventricular (AV) block. During second-degree AV block, the atrial impulse is intermittently blocked at the AV node; the P wave (*arrow*) is not followed by a QRS complex.

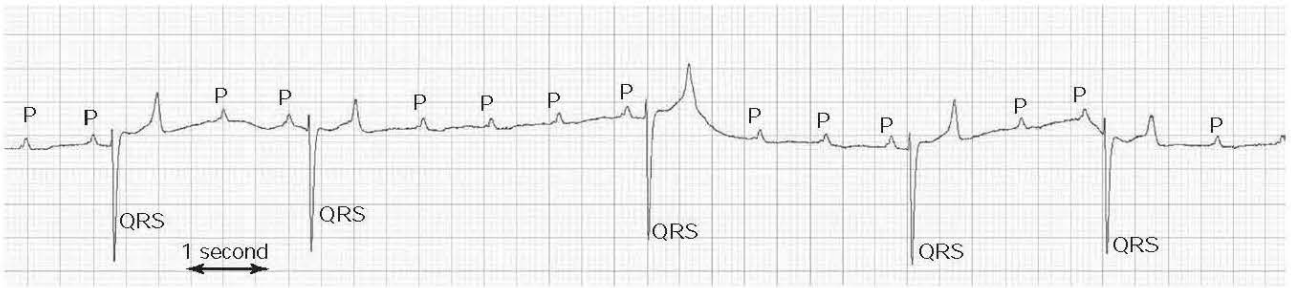

FIGURE 2 Advanced second-degree atrioventricular (AV) block. The term *advanced second-degree AV block* is used when three or more consecutive P waves are blocked at the AV node while AV conduction is still present. The latter implies that QRS complexes are preceded by conducted P waves and that the PQ interval is fixed.

 ElibVet.com

- Pacemaker implantation (see "Atrioventricular Block, Third Degree" in this section)

POSSIBLE COMPLICATIONS

Advanced second-degree AV block, even with no clinical signs at rest, may suddenly deteriorate to third-degree AV block with severe signs of syncope.

RECOMMENDED MONITORING

- Advanced second-degree AV block
  - Monitor heart rate
  - Monitor exercise tolerance
  - Monitor ECG to assess response to medical treatment

PROGNOSIS AND OUTCOME

- Excellent for physiologic second-degree AV block
- Guarded to severe for advanced second-degree AV block that does not respond to steroid therapy

PEARLS & CONSIDERATIONS

For advanced second-degree AV block, the client should be aware of the risk of syncope or collapse. These animals should not be ridden because the risk to the rider is significant. The horse's environment should be adjusted to minimize trauma in case syncope occurs.

AUTHOR: **GUNTHER VAN LOON**

EDITOR: **MARY M. DURANDO**

Atrioventricular Block, Third Degree

BASIC INFORMATION

DEFINITION

Total dissociation between the atrial (P waves) and ventricular (QRS complexes) rhythm because there is no conduction through the atrioventricular (AV) node. The ventricles depend on their own (slow) escape rhythm.

SYNONYM(S)

- Third-degree AV block
- Third-degree heart block
- Complete heart block
- The term *high-grade* or *high-degree AV block* is used for both advanced second- and third-degree AV block.

EPIDEMIOLOGY

RISK FACTORS Anesthetized foals with uroperitoneum

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Marked exercise intolerance
- Weakness
- Syncope or collapse

PHYSICAL EXAM FINDINGS

- Progressive filling of the jugular vein during long diastolic pauses with visible pulsation secondary to right atrial contractions.
- Auscultation
  - Bradycardia
  - Regular or irregular rhythm
  - Loud first heart sound
  - Soft atrial sounds can often be heard, usually at an increased rate (>60/min)
- Signs of congestive heart failure may be found.
- Intermittent syncope or presyncope caused by long diastolic pauses. Immediately before syncope, the horse briefly shows an increased respiratory effort. Horses usually fall backward, sideways, or both.
- Lifting the head of a bradycardic horse may induce syncope.
- Syncopal episodes are usually short (seconds) and, after a few moments, the horse is able to stand again and looks relatively normal.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology
  - Structural lesions of the AV node (fibrosis, inflammation, degeneration) that may be associated with endocarditis, myocarditis, or infiltrative processes
  - Severe hyperkalemia
  - Intoxication (rattlesnake envenomation)
  - Immediately after delivery of an intracardiac direct current electrical shock (eg, treatment of atrial fibrillation), a temporary high-degree AV block may occur
  - Idiopathic
- Pathophysiology
  - Clinical signs of weakness and intermittent syncope are related to the ability of the ventricles to generate their own (slow) escape rhythm.
  - The escape rhythm may emanate from pacemaker cells from the distal AV node, His bundle, or ventricle.
  - Bradycardia results in low blood pressure and a reflex increase in the atrial rate (commonly 60–120/min).
  - Lifting the horse's head seems to further decrease blood flow to the brain and may elicit syncope.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Causes of fainting or collapse
  - Other cardiovascular causes such as tachyarrhythmias, structural cardiovascular disease (congenital defects, aortocardiac fistula, cardiomyopathy), severe pulmonary hypertension, systemic hypertension, embolism, intracardiac neoplasia.
  - Intracranial disease.
  - Narcolepsy (cataplexy): A narcoleptic episode usually starts with lowering the head and buckling at the knees and may progress to collapse.
  - Vasovagal syncope.
  - Metabolic (eg, hypoglycemia).
- Causes of bradycardia
  - Sinus bradycardia: Slow rate of P waves, normal AV conduction.
  - Sinus arrest: Pause without P wave or QRS complex; AV conduction is normal.
  - Advanced second-degree AV block: Three or more consecutive P waves are blocked at the AV node; AV conduction is still present.
- Electrocardiographic (ECG) features: Atrial flutter (or high-rate atrial tachy-

 ElibeVet.com

cardia). The PQ interval may vary; there are more P waves than QRS complexes and a clear relation between atrial and ventricular complexes is not present. However, the atrial rate (≈180–250/min) is much higher than in horses with third-degree AV block (≈60–120/min).

INITIAL DATABASE

- A good history: Knowing the manner in which the horse collapses and other associated events and timing of collapse helps to differentiate between the different causes of collapse.
- ECG to confirm the diagnosis (Figure 1)
  - P waves generally occur at an increased rate (>60/min) and have no relationship to the QRS complexes. PQ intervals have a variable duration.
  - Ventricular rate is slow (bradycardia).
  - QRS complexes have a normal (AV nodal or His bundle origin) or abnormal (ventricular origin) morphology and duration and occur at a slow rate.
  - RR intervals are regular (usually monomorphic QRS, idionodal rhythm) or irregular (monomorphic or polymorphic QRS, idioventricular rhythm).
- Echocardiography: To look for structural cardiovascular disease.

ADVANCED OR CONFIRMATORY TESTING

- Myocardial markers (eg, cardiac troponin I).
- Complete blood count, serum biochemistry. These are usually normal. Congestive heart failure may result in increased γ-glutamyltransferase, creatinine, or lactate concentrations.

TREATMENT

THERAPEUTIC GOAL(S)

- Increase heart rate
- Increase blood pressure
- Reduce inflammation

ACUTE GENERAL TREATMENT

- Medical treatment: Unrewarding in most cases
  - Vagolytic drugs such as atropine or glycopyrrolate IV (0.01 mg/kg): Usually no effect (risk for colic).
  - Corticosteroids (if no infectious underlying process): Dexamethasone IV (0.05–0.2 mg/kg) followed by oral prednisolone.
  - Isoproterenol at 0.05 to 0.2 µg/kg/min to stimulate ectopy should be used with care because it may induce ventricular tachyarrhythmias.
  - Some horses regain AV conduction but still have advanced second-degree AV block. These animals are at risk for recurrence of third-degree AV block because part of their conductive tissue might remain nonfunctional.
- Temporary pacing until a permanent pacemaker can be implanted
  - Insert the temporary pacing catheter in the lower jugular vein and position the catheter tip in right ventricular apex under ultrasound guidance.
  - Connect electrodes to a temporary pacing device fixed to the horse's back.
  - Start ventricular pacing at two or three times the threshold at a rate of about 40 beats/min.
  - Prepare for permanent pacemaker implantation.
- Permanent pacemaker implantation.

CHRONIC TREATMENT

- Permanent pacemaker implantation can be performed in the standing horse. Temporary pacing is performed during the procedure to prevent bradycardia and syncope.
  - Depending on the pacemaker type, one or two pacemaker leads are inserted via the cephalic vein or the jugular vein.
  - The lead tip is positioned in the right atrium, right ventricle, or both under ultrasound guidance.
  - A fixation mechanism at the lead tip preserves endomyocardial contact. Fixation of the atrial lead is the most difficult part of the procedure because it more easily dislodges and is more difficult to visualize on ultrasonography.
  - The leads are connected to a pacemaker that is implanted in a subcutaneous pocket at the chest.
  - Via the electrode(s), the pacemaker is able to sense intrinsic activity of the myocardium and to stimulate the myocardium by delivering an electrical pulse.
- Pacemaker types (in order of complexity)
  - Ventricular (single-chamber) pacemaker: One lead is implanted in the right ventricle. The pacemaker prevents bradycardia by maintaining a minimal ventricular rate.
  - Ventricular rate-adaptive pacemaker: Ventricular pacemaker with an activity sensor. When physical activity is detected, the paced heart rate progressively increases and decreases.
  - Dual-chamber pacemaker (Figure 2): One lead is implanted in the right ventricle, and one lead is implanted in the right atrium. Both chambers can be sensed and paced. The pacemaker is programmed to stimulate the ventricle each time an atrial depolarization is sensed, which results in a physiologic adaptation of heart rate. This type of pacemaker provides the best result with third-degree AV block.
  - Dual-chamber rate-adaptive pacemaker: Dual-chamber pacemaker is able to adapt heart rate when it senses physical activity of the horse. This type is indicated more for sinus bradycardia and sick sinus syndrome.

POSSIBLE COMPLICATIONS

- Complications associated with syncope, such as trauma
- Complications associated with temporary pacing: Embolism, lead dislodgement, loss of capture, infection
- Complications associated with pacemaker implantation: Lead dislodgement, loss of capture (fibrosis around lead tip), infection

RECOMMENDED MONITORING

- Periodic monitoring of heart rate, exercise tolerance, and ECG for horses with third-degree AV block that reverts to second-degree AV block

PROGNOSIS AND OUTCOME

- Fair to good with permanent pacemaker implantation.
- Fair to good for horses in which third-degree AV block reverts to normal conduction. In some horses, recurrence of third-degree AV block may occur.
- Grave when third-degree AV block persists and when a pacemaker cannot be implanted. The condition leads to congestive heart failure and death.

PEARLS & CONSIDERATIONS

Inform the client of the risk of a collapsing horse. These horses should never be ridden because of the danger to the rider.

EDITOR: **MARY M. DURANDO**

Back Pain (Thoracolumbar Dysfunction)

BASIC INFORMATION

DEFINITION

Abnormal function of the thoracolumbar region caused by pain, muscle hypertonicity, or stiffness. Severe cases include neurologic deficits.

SYNONYM(S)

- Thoracolumbar hyperesthesia
- Thoracolumbar hyperpathia
- Cold back syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX Congenital vertebral malformations are more likely to be observed in young horses.

GENETICS AND BREED PREDISPOSITION

- Hyperkalemic periodic paralysis (HyPP) in Quarter Horses
- Hereditary equine regional dermal asthenia (HERDA) or hyperelastosis cutis in Quarter Horses
- Polysaccharide storage myopathy (PSSM) in Quarter Horse–related breeds, Warmbloods, and draft horses
- Breed predisposition for dorsal spinous process impingement or overriding in Thoroughbreds and lordosis in Saddlebreds

RISK FACTORS

- Vertebral column malformations
- Trauma or flipping over backward
- Exercise-induced myopathies
- Poor musculoskeletal conditioning or overuse
- Pelvic limb lameness
- Improper or poorly fitting saddle, saddle pads, or harness
- Unskilled or overweight riders

CONTAGION AND ZOONOSIS Supraspinous bursitis (fistulous withers) has a zoonotic potential caused by *Brucella abortus* infection.

ASSOCIATED CONDITIONS AND DISORDERS

- Poor performance
- Lameness or altered gait

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital: Vertebral malformations, ankylosis
- Degenerative: Osteoarthritis, spondylosis
- Acquired: Dorsal spinous process impingement
- Traumatic: Pressure sores from ill-fitting tack, spinous process or vertebral body fractures
- Infectious: Equine protozoal myeloencephalitis (EPM), equine herpesvirus type 1 (EHV-1) myeloencephalitis
- Metabolic: PSSM
- Iatrogenic: Improper or ill-fitting saddle, saddle pads, or harness

HISTORY, CHIEF COMPLAINT

- Skin lesions or bumps in the saddle region
- Asymmetric sweat marks on the back or dirt patterns on the saddle pad
- Painful or stiff back
- Change in spinal posture or soft tissue swelling
- Resentment to grooming, saddle placement, or tightening of the girth or cinch
- History of flipping over backward
- Bucking and rearing when mounted or ridden
- Pins ears or swishes tail when mounted or ridden
- Poor performance and vague gait abnormalities
- Difficulty with collection
- Reluctance to jump

ElibeVet.com

PHYSICAL EXAM FINDINGS

- Dermatitis or skin lesions
- Alopecia or white hairs in the region of saddle or harness
- Increased heat or palpable swelling
- Pain elicited on palpation of the thoracolumbar soft tissues or dorsal spinous processes
- Thoracic lordosis, lumbar kyphosis, or scoliosis
- Flattened and widened dorsal contour of the withers
- Dorsally prominent or laterally deviated dorsal spinous process
- Reduced active and passive range of spinal motion in lateral bending or extension
- Generalized lack of muscle development or local muscle atrophy
- Epaxial muscle hypertonicity or fasciculations
- Exaggerated cutaneous trunci reflex or spinal reflexes
- Ataxia, spasticity, or weakness (in pelvic limbs only)
- Reduced dorsoventral spinal mobility at the walk, trot, or canter
- Poor pelvic limb engagement and propulsion during the canter
- Precipitated or aggravated back problem only when ridden

ETIOLOGY AND PATHOPHYSIOLOGY

Numerous tissues may be the source of back pain or stiffness:

- Soft tissue
  - Trauma: Poorly fitting saddle, muscle strain, postanesthetic myopathy
  - Inflammation: Supraspinous ligament desmitis, thoracolumbar fasciitis
  - Infection: Dermatitis (bacterial or fungal)
  - Metabolic: PSSM
  - Endocrine: Hyperadrenocorticism
  - Genetic: HERDA or hyperelastosis cutis, PSSM, HyPP
  - Nutritional: Vitamin E and selenium deficiency (nutritional myodegeneration or white muscle disease, equine rhabdomyolysis)
- Vertebral column
  - Congenital: Hemivertebrae or block vertebrae
  - Degeneration: Osteoarthritis, spondylosis
  - Trauma: Dorsal spinous process or vertebral body fractures
  - Infection: Vertebral osteomyelitis, discospondylitis
- Neurologic
  - Trauma: Thoracolumbar spinal cord compression
  - Infection: EPM, EHV-1 myeloencephalitis
  - Neoplasia (space-occupying mass): Malignant melanoma
  - Nutritional: Vitamin E deficiency (equine degenerative myeloencephalopathy (EDM), equine motor neuron disease (EMND)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Back pain or dysfunction is a nonspecific clinical sign and is a diagnostic challenge for practitioners. Diagnosis is based on a diagnosis of exclusion of soft tissue, orthopedic, and neurologic disorders of the thoracolumbar region. For specific differential diagnoses, see "Etiology and Pathophysiology" above.

INITIAL DATABASE

- Inspection of trunk conformation, posture, muscle symmetry, and development
- Gait evaluation to assess limb lameness, propulsion, and dorsoventral spinal mobility
- Saddle fit assessment
- Evaluation of ridden exercise or athletic activity
- Neurologic examination
- Soft tissue and bony palpation
- Active and passive joint range of motion in flexion-extension and lateral bending
- Spinal and cutaneous trunci reflexes
- Rectal examination
- Thoracolumbar spinal radiography
- Microbial culture and sensitivity of any draining wounds
- Serum vitamin E and selenium levels
- Serum potassium levels
- Urinalysis to assess myoglobinuria

ADVANCED OR CONFIRMATORY TESTING

- Diagnostic local anesthesia of dorsal spinous processes, articular facets, or intertransverse joints
- Nuclear scintigraphy
- Ultrasonography of supraspinous ligament, dorsal spinous processes, or articular processes
- Transrectal ultrasonography to assess the lumbosacral joint and intervertebral disc space
- Serum creatine kinase and aspartate aminotransferase levels before and after exercise
- Muscle biopsies for histologic and histochemical analysis
- Pressure algometry to assess mechanical nociceptive thresholds
- Therapeutic trial with high dosage of nonsteroidal antiinflammatory drugs (NSAIDs) for 7 to 10 days
- Cerebrospinal fluid analysis
- Electromyography
- Thermography
- Serology and virus isolation
- Genetic testing: HyPP, PSSM, and HERDA

TREATMENT

THERAPEUTIC GOALS

- Eliminate or reduce pain so that affected horses can resume regular training programs
- Reduce muscle hypertonicity
- Promote full joint range of thoracolumbar motion in flexion-extension and lateral bending
- Eliminate any sources of infection
- Establish proper saddle fit and ridden exercise
- Develop effective therapeutic exercise and training programs
- Increase muscle mass and symmetry
- Restore athletic and performance capabilities

ACUTE GENERAL TREATMENT

- Stall confinement or exercise restriction, only as needed
- Controlled hand walking
- Slow and prolonged warmup period
- Temporary reduction in intensity, duration, or frequency of exercise or training program
- Passive thoracolumbar mobilization
- Cryotherapy to reduce heat, swelling, or pain
- Antiinflammatory drugs: NSAIDs, corticosteroids, dimethyl sulfoxide
- Muscle relaxants
- Periarticular or interspinous space corticosteroid injections
- Low-level light or laser therapy
- Electroacupuncture and mesotherapy
- Electric muscle stimulation
- Surgical exploration or debridement of puncture wounds or draining tracts
- Tiludronate

CHRONIC TREATMENT

- Active and passive thoracolumbar range of motion and stretching exercises
- Core stabilization and strengthening exercises
- Moist heat therapy
- Acupuncture
- Chiropractic treatment to reduce pain and muscle hypertonicity, increase spinal mobility, and restore symmetric spinal motion
- Daily physical therapy and rehabilitation
- Massage therapy
- Electromagnetic stimulation
- Extracorporeal shock-wave therapy
- Antioxidant supplementation with vitamin E
- Surgical resection of refractory impinged dorsal spinous processes
- Warmup or flexibility exercises: "long and low," circles, figure-8, serpentine
- Ground poles, cavalletti, and incline work
- Maintain proper body conditioning

ElibVet.com

DRUG INTERACTIONS

- Complications associated with excessive dosages or long-term phenylbutazone use in horses include gastrointestinal ulceration, renal medullary crest necrosis leading to acute or chronic renal failure, and ulceration of the right dorsal colon.
- NSAIDs should not be used in conjunction with corticosteroids.

POSSIBLE COMPLICATIONS

- Worsening or recurrence of clinical signs
- Adverse reaction to antiinflammatory medications
- Development of behavioral issues related to chronic pain

RECOMMENDED MONITORING

- Monitor signs of pain, muscle tone, and flexibility daily.
- Repeat physical and chiropractic examination to assess response to therapy or rehabilitation.
- Periodically modify and increase therapeutic exercise and training programs.
- Repeat saddle fit assessment during changes in body condition and muscle development.

PROGNOSIS AND OUTCOME

- Highly variable depending on the specific cause and the severity of the underlying disease process
- Dependent on the type, severity, and number of concurrent spinal lesions present
- Dependent on the rider's ability to correctly use the horse and to engage its back

PEARLS & CONSIDERATIONS

COMMENTS

- Long-term rest or pasture turnout without active rehabilitation is often contraindicated.
- Localization of pain to affected structures requires detailed physical and chiropractic examinations.
- Active and passive trunk range of motion is useful for identifying affected vertebral levels and laterality of the thoracolumbar dysfunction.

PREVENTION

- Turnout as much as possible
- Establish proper saddle fit and saddle pad use
- Importance of maintaining trunk flexibility and range of motion exercises
- Nutritional management with a high-fat, low-carbohydrate diet
- DNA testing and selective breeding to noncarriers of genetic-based diseases

CLIENT EDUCATION

- Owner should monitor recurrence of signs that warrant repeat examination.
- Avoid riding exercise in any horse with neurologic deficits.
- Proper saddle fit is difficult in horses with fractured withers and displaced dorsal spinous processes.
- If an appropriate therapeutic response is not noted with conservative care, then additional diagnostics and advanced imaging techniques are warranted.

Biliary Atresia

BASIC INFORMATION

DEFINITION

In horses, biliary atresia is a rare congenital absence of the common bile duct.

EPIDEMIOLOGY

SPECIES, AGE, SEX Considered a congenital disease; the signalment is a newborn to 1-month-old foal.

ASSOCIATED CONDITIONS AND DISORDERS

- Clinical signs of biliary atresia are associated with hepatic insufficiency and are generally nonspecific.
- Differential diagnoses for hepatic disease, gastrointestinal disease, or septicemia should be excluded.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Nonspecific clinical signs include lethargy, decreased appetite, failure to thrive, colic, icterus, fever, polydipsia, and polyuria.

PHYSICAL EXAM FINDINGS Physical examination findings are nonspecific and include fever, icterus, poor body condition, abdominal pain, and lethargy.

ETIOLOGY AND PATHOPHYSIOLOGY Extrahepatic biliary atresia is a congenital absence of the entrance to common bile duct or absence of the duct itself in neonatal foals, resulting in intrahepatic biliary hypertrophy that displaces hepatocytes and causes periportal or perilobular hepatocellular damage, fibrosis, and ultimately liver failure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Portosystemic shunt
- Biliary obstruction secondary to duodenal stricture

INITIAL DATABASE

- Complete Blood count with fibrinogen: Normal or consistent with acute or chronic inflammation
- Sorbitol dehydrogenase (SDH) activity: Normal to mildly increased
- Gamma glutamyltransferase (GGT): Markedly increased
- Serum conjugated bilirubin concentration: Increased
- Serum bile acids concentration: Markedly increased

ElibEVet.com

ADVANCED OR CONFIRMATORY TESTING

- Ultrasound examination of the liver and abdomen
- Liver biopsy reveals extensive biliary proliferation with absence of bile, degenerative hepatocytes, and fibrosis
- Nuclear hepatobiliary scintigraphy (see "Diagnostic Imaging of the Liver" in Section II)

TREATMENT

Therapeutic options are not currently available for congenital biliary atresia in horses.

PROGNOSIS AND OUTCOME

Biliary atresia is accompanied by a fatal prognosis.

SUGGESTED READING

van der Luer RJ: Biliary atresia in a foal. *Equine Vet J* 14:91, 1982.

Witzelben CL, Buck BE, Schnaufer L, Brzosko WJ: Studies on the pathogenesis of biliary atresia. *Lab Invest* 38:525, 1978.

Biliary Obstruction

BASIC INFORMATION

DEFINITION

Large colon displacement and cholelithiasis are the most common causes of acute biliary obstruction in adult horses. Rarely, foals may develop biliary obstruction secondary to duodenal stricture.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Middle-aged to older horses
- Neonatal foals secondary to duodenal stricture

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Depression, anorexia, and colic.
- Bruxism and salivation may be present in foals.

PHYSICAL EXAM FINDINGS

- Fever, variable icterus, and colic.
- Clinical signs of hepatoencephalopathy and photosensitization may also be present.
- Clinical signs may be intermittent if a partial obstruction is present.
- Foals with duodenal stricture may have excessive gastric reflux.

ETIOLOGY AND PATHOPHYSIOLOGY

- Obstruction of the biliary tract in a mature horse may be attributable to cholelithiasis, right dorsal colon displacement, neoplasia, hepatic torsion, or portal vein thrombosis. Duodenal stricture in foals may be secondary to duodenal ulceration.
- Acute biliary obstruction causes cholestasis, biliary distension, and variable pain.
- Chronic biliary obstruction results in hepatic fibrosis, originating around the obstructed biliary branch(es).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cholelithiasis
- Pyrrolizidine alkaloid toxicity
- Chronic active hepatitis
- Biliary atresia in foals

INITIAL DATABASE

- The diagnosis of obstruction of the common bile duct in horses is difficult. Exploratory celiotomy may be necessary to identify the possible location or cause of the obstruction.
- The presence of concentric fibrosis around intrahepatic bile ducts on histopathology supports obstruction of the common bile duct.

ADVANCED OR CONFIRMATORY TESTING

- Hepatic ultrasonography may reveal hepatomegaly, increased echogenicity of the liver parenchyma, and bile duct dilation.
- The visualization of well-defined hyperechoic foci with acoustic shadows within dilated bile ducts confirms the diagnosis of biliary obstruction caused by the presence of choleliths.
- Rectal examination may be helpful in the diagnosis of a right dorsal colon displacement.
- Evidence of delayed gastric emptying in foals is supportive evidence for duodenal stricture.

TREATMENT

THERAPEUTIC GOAL(S)

Treatment should be directed to the underlying cause.

ACUTE GENERAL TREATMENT

General and supportive care with IV balanced fluids.

PROGNOSIS AND OUTCOME

The prognosis depends on the extent of liver involvement, severity of clinical signs, degree of secondary hepatic fibrosis, and number and location of the biliary obstruction.

SUGGESTED READING

EDITOR: **MICHELLE HENRY BARTON**

ElibeVet.com

Black Walnut Toxicosis

BASIC INFORMATION

DEFINITION

- Black walnut trees are large (50–100 feet) deciduous forest trees often planted as ornamentals.
- The demand for black walnut lumber has increased, and the wood shavings are sold for animal bedding. Shavings that contain even a small percentage of black walnut can cause laminitis when used as bedding for horses. Colic and respiratory distress have been reported in horses after they have chewed on black walnut bark.

SYNONYM(S)

Walnut family, including English walnut, butternuts, hickories, and pecans

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals and yearling horses are often unaffected or recover quickly.

RISK FACTORS

- Horses that are bedded on more than 5% to 20% walnut shavings may develop laminitis (Figures 1 and 2).
- Not all black walnut trees have naturally occurring toxicity.

GEOGRAPHY AND SEASONALITY Black walnut (*Juglans nigra*) is a common hardwood species that ranges from the Great Plains to the east coast of North America. The species has been widely planted outside of its natural range and can be found all over North America. Laminitis may occur any time of the year, whenever walnut bedding is used.

ASSOCIATED CONDITIONS AND DISORDERS Consumption of the shavings or bark may cause laminitis as well as mild colic. Horses on pasture may show mild respiratory signs from chewing on bark, pollen, or fallen leaves.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Laminitis
- Limb edema
- Respiratory distress
- Colic

HISTORY, CHIEF COMPLAINT

- History of new bedding material introduced with dark-colored shavings.
- Horses (often several animals in a stable) with clinical signs of laminitis.
- Signs usually develop within 8 to 18 hours of contact.
- Affected horses become unwilling to move or have their feet picked up, are often depressed, and may have limb edema.

PHYSICAL EXAM FINDINGS

- Laminitis
- Edema of the legs ("stocking up")
- Anorexia and depression
- Increased heart rate, respiratory rate, body temperature, and coronary band and hoof temperature
- Pounding digital pulse

ETIOLOGY AND PATHOPHYSIOLOGY

- The toxic principle is not known. Juglone was once believed to be involved because it was found in high concentrations in the hull of the nut. However, aqueous extracts of black walnut heartwood, which contain no juglone, consistently induce laminitis.
- The toxin appears to be absorbed through the coronary band and skin.
- The pathogenesis is not completely understood but is believed to be similar to other causes of acute laminitis.
- Black walnut shavings or aqueous extract induce alterations in the hemodynamics of blood flow to the hoof.
- Overall, blood flow to the foot is increased, and perfusion to the hoof is decreased.
- The toxin appears to act by causing a sensitization of vessels of the foot to the effects of adrenergic agonists, leading to an acute reduction in the functional blood flow to the foot that reaches the dorsal laminae.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of acute laminitis.
- If the hind legs are involved, affected horses have a gait that resembles "tying up," or myositis.

INITIAL DATABASE

- The complete blood count reveals a transient neutropenia in horses given an aqueous extract of black walnut orally at approximately 4 hours before the onset of the initial stages of laminitis.
- A sustained increase in plasma cortisol levels.

ADVANCED OR CONFIRMATORY TESTING

- Severity of the laminitis can be determined by radiography of the feet.
- Identification of shavings should be performed by a specialist in wood science.
- Histopathology is typical of acute laminitis, with necrosis of the dorsal laminae followed by mitotic activity in an effort to repair the damage.

FIGURE 1 Pine and spruce wood shavings (*right*) and walnut wood shavings (*left*).

FIGURE 2 Pine shavings contaminated with walnut wood shavings.

ElibeVet.com

TREATMENT

THERAPEUTIC GOAL(S)

- Begin treatment immediately.
- Remove all horses from the bedding and remove the bedding.
- Treatment is symptomatic and supportive; no specific antidote exists.

ACUTE GENERAL TREATMENT

- Wash the legs with mild detergent to remove any remaining residues.
- Conduct gastrointestinal decontamination with mineral oil or activated charcoal.
- Provide symptomatic therapy to control pain (eg, phenylbutazone administration).
- Give acepromazine or a more specific α-blocker to restore circulation to the dorsal laminae.
- Heparin may be used to prevent microthrombi formation.
- Refer to "Laminitis, Acute" and "Laminitis, Chronic" in this section for more information on therapy.

CHRONIC TREATMENT

- Place affected animals in sand stalls for relief of pain.
- Consider removing the shoes.

POSSIBLE COMPLICATIONS

Rotation of the third phalanx through the sole with permanent damage and sloughing of the hoof.

RECOMMENDED MONITORING

Radiography of the hoof

PROGNOSIS AND OUTCOME

- Animals removed from the bedding and given supportive care usually have a good prognosis.
- Symptoms usually disappear within a few days after the shavings are removed.
- Horses with severe laminitis and rotation of P3 have a very guarded prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Horses on pasture may show mild respiratory signs from chewing on bark, pollen, or fallen leaves.
- Remember that the other members of the walnut family may also be a problem for horses.

PREVENTION

Do not use fresh shavings from black walnut trees or any of the walnut family for bedding.

CLIENT EDUCATION

Bedding from a hardwood mill or a furniture factory may contain black walnut shavings that can be very harmful to horses. If you are not sure, contact an expert with a sample of the shavings.

Black Widow Spider Toxicosis

BASIC INFORMATION

DEFINITION

The female black widow spider, *Latrodectus* spp., is recognized by its characteristic red hourglass marking on the adult ventral abdomen. Only the bite of the female spider is of toxicologic importance.

SYNONYM(S)

- Brown widow, red-legged spider, hourglass spider

EPIDEMIOLOGY

SPECIES, AGE, SEX Although cases are not well documented in horses, all are potentially susceptible.

RISK FACTORS

GEOGRAPHY AND SEASONALITY Distributed throughout North America, found in barns and other structures and outdoor wood and brush piles.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Black widow spider envenomation generally results in neuromuscular signs.

PHYSICAL EXAM FINDINGS Muscle fasciculations and rigidity, ataxia, and flaccid paralysis can progress to an ascending paralysis. The muscles of respiration may eventually become involved, leading to dyspnea and other breathing abnormalities. Restlessness, pain, abdominal rigidity, and cramping of the large muscle masses may also be observed.

ETIOLOGY AND PATHOPHYSIOLOGY The most important toxin in black widow spider venom is α-latrotoxin, a biologically active protein neurotoxin. Both calcium-dependent and -independent mechanisms lead to the release of numerous neurotransmitters because of increased movement of synaptic vesicles to the presynaptic neuronal membranes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Colic, tying up, botulism, tetanus

INITIAL DATABASE

Elevated creatine kinase and aspartate transaminase levels may be detected.

ADVANCED OR CONFIRMATORY TESTING

Identification of the spider (if found)

TREATMENT

THERAPEUTIC GOAL(S)

- Respiratory and cardiac monitoring
- Pain management

ACUTE GENERAL TREATMENT

Administration of a 10% calcium gluconate solution is recommended in most veterinary references for the reversal of muscle fasciculations and weakness,

ElibVet.com

although its efficacy appears to be inconsistent in humans. Initial symptomatic treatment for human patients instead typically consists of morphine and diazepam.

PROGNOSIS AND OUTCOME

Most animals completely recover within days to weeks with symptomatic and supportive care.

PEARLS & CONSIDERATIONS

Several antivenin products have been developed and may be extremely useful for patients that do not adequately respond to symptomatic care alone and are commonly administered to severely affected humans either IV or IM. The newer antivenins have fewer human allergic reactions because of a lack of protein impurities. The efficacy and adverse effects of these products in horses have not been documented.

EDITOR: **CYNTHIA L. GASKILL**

Blister Beetle Toxicosis

BASIC INFORMATION

DEFINITION

Blister beetles (*Epicauta* spp.) are insects that contain the toxin cantharidin, a potent vesicating agent that is readily absorbed from the gastrointestinal (GI) tract and skin. Cantharidin is a direct irritant that can cause shock and death within 4 hours after a massive dose or affect various organ systems, depending on the dose.

SYNONYM(S)

- Cantharidin toxicosis
- Cantharidiasis

EPIDEMIOLOGY

RISK FACTORS Feeding hay, pellets, or cubes that contain alfalfa, particularly after it has been crimped

GEOGRAPHY AND SEASONALITY

- Beetles can be a variety of colors, depending on their location (eg, black, gray with black spots, orange with black spots). Striped blister beetles, *Epicauta lemniscata*, are often found in alfalfa hay in the southwestern United States (Figure 1).
- Most blister beetles live in the South.
- Most cases occur in the winter when more hay is fed.
- Cases can occur year round if contaminated alfalfa products are fed.
- Cases can occur anywhere contaminated alfalfa is shipped.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute: Massive dose
- Subacute: Lower dose

HISTORY, CHIEF COMPLAINT

- Sudden death: The horse is found dead in the morning after appearing normal when fed the previous night
- Depressed
- Anorectic
- Any clinical signs associated with colic
- Playing in water with muzzle
- Client's observation that animal is "not acting right"

PHYSICAL EXAM FINDINGS

Not all horses exhibit all the following clinical signs:

- Increased pulse
- Increased respiratory rate
- Diaphragmatic flutter
- Muscle fasciculations
- Tachycardia
- Sweating
- Frequent painful urination
- Depression
- Colic
- Diarrhea
- Oral lesions
- Salivation
- Restlessness
- Congested mucous membranes
- Increased capillary refill time
- Stiff gait
- Hematuria
- Fever

ETIOLOGY AND PATHOPHYSIOLOGY

- Cantharidin is a powerful vesicant.
- Concentration depends on the species, sex, and whether the insects have mated.
- Found in the hemolymph of male blister beetles.
- Transferred to females during mating.
- Affects mitochondrial membrane permeability.
- Has a direct irritant effect on entire GI tract.
- Rapidly absorbed from the GI tract.
- Excreted unchanged in the kidney and may cause irritation of the urinary system.
- May cause myocardial necrosis.
- Four grams of dried beetles may be lethal to a horse, with approximately 0.5 to 0.1 mg of cantharidin per kilogram of body weight being the estimated lethal dose.

FIGURE 1 Blister beetles in alfalfa hay.

ElibVet.com

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other types of colic
- Ionophore toxicosis

INITIAL DATABASE

- Decreased serum calcium
- Decreased serum magnesium

ADVANCED OR CONFIRMATORY TESTING

- Examination of alfalfa hay for the presence of beetles.
- Detection of cantharidin in urine by gas chromatography/mass spectrometry (GC/MS) or high-performance liquid chromatography (HPLC).
- Possible detection of cantharidin in serum, GI content, liver, or kidney, but these are not the specimens of choice.
- Cantharidin has been detected in pelleted feed and hay cubes.
- Postmortem lesions range from none to severe irritation and ulceration from the mouth throughout the entire GI tract and urinary bladder. White streaks have been observed on the heart. Gastroenteritis, nephrosis, cystitis, urethritis, and myocarditis have been seen microscopically.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce the absorption and enhance elimination of the toxin.
- Control pain.
- Control diarrhea.
- Reinoculate the gut.

ACUTE GENERAL TREATMENT

Aggressive therapy (day 1):

- Fluids
- Calcium in the form of calcium gluconate 23% solution 0.1 mL/kg/h IV (large amounts in fluids until levels become normal)
- Magnesium in the form of magnesium sulfate 50 mg/kg IV diluted in 1 L of fluids for the first hour followed by continuous-rate infusion of 25 mg/kg/h
- Activated charcoal
- Nonsteroidal antiinflammatory drugs (NSAIDs)

CHRONIC TREATMENT

Days 2 to 5:

- NSAIDs
- Fluids
- Calcium, magnesium
- Diatomaceous earth
- Omeprazole
- Probiotics

POSSIBLE COMPLICATIONS

- Nephrosis
- Cardiac dysfunction

RECOMMENDED MONITORING

Serum calcium and magnesium

PROGNOSIS AND OUTCOME

- Prognosis is good if recognized early and treated aggressively.
- Prognosis is guarded to poor if high dose, the animal is not diagnosed early, or therapy is not aggressive.

PEARLS & CONSIDERATIONS

COMMENTS

- The owner's observation that horse that has been eating alfalfa is "just not right," low serum calcium, diaphragmatic flutter, and playing in the water should initiate aggressive therapy.
- Diagnostic confirmation can be done in 4 to 24 hours.
- Cantharidin is very stable in hay and hay products.
- Contamination can occur even if blister beetles have not been observed. It is not practical to check every inch of hay.

PREVENTION

- Do not feed alfalfa hay, pellets, or cubes.
- Purchase hay that has not been crimped before baling and that has been baled before bloom stage or after a frost to decrease the incidence of beetle contamination.

CLIENT EDUCATION

- Clients can learn to identify blister beetles.
- Beetles tend to swarm, so multiple beetles generally can be observed in individual flakes of hay.

AUTHOR: **SANDRA E. MORGAN**

EDITOR: **CYNTHIA GASKILL**

Borna Disease

BASIC INFORMATION

DEFINITION

- Borna disease virus (BDV) is an enveloped, single-stranded RNA virus that causes polioencephalomyelitis in horses.
- Transmission most likely occurs through contact with infected nasal, lacrimal, or salivary secretions with viral ascent through the olfactory (and possibly trigeminal) nerve. The incubation period is extended, and infection appears to be restricted to the central nervous system (CNS).
- Affected horses present with alterations in behavior, sensorium, and consciousness that may progress to cranial nerve abnormalities, spinal cord abnormalities, and death. There is no effective treatment or vaccine. The prevalence and incidence of the disease worldwide are unknown.

SYNONYM(S)

Hot-headed disease, brain fever, subacute meningoencephalitis, hypersomnia of horses

EPIDEMIOLOGY

SPECIES, AGE, SEX

- There is no species or sex predilection.
- Age may be a factor in clinical disease because there is a high rate of sero-

ElibeVet.com

prevalence but a low rate of disease in endemic areas.

GENETICS AND BREED PREDISPOSITION Genetics may be a factor in clinical disease because there is a high rate of seroprevalence but a low rate of disease in endemic areas.

RISK FACTORS Exposure to affected horses

CONTAGION AND ZOONOSIS

- The route of transmission of BDV is unknown. The virus has been detected in nasal, lacrimal, and salivary secretions of affected animals, so it is postulated that direct and indirect contact with infected horses can spread the virus.
- Whether BDV is a zoonotic agent that causes overt illness in humans is unknown. It does appear that humans can be affected by either the Borna virus or a Borna-like virus. Seroprevalence studies have revealed BDV antibodies in humans with psychiatric disorders and in humans without disease (similar to horses). However, the exact pathology of the virus in humans, whether it is transmitted to humans from horses, and whether it is a causative agent of disease in people, is unknown at this time.
- Veterinarians should take universal precautions when handling and performing necropsies on horses with any neurologic disease.

GEOGRAPHY AND SEASONALITY

- Clinical BDV has been recognized in horses in Germany, Switzerland, Liechtenstein, and Austria. Seroprevalence studies in Germany reveal that there is a large discrepancy between the incidence of disease (low) and the prevalence of BDV-specific antibodies (11%–20% normally; 55% during outbreaks). New occurrences of disease may occur anywhere from 2 months to several years after the initial outbreak. There is no seasonal trend to the virus.
- BDV is not likely restricted to Europe. Seroprevalence studies have revealed BDV antibodies in horses worldwide, including Europe, Turkey, the Middle East (Israel and Iran), Asia (Japan and China), Australia, and the United States. However, the incidence of disease caused by BDV infection in these countries is unknown.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Peracute, acute, subacute, chronic polioencephalomyelitis

HISTORY, CHIEF COMPLAINT Horses present initially with alterations in behavior and consciousness.

PHYSICAL EXAM FINDINGS

- Initial clinical signs involve changes in personality and sensorium. Movements are deliberate and slow and include general hypokinesia, postural unawareness, and slow eating or chewing with no food in the mouth. Many horses demonstrate rhythmic or repetitive movements and often yawn frequently and head press. Changes in personality and mental status, including hyperexcitability, fear, aggression, lethargy, somnolence, and stupor, may also occur. Loss of the cutaneous trunci reflex may also be noted early in the disease. A fever refractive to nonsteroidal antiinflammatory drugs may also occur.
- As the disease progresses, neurologic deficits increase. Cranial nerve abnormalities are often seen, including alterations in cranial nerve (CN) III (strabismus and miosis), CN V/VII (bruxism, trismus), CN VII/XI (nystagmus), CN VIII (head tilt), CN IX/X (dysphagia, pharyngeal paralysis), and CN XII (tongue paralysis). Spinal cord abnormalities are also present, including ataxia, imbalance, abnormal postures, hyporeflexia of spinal reflexes, and proprioceptive deficits. Changes in personality may progress.
- In the latter, end stages of BDV, the horse appears extremely unbalanced and often stops eating or drinking. Neurogenic torticollis accompanied by dystonia of the neck muscles with or without circular walking is often present. Head tremors, convulsions, head pressing, loss of the pupillary light reflex, and comatose states occur.

ETIOLOGY AND PATHOPHYSIOLOGY

- BDV mainly affects horses and sheep, although it has also been found to affect other equids, cattle, goats, and rabbits.
- The incubation period is extended and ranges from 2 weeks to several months (average, 2–3 months) after exposure.
- Enveloped negative-sense, single-stranded RNA virus.
- Released by budding from the cell.
- Initial infection most likely occurs through direct contact with viral particles from an infected animal or fomite.
- The virus appears to remain restricted to the CNS.
- The virus may invade the CNS through the following:
  - Intranasal infection through the olfactory nerve
  - Oral infection through the trigeminal nerve
- The virus migrates along the olfactory or trigeminal axons and replicates in the neuron cell bodies and glial cells of the limbic system.
- Over time, the virus disseminates throughout the CNS and then spreads to the peripheral nervous system and retina.
- This coincides with the progression of clinical signs.
- Pathologic changes are indicative of polioencephalomyelitis.
  - Mainly involves the gray matter of the CNS and spinal cord
  - Retinal changes may also be seen.
  - Histopathologically, perivascular cuffing, parenchymal inflammation, astrocytosis, and loss of pyramidal cells may be seen.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Viral
  - Alphavirus encephalitis (Eastern equine encephalitis, Western equine encephalitis, Venezuelan equine encephalitis)
  - Flavivirus encephalitis (West Nile virus, Kunjin virus,* Japanese encephalitis,* Murray Valley fever*)
  - Rabies
  - Equine herpesvirus type 1
  - Equine encephalosis virus*
  - Nipah virus*
- Bacterial: Botulism
- Parasitic
  - *Halicephalobus gingivalis*
  - Setaria
  - *Strongylus vulgaris*
  - Equine protozoal myeloencephalitis
- Noninfectious
  - Hypocalcemia
  - Tremorogenic toxicities
  - Hepatoencephalopathy
  - Leukoencephalomalacia

INITIAL DATABASE

- Cerebrospinal fluid (CSF)
  - Increased proteins (>70 mg/dL)
  - Increased cell count (lymphomonocytic pleocytosis)
  - Chronic cases: CSF is usually normal except with elevated lactate levels
- Complete blood count and serum chemistries
  - Normal
  - Hyperbilirubinemia from decreased food intake

ADVANCED OR CONFIRMATORY TESTING

- BDV antibody detection: Titer ranges between 1:2 and 1:1280
- There is no correlation between disease severity and antibody titers.
- May or may not be present early in the course of disease or in corticosteroid-treated horses

*Foreign animal diseases not yet documented in North America.

ElibeVet.com

- Tests
  - Enzyme-linked immunosorbent assay
  - Western immunoblot
  - Indirect immunofluorescence assay
- Postmortem testing
  - Histopathology
  - Immunohistochemistry
  - Western immunoblot
  - Reverse transcription polymerase chain reaction

TREATMENT

THERAPEUTIC GOAL(S)

Supportive care

ACUTE GENERAL TREATMENT

- There is no known effective treatment for BDV.
- Treatment strategies should focus on supportive care and the relief of anxiety.
  - Corticosteroids
  - Mannitol (0.25–2.0 g/kg q24h IV) may relieve brain edema.

PROGNOSIS AND OUTCOME

- Infection with BDV leads to death approximately 1 to 4 weeks after the onset of clinical signs in approximately 80% of animals.
- Approximately 10% of infected horses demonstrate a chronic, recurrent course of disease.
- With less severe cases, recovery can occur. There may be a persistent CNS infection.

PEARLS & CONSIDERATIONS

COMMENTS

- The prevalence and incidence of the disease outside of Europe is not known.
- Thus quarantine and having BDV on the differential list for horses with any neurologic disease is important.

PREVENTION

- There is no licensed vaccine for the prevention of BDV.
- The environment should be decontaminated with standard decontaminating agents.
- Affected horses and new arrivals should be quarantined.
- Proper universal precautions should be taken by all humans in contact with affected or suspect horses.

Bots

BASIC INFORMATION

DEFINITION

Infection with larvae of one or more species of botfly. Second- and third-stage larvae of *Gasterophilus intestinalis* and *Gasterophilus nasalis* cause focal mucosal irritation in the equine stomach or intestine, where they attach.

EPIDEMIOLOGY

RISK FACTORS Exposure to adult botflies and ingestion of eggs laid on the horse's hair.

CONTAGION AND ZOONOSIS

- Bots are not directly contagious from horses to people.
- There are occasional reports of human infection with horse botfly larvae, several of which involved patients with known exposure to horses.
- Migration of first-stage larvae is associated with cutaneous and ocular myiasis in humans.
- The burrowing of larvae beneath the skin may produce a tortuous path with severe pruritus.

GEOGRAPHY AND SEASONALITY

- Infection with botfly larvae occurs in horses worldwide.
- *G. intestinalis* and *G. nasalis* are the most common species in North America.
- *G. pecorum* is found in Asia.
- Adult fly activity is most common in the summer and fall.
- Larvae persist in the stomach and intestine through the winter and spring.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Bot larvae cause minimal pathology in most horses.

HISTORY, CHIEF COMPLAINT

- Most horses show no recognizable clinical signs.
- Abnormal behavior may be caused by attempts at fly evasion.
- Signs associated with minor gingival irritation and necrosis, including increased salivation, abnormal mastication, and swallowing.
- Signs of colic and endotoxemia in the rare horse with gastric ulceration and rupture, gastritis, peritonitis secondary to gastroduodenal perforation, or gastroesophageal reflux.
- Aberrant larval migration may cause more unusual clinical signs.

PHYSICAL EXAM FINDINGS

- Most horses show no abnormalities on physical examination that can be directly related to botflies except for the presence of botfly eggs attached to the hairs.
- Physical examination findings consistent with abdominal pain and endotoxemia in rare horses with gastric ulceration and rupture, gastritis, peritonitis secondary to gastroduodenal perforation, and gastroesophageal reflux.
- Gingival hyperemia and necrosis on oral examination.
- *G. pecorum* infection may cause esophageal constriction and hypertrophy of muscles of the oropharynx and esophagus with resultant dysphagia and death. It may also cause epidemic deaths of horses resulting from attachment of large numbers of bots to the soft palate.

ETIOLOGY AND PATHOPHYSIOLOGY

- Adult botflies are similar in size and appearance to honeybees.
  - The common horse botfly (*G. intestinalis*) lays yellow to gray eggs on the hairs of the forelegs, mane, and flanks.
  - Throat botfly eggs (*G. nasalis*) are attached to the long hairs beneath the mandible and chin.
  - Nose botfly eggs (*G. haemorrhoidalis*) are deposited on hairs around the muzzle.
- Hatching of eggs is stimulated by warmth and moisture associated with licking the eggs during normal grooming behavior.
- Larvae spend about 3 weeks migrating in soft tissue of the oral cavity and

ElibeVet.com

then migrate to the stomach or small intestine, where they attach to the mucosa.
- Larvae remain in the stomach until spring or early summer, when they detach, are passed in feces, enter the soil below the manure pile, and pupate.
- In weeks to months, adult flies emerge.
- Adult *G. pecorum* bots lay eggs in batches on grass, and eggs are ingested when horses graze.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Definitive diagnosis is by visual identification of parasites, usually by gastroscopy.
- Bot larvae are occasionally identified in gastroesophageal reflux fluid.
- Internal larval presence should be highly suspect in horses that have not recently received avermectin anthelminthics and that have obvious botfly eggs attached to the hairs of their legs or face.

TREATMENT

THERAPEUTIC GOAL(S)

Eliminate all botfly larvae.

ACUTE GENERAL TREATMENT

- Avermectin anthelminthic treatment
- Physical removal of botfly eggs from hairs

PROGNOSIS AND OUTCOME

Prognosis is excellent for most horses.

PEARLS & CONSIDERATIONS

COMMENTS

The most effective time to administer boticides is in the late fall after the first hard frost, when adult fly activity has ceased.

CLIENT EDUCATION

Instruct clients that regular grooming to remove bot eggs from the horse's hair is helpful.

EDITORS: **MAUREEN T. LONG** and **DEBRA C. SELLON**

Botulism

BASIC INFORMATION

DEFINITION

A neuromuscular disorder of horses and other mammals caused by neurotoxins of *Clostridium botulinum*. Toxicoinfectious botulism occurs through oral ingestion of botulism and elaboration in the intestine of affected animals.

SYNONYM(S)

Shaker foal syndrome, forage poisoning, grass sickness

EPIDEMIOLOGY

SPECIES, AGE, SEX Botulism neurotoxins type B and C are most commonly reported in foals. Shaker foal syndrome (toxicoinfectious) is associated with 1- to 3-month-old foals but may occur as early as age 7 days. In adult horses, a form

ElibeVet.com

of adult toxicoinfectious botulism (grass sickness) occurs in Europe.

RISK FACTORS

- Decaying vegetable matter in food and water
- Feeding practices including silage, haylage, round baled hay, animal tissue contamination of feeds, bird and animal contamination of standing water sources

GEOGRAPHY AND SEASONALITY

Equine botulism is most frequently observed in Kentucky and the mid-Atlantic region of the eastern United States, although the disease has been reported worldwide. Botulism type B can be found throughout United States but is more predominant in the north and central east. Type A botulinum is isolated from soil primarily in western and northwestern states. Botulism type C occurs in Florida.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Flaccid paralysis of adult horses (wound and forage poisoning)
- Shaker foal syndrome (toxicoinfectious)
- Grass sickness (Europe)

HISTORY, CHIEF COMPLAINT

- Sudden, unexplained death
- Clinically affected horse with intermittent paralysis

PHYSICAL EXAM FINDINGS

- The time to onset of clinical signs after exposure to toxin varies from 12 hours to several days. Sudden, unexplained death of one or more horses may be the initial signal of the onset of an outbreak.
- Decreased eyelid, tongue, and tail tone may be observed early in disease. Horses that walk may have a stilted, short-strided gait without ataxia. Muscle trembling and weakness may be apparent, particularly in foals.
- Pupillary dilation with sluggish pupillary light reflexes is common.
- There is normal cutaneous sensation with depressed spinal reflexes.
- Pharyngeal paralysis is frequently observed in adult horses with botulism and may be confirmed by endoscopic examination of the upper airway.
- Clinical signs may rapidly progress to recumbency.
- Tachycardia may occur, particularly in foals. Foals may appear or become constipated and dysuric.
- Signs of colic may be associated with diminished gastrointestinal (GI) motility.
- Dyspnea and cyanosis may be present initially or terminally.
- Death is generally attributed to respiratory failure secondary to respiratory muscle paralysis.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Clostridium botulinum*
- Neurotoxins A, B, C, and D
- Three methods of toxin exposure in horses:
  - Forage poisoning: Ingestion of preformed toxin elaborated in feedstuffs by vegetative form of *C. botulinum*
  - Toxicoinfectious: Ingestion of spores, formation of vegetative state, multiplication, and elaboration of toxins within the GI tract after in vivo toxin production
  - Wound botulism: Contamination of a wound with spores, formation of vegetative state, multiplication, and elaboration of toxins within the tissues after in vivo toxin production
- Botulism intoxication occurs by a multistep process: binding to the target cell and internalization, translocation, and inhibition of neurotransmitter release.
- Botulinum neurotoxin (BoNT) prevents exocytosis of acetylcholine at the neuromuscular synapse by the cleavage of soluble *N*-ethylmaleimide sensitive factor attachment receptor proteins involved in the fusion of synaptic vesicles with the plasma membrane.
- The clinical effect is flaccid paralysis of large motor neuron units with lower motor neuron disease of the limbs, respiratory intercostal muscles, and pharyngeal muscles.
- Without intervention and supportive care, respiratory paralysis and death occur.
- Overwhelming exposure may result in death.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Foals
  - Hypocalcemia
  - Severe electrolyte imbalances
  - Cranial trauma if recumbent
- Adults
  - West Nile virus: May have intermittent weakness and paralysis
  - Equine protozoal myeloencephalitis: Should have muscle wasting
  - Early onset of rabies
  - Pharyngeal disorders, including choke and trauma
  - Tick paralysis

INITIAL DATABASE

- Complete blood count: Normal
- Serum biochemical analysis: Normal
- Urinalysis: Normal

ADVANCED OR CONFIRMATORY TESTING

- Electromyography: May demonstrate lower motor neuron abnormalities. Negative findings should not rule out the disease.
- Definitive diagnosis: Detection of toxin in serum, feces, GI contents, or feed)
  - Format detection: Enzyme-linked immunosorbent assay, radioimmunoassay, polymerase chain reaction
  - Specific toxin activity: Mouse inoculation test
- Isolation of *C. botulinum* from serum, feces, GI contents, or feed

TREATMENT

THERAPEUTIC GOAL(S)

- Blockade of remaining circulating toxin
- Supportive care

ACUTE GENERAL TREATMENT

- Botulism antitoxin: Equine-origin polyvalent (anti-B and anti-C) botulism antitoxin (Botulism Laboratory, New Bolton Center, Kennett Square, PA) or monovalent (anti-B) botulinum antitoxin (Veterinary Dynamics, Templeton, CA)
- Adults and foals with mild respiratory failure (normal pH and mild to moderate increase in arterial carbon dioxide tension [$PaCO_2$]) may frequently be treated with intranasal oxygen insufflation, positioning in sternal recumbency, and repeated arterial blood gas (ABG) monitoring to detect worsening respiratory failure.
- Mechanical ventilation may ameliorate ABG abnormalities and allow time for the patient to recover cholinergic neuromuscular control.
- Antimicrobial administration, although not required for treatment unless wound botulism is suspected, is frequently used in an effort to prevent or reduce some of the complications of the disease, such as aspiration pneumonia caused by dysphagia.

CHRONIC TREATMENT

- Nutritional management must be considered in horses with botulism and can generally be achieved in foals by feeding milk or milk replacer via indwelling nasogastric or nasoesophageal tubes (Kangaroo, 12-Fr, 43-inch enteral feeding tube, Sherwood Medical, St. Louis, MO) as small, frequent meals (every 2 hours).
- In adult horses, periodic nasogastric intubation of slurry meals can be provided. In prolonged cases, it may be beneficial to consider commercially

ElibeVet.com

available liquid diets. Parenteral nutrition is generally not necessary.
- Nursing care is an important part of treatment, and equine patients should be protected as much as possible from development of decubital ulcers, corneal ulcers, and inadvertent aspiration.
- Ocular examination should be performed at least daily and ocular lubricant ointments used to prevent exposure keratitis.

DRUG INTERACTIONS

Antimicrobial drugs that might potentiate neuromuscular blockage (eg, procaine penicillin, aminoglycosides, and tetracyclines) should be avoided.

POSSIBLE COMPLICATIONS

Close ABG monitoring is required for the first 24 to 48 hours of treatment.

RECOMMENDED MONITORING

- Close ABG monitoring is required for the first 24 to 48 hours of treatment because administration of botulinum antitoxin does not remove toxin already bound to receptors within the terminal neuromuscular junction of the axon, and the equine patient may deteriorate further during this period.
- ABG analysis should also be performed if the patient's condition appears to change; these horses may suddenly alter their respiratory rate and pattern as respiratory failure worsens.
- Increased nostril flare, decreased chest excursion, and restlessness may be physical indicators of worsening respiratory failure.
- Adult horses with botulism that remain standing have a good prognosis for recovery; however, it may require several weeks to months before affected horses regain sufficient strength to return to work.
- Horses that become recumbent have a poorer prognosis even with antitoxin administration and excellent nursing care. This is related in part to their size and the secondary effects of prolonged recumbency.
- The degree of respiratory compromise can be severe, and long-term (days) mechanical ventilation of adult horses is a difficult undertaking.

PROGNOSIS AND OUTCOME

- The survival rate for botulinum neurointoxication in appropriately treated foals younger than 6 months of age is greater than 90%.
- Approximately 50% of affected foals require some form of ventilatory support, ranging from intranasal oxygen insufflation to mechanical ventilation, and all affected foals should have repeated ABG analysis performed during the first 48 hours of treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Careful physical and neurologic examination and the early identification and treatment with antitoxin is essential for successful outcome of clinical botulism in horses.
- In standing but weak horses, endoscopic examination and assessment of pharyngeal function should be performed.
- Abnormal pharyngeal function in the presence of neuromuscular weakness should lead to botulism as a top differential diagnosis.

PREVENTION

- Vaccination (*C. botulinum* type B toxoid, Neogen, Tampa, FL) is thought to be almost 100% protective in adult horses.
- Vaccination of pregnant mares is the most efficient way to protect foals in endemic areas; however, foals from vaccinated mares have developed disease.
- Passively transferred antibody levels may be variable and have variable decay rates in individuals.
- Adults
  - Broodmares: Initial three-dose series at 30-day intervals with the last dose 4 to 6 weeks before anticipated parturition date, and annually thereafter, 4 to 6 weeks prepartum.
  - Other adult horses: Should consider vaccination, particularly if in endemic regions. Initial three-dose series and then annual booster.
- Foals
  - From vaccinated mares: Three-dose series of toxoid at 1-month intervals starting at 2 to 3 months of age
  - From unvaccinated mares: Foals may benefit from (1) toxoid at 2, 4, and 8 weeks of age; (2) transfusion of plasma from a vaccinated horse; or (3) antitoxin (efficacy needs further study).

CLIENT EDUCATION

- Vaccination procedures should be reviewed in endemic areas.
- Proper feeding and storage of hay and grain are essential.
- Avoidance of silage and haylage in equines is recommended.
- If bulked baled hay is an important source of feed, education of clients of recognition of poor hay quality and hay management from supplies is important.

Bracken Fern and Horsetail Toxicosis

BASIC INFORMATION

DEFINITION

Bracken fern and horsetails cause neurotoxicity in horses as a result of thiamine depletion.

SYNONYM(S)

- Bracken or bracken fern (*Pteridium aquilinum*)
- Horsetail, field or western horsetail, scouring rush (*Equisetum arvense*)
- Scouring rush horsetail (*Equisetum hyemale* or *Hippochaete hyemalis*)

EPIDEMIOLOGY

RISK FACTORS Poor-quality hay containing these plants is a risk to hungry horses.

GEOGRAPHY AND SEASONALITY

- Bracken fern is distributed throughout the world except in very low-precipitation areas.

 ElibeVet.com

FIGURE 1 Bracken fern (*Pteridium aquilinum*).

FIGURE 2 Horsetail (*Equisetum arvense*).

FIGURE 3 Scouring rush horsetail (*Equisetum hyemale* or *Hippochaete hyemalis*).

- Bracken fern is a deciduous perennial that develops from a black extensive root system with erect, triangular-shaped fronds 3 to 5 feet in height. The stems are smooth and green except at the base. Reproduction occurs via spores formed on the underside of fronds following the edge of the leaflets (Figure 1).
- Horsetail is widely distributed in North America, preferring moist areas. It is an invasive, deciduous perennial plant that forms large colonies from branching rhizomatous roots. The stems are erect, hollow, ribbed, and jointed. The leaves are vestigial (scale-like) in whorls at the nodes. Some species have branches in whorls at the nodes. Horsetails are flowerless and reproduce from spore-forming cones at the ends of fertile stems (Figures 2 and 3).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Gradual onset over several days of weakness, depression, and incoordination leading to difficulty standing and recumbency. Seizures can occur terminally.

PHYSICAL EXAM FINDINGS

- Weight loss, incoordination, muscle tremors, and crouching stance when the head is raised.
- Recumbency followed by seizures and eventually death.
- Appetite may initially be good.

ETIOLOGY AND PATHOPHYSIOLOGY

- The primary toxin in bracken fern responsible for the neurologic syndrome in horses is thiaminase. Thiaminase creates a thiamin deficiency by breaking down thiamin and competitively inhibiting thiamin activity.
- Consumption of a diet of 20% to 25% bracken fern for 3 weeks or more is necessary to produce signs.
- Dried plant material retains its toxicity.
- Ruminants are not affected by the thiaminase because their rumen microflora degrades it.
- Bracken fern also contains ptaquiloside, which is carcinogenic and causes thrombocytopenia and hemangiomas of the bladder in cattle. This is not reported in horses.
- The rhizomes and rapidly growing young fronds are the most toxic.
- The toxin in *Equisetum* spp. is also a thiaminase.
- Most poisoning occurs in horses fed hay contaminated with horsetail.
- Consumption of hay with 20% or more horsetail for 2 to 3 weeks is necessary to cause poisoning.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine leukoencephalomalacia
- Encephalitis: Rabies, West Nile virus, Eastern and Western equine encephalitis virus
- Equine herpesvirus
- Sage poisoning
- Pyrrolizidine alkaloid toxicity

INITIAL DATABASE

Serum pyruvate and lactate increase due to inhibition of pyruvate dehydrogenase.

ADVANCED OR CONFIRMATORY TESTING

- Blood thiamine levels in horses decrease to 25 to 30 μg/L.
- Postmortem findings are generally nonspecific, with congestion of the brain and other organs.
- Histologically, necrosis of neurons may be seen.
- Response to thiamine treatment may be the only practical confirmatory test.

TREATMENT

THERAPEUTIC GOAL(S)

Replenish thiamine.

ACUTE GENERAL TREATMENT

- Thiamine (vitamin B_1): 0.5 to 1.0 g/d parenterally, decreasing the dose over several days
- Provide a palatable and nutritious diet.

RECOMMENDED MONITORING

Monitor serum pyruvate, lactate, and thiamine levels.

PROGNOSIS AND OUTCOME

If the condition is recognized and treatment initiated before the horse becomes recumbent, recovery in a few days is likely.

ElibVet.com

PEARLS & CONSIDERATIONS

COMMENTS

Bracken fern and horsetail poisoning in horses is unusual and is often the result of feeding poor-quality hay.

PREVENTION

Feed weed-free hay

CLIENT EDUCATION

Recognition of green and dried bracken fern and horsetail is essential.

AUTHOR: **ANTHONY P. KNIGHT**

EDITOR: **CYNTHIA L. GASKILL**

Branchial Cysts

BASIC INFORMATION

DEFINITION

Branchial cysts are congenital epithelial cysts that arise as malformations of the branchial arches during embryogenesis. They are uncommon, but when they are present, they are described most often in and around the head and neck from a failure of obliteration of the second branchial cleft.

SYNONYM(S)

Lateral cervical cyst

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Clinical signs may not be immediately apparent, but when the cysts are large or surround critical structures such as the larynx or esophagus, they may be apparent very soon after birth.
- Branchial cysts are rare, and no gender predisposition has been noted.

GENETICS AND BREED PREDISPOSITION This is a congenital abnormality, but no genetic or breed predisposition has been established.

ASSOCIATED CONDITIONS AND DISORDERS

- Surrounding vascular, neural, and anatomic structures may be affected and should be examined as part of the preoperative planning.
- Cysts may become infected and develop abscesses.
- Aspiration pneumonia may be present.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Unilateral or bilateral retropharyngeal, laryngeal, or cervical swelling, which may rapidly increase in size over a short period

PHYSICAL EXAM FINDINGS

- Firm, nonpainful mass in the area of the caudal mandible to mid-cervical region.
- Unilateral or bilateral mucopurulent discharge may be present.
- Respiratory crackles may be present upon thoracic auscultation.
- Dyspnea.
- Inspiratory stridor.

ETIOLOGY AND PATHOPHYSIOLOGY

- During the fourth week of embryonic life, the development of branchial (or pharyngeal) clefts results in five ridges known as the branchial (or pharyngeal) arches, which contribute to the formation of various structures of the head, neck, and thorax.
- The second arch grows caudally and, ultimately, covers the third and fourth arches. The buried clefts become ectoderm-lined cavities, which normally involute around week 7 of development.
- If a portion of the cleft fails to involute completely, the entrapped remnant forms an epithelium-lined cyst with or without a sinus tract to the overlying skin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Salivary mucocele
- Cervical abscess
- Lymphadenopathy

INITIAL DATABASE

- Complete blood count to evaluate concurrent disease.
- Survey radiographs of the laryngeal and cranial cervical regions.
- Endoscopy of the pharynx, larynx, guttural pouches, and trachea may aid in the detection of affected structures and further preoperative planning.

ADVANCED OR CONFIRMATORY TESTING

- A sinogram may be obtained. If a sinus tract exists, radiopaque dye can be injected to delineate the course and to examine the size of the cyst.
- Ultrasonography helps delineate the cystic nature of these lesions.
- A contrast-enhanced computed tomography scan shows a cystic and enhancing mass in the neck. It may aid preoperative planning and identify compromise of local structures.
- Magnetic resonance imaging allows finer resolution during preoperative planning. The wall of the cyst may be enhanced on gadolinium scans.

HISTOPATHOLOGY

- Most branchial cleft cysts are lined with stratified squamous epithelium with keratinous debris within the cyst.
- The cyst may be lined with respiratory (ciliated columnar) epithelium.
- Lymphoid tissue is often present outside the epithelial lining.
- In infected or ruptured lesions, inflammatory cells are seen within the cyst cavity or the surrounding stroma.

TREATMENT

THERAPEUTIC GOAL(S)

Complete removal of cyst and cystic epithelial lining

ACUTE GENERAL TREATMENT

- Surgical incision and drainage of abscesses are indicated, if present, usually along with concurrent antimicrobial therapy.
- Percutaneous aspiration and surgical drainage of cysts are considered inappropriate because most cysts will reappear if any epithelium remains.
- Injection of cysts with a sclerosing agent may be considered if surgery is not possible.

POSSIBLE COMPLICATIONS

- Untreated lesions may cause difficulty swallowing and breathing and are prone to recurrent infection and

ElibeVet.com

abscess formation with resultant scar formation and possible compromise of local structures.
- Complications of surgical excision result from damage to nearby vascular or neural structures.

RECOMMENDED MONITORING

Postoperatively, patients should be monitored for recurrence.

PROGNOSIS AND OUTCOME

- Prognosis is good after complete removal of the cystic epithelial lining.
- In humans, recurrence is uncommon after surgical excision, with a risk estimated at 3% unless previous surgery or recurrent infection has occurred, in which case it may be as high as 20%. The data are unknown in horses.

PEARLS & CONSIDERATIONS

The owner should be reminded that this is a benign, congenital problem. No genetic or breed disposition has been established.

AUTHOR: **JARRED WILLIAMS**

EDITORS: **ELIZABETH M. SANTSCHI** and **PHOEBE A. SMITH**

Bronchopneumonia, Bacterial

BASIC INFORMATION

DEFINITION

Bacterial infection and inflammation of the airways, lung parenchyma, or both

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION

- There is no genetic or breed predisposition, except in cases in which horses are immune compromised (eg, Arabian foals with combined immunodeficiency disorder).
- Performance horses (Thoroughbred racehorses and show jumpers) have an increased risk of developing pneumonia, most likely reflecting an increase in several risk factors (eg, long-distance transport, strenuous exercise, and increased exposure to respiratory viruses).

RISK FACTORS Any disease or situation that compromises the respiratory defenses or increases the risk of aspiration:

- Compromised respiratory defenses (more common)
  - Strenuous exercise
  - Long-distance transport with the head elevated
  - Concurrent respiratory viral infection (equine influenza; equine herpesvirus [EHV] -1, -2, and -4; equine arteritis virus; equine rhinovirus A and B)
  - Mechanical ventilation (general anesthesia)
  - Exercise-induced pulmonary hemorrhage
- Increased risk of aspiration: Laryngeal or pharyngeal dysfunction (less common)
  - Primary neuropathy of cranial nerve IX or X (equine protozoal myeloencephalitis, botulism, *Streptococcus equi*, subsp. *equi* infection, guttural pouch mycoses)
  - Primary myopathy of pharyngeal, laryngeal or esophageal musculature (vitamin E and selenium deficiencies, megaesophagus)
  - Physical limitation of laryngeal function after tie-back surgery
  - Esophageal obstruction (choke)

ASSOCIATED CONDITIONS AND DISORDERS Lung abscesses, pleuropneumonia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The chief complaint may be related to pneumonia or to a predisposing condition. The history may include recent long-distance transportation, exposure to horses with respiratory viruses, or recent esophageal obstruction.
- Pneumonia
  - In acute stages, some animals will not have obvious clinical signs related to respiratory tract disease.
  - Exercise intolerance is sometimes the earliest and only complaint at presentation.
  - May include vague history of fever, depression, and inappetence.
  - Cough
  - Weight loss
  - Mucopurulent nasal discharge.
- Laryngeal or pharyngeal dysfunction
  - Dysphagia
  - Inspiratory stridor
  - Cough

PHYSICAL EXAM FINDINGS

- Physical examination findings are variable and depend on the stage, severity, and cause of the disease. A lack of physical examination findings referable to the respiratory system cannot definitively rule out bronchopneumonia.
- Crackles and wheezes (focal or diffuse): Lung sounds should be assessed both before and after application of a rebreathing bag (if no respiratory distress is present) because the deep breaths achieved after rebreathing can be invaluable in more accurately ausculting the presence and degree of abnormal lung sounds.
- Mucopurulent nasal discharge
- Fever
- Tachypnea or respiratory distress
- Tachycardia
- Cough
- Depression

ETIOLOGY AND PATHOPHYSIOLOGY

- In adult horses, bacterial pneumonia occurs most frequently as a sequela to a predisposing condition or disease that reduces the respiratory immune defenses, limits ciliary clearance of bacteria from the lower respiratory tract, or increases the aspiration or inhalation of bacteria.
- These conditions result most commonly in polymicrobic infections of bacteria that normally inhabit the upper respiratory tract or gastrointestinal tract.
  - The most common gram-positive bacterial isolates include *Streptococcus equi* subsp. *zooepidemicus*,

ElibeVet.com

Staphylococcus aureus, and *Streptococcus pneumoniae*.
  - The most common gram-negative bacterial isolates include *Pasteurella* and *Actinobacillus* spp., *Escherichia coli, Klebsiella pneumoniae,* and *Bordetella bronchiseptica*.
  - The most common anaerobic bacterial isolates include *Bacteroides fragilis, Peptostreptococcus anaerobius,* and *Fusobacterium* spp.
- Compromised respiratory defenses: Strenuous exercise
- Increased bacterial contamination of the lower airway (10- to 100-fold increase in bacterial counts from tracheal washes after a single bout of high-intensity exercise)
- Reduced mucociliary clearance
- Alterations of systemic immune defenses, predisposing animals to both viral and bacterial pulmonary infections: Long-distance transport
- Reduced mucociliary clearance when the head is tied
- As little as 6 hours of elevated head position during transport increases pulmonary neutrophilic inflammation and accumulation of *Actinobacillus, Pasteurella*, and *Streptococcus* bacterial species
- Reduced efficacy of systemic antimicrobial defenses (such as reduced phagocytosis by peripheral blood mononuclear cells): Concurrent respiratory viral infection
- Damage to respiratory epithelial cells enhances bacterial attachment
- Reduced mucociliary clearance and alveolar macrophage dysfunction for up to 30 days after infection: Mechanical ventilation (general anesthesia)
- Increased risk of aspiration: Laryngeal or pharyngeal dysfunction
  - Increased aspiration of bacteria secondary to dysphagia is a less common cause of bacterial pneumonia in adult horses.
  - Most often associated with esophageal obstruction in horses with poor dental health.
  - Other causes of dysphagia should also be considered and include neuropathy of cranial nerve IX or X (equine protozoal myeloencephalitis, botulism, *S. equi* infection, guttural pouch mycoses) and primary myopathy of pharyngeal, laryngeal, or esophageal musculature (vitamin E and selenium deficiencies, megaesophagus).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Noninfectious lower airway diseases such as inflammatory airway disease, recurrent airway obstruction, and idiopathic pulmonary fibrosis
- Fungal pneumonia (especially if unresponsive to antimicrobial therapy)
- Pulmonary neoplasia
- Respiratory parasites

INITIAL DATABASE

- Complete blood count (CBC): Leukocytosis and neutrophilia (with or without left shift) may be present, although neutropenia may be present in cases of severe gram-negative bacterial pneumonia (associated with the effects of endotoxin). Hyperfibrinogenemia, hyperglobulinemia, and anemia of chronic disease are compatible with chronic bacterial pneumonia.
- Serum biochemistry profile: Usually normal
- Thoracic radiography: Alveolar and interstitial patterns in dependent areas of the lung

ADVANCED OR CONFIRMATORY TESTING

- Tracheal wash: Degenerative neutrophils, intracellular bacteria
- Tracheal wash culture: Isolation of pathogenic bacteria
- Arterial blood gas analysis: Hypoxemia may be present and is generally indicative of more severe lower airway disease
- Upper airway endoscopic examination: Possible laryngeal or pharyngeal dysfunction
- Other tests for underlying laryngeal dysfunction (eg, EHV1 polymerase chain reaction or enzyme-linked immunosorbent assay, or serum vitamin E or selenium level

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate pathogenic bacteria.
- Correct any underlying laryngeal or pharyngeal dysfunction.

ACUTE GENERAL TREATMENT

- Broad-spectrum antimicrobial therapy until culture results are available and antimicrobial therapy can be tailored. Any combination should at least initially cover both aerobic and anaerobic bacteria.
  - For more severely affected animals, use IV antibiotic combinations such as potassium penicillin (22,000 IU/kg IV q6h) or ceftiofur (4.4 mg/kg IV q12h) and an aminoglycoside (gentamicin is most cost effective in adults; 6.6 mg/kg IV q24h) or fluoroquinolone (enrofloxacin, 5–10 mg/kg IV q24h). Metronidazole can also be added to increase anaerobic coverage (15 mg/kg PO q6h), especially against the penicillin-resistant *B. fragilis*.
  - Because the most commonly isolated bacteria in cases of mild bacterial pneumonia is *S. equi* subsp. *zooepidemicus*, treatment of mild cases before return of sensitivity panels might be limited to ceftiofur because this antibiotic has good efficacy against *S. equi* subsp. *zooepidemicus* as well as several common gram-negative species.
  - In less severe cases, oral antibiotics may be sufficient, such as potentiated sulfonamides (trimethoprim-sulfadiazine 30 mg/kg PO q12h, although the efficacy of this antibiotic against *S. equi* subsp. *zooepidemicus* in vivo for the treatment of pulmonary infections has been recently challenged despite good in vitro sensitivity), chloramphenicol (50 mg/kg PO q12h), or doxycycline (10 mg/kg PO q12h).
- Nonsteroidal antiinflammatory drugs (NSAIDs) such as flunixin meglumine can be given for pain (0.5–1.1 mg/kg IV or PO q12h) and for antiendotoxic effects (0.25 mg/kg IV or PO q6h).
- Maintain adequate hydration, especially important if aminoglycosides or NSAIDs are used in treatment. IV fluids may be necessary if the animal is depressed and not drinking sufficiently.
- Intranasal oxygen, bronchodilators (eg, inhaled albuterol 600–720 µg puffs q4–6h) and laminitis prophylaxis measures may be necessary depending on the type and severity of disease.
- Provide palatable food choices to maintain appetite.

CHRONIC TREATMENT

- Identification and resolution of any underlying disease with increased risk of aspiration pneumonia.
- Continuation of antibiotic therapy at least 1 week past the resolution of clinical signs and significant improvement of thoracic radiographic abnormalities.
- Some horses with laryngeal or pharyngeal dysfunction may require placement of an esophagostomy tube for feeding to avoid continued aspiration until the dysfunction resolves.

POSSIBLE COMPLICATIONS

- Lung abscessation
- Pleuropneumonia
- Laminitis from severe gram-negative infection

RECOMMENDED MONITORING

- Clinical signs: Animals should be reevaluated in 48 to 72 hours for signs

ElibEVet.com

of improvement. Lack of improvement in this period may indicate the necessity for an antibiotic change.
- Thoracic radiographs should be reevaluated 7 to 10 days after the initiation of treatment and may lag behind clinical signs by 2 to 3 days.
- Repeat arterial blood gas analysis: For severe pneumonia, repeated analysis of gas exchange may provide information about the response to treatment.
- CBC: Resolution of neutrophilia or neutropenia should occur within 7 to 10 days.

PROGNOSIS AND OUTCOME

- The prognosis is variable and depends on the severity of the disease and the predisposing factors; however, the prognosis is generally good if early aggressive treatment is initiated.
- The risk of recurrence is high for animals with unresolved underlying disease.
- The prognosis is guarded if complications such as lung abscesses or pleuropneumonia are present.

PEARLS & CONSIDERATIONS

COMMENTS

- Bacterial pneumonia in adult horses is usually the result of an underlying disease or stressor.
- Therefore any adult equid that presents with bacterial pneumonia should be carefully evaluated for underlying risk factors.

PREVENTION

- Preventive measures involve reducing the occurrence of risk factors.
  - Avoid long-distance transport, especially with head restraint. Studies have shown that simple measures such as increased rest stops and trailer cleaning can minimize or eliminate respiratory insult during long-distance transport.
  - Adequate immunization against respiratory viral diseases (EHV, equine influenza) that can predispose animals to the development of secondary bacterial pneumonia.
  - Adequate dental care in older horses to avoid esophageal obstruction.

CLIENT EDUCATION

Clients should be informed of possible risk factors and advised on appropriate measures to avoid recurrence.

Brucellosis

BASIC INFORMATION

DEFINITION

- An infectious disease caused by infection with species of the genus *Brucella*, especially *Brucella abortus* and *Brucella suis*. *B. abortus* has a predilection for the tendons, muscles, bones, and joints of horses.
- It is most often associated with septic bursitis of the supraspinous bursa over the second and third dorsal vertebral spinous processes (fistulous withers) or supraatlantal bursa over the first and second cervical vertebra (poll evil).

SYNONYM(S)

- Fistulous withers
- Poll evil

EPIDEMIOLOGY

SPECIES, AGE, SEX Most infected horses are older than 3 years.

RISK FACTORS Most affected horses have a history of contact with cattle.

CONTAGION AND ZOONOSIS

- Brucellosis is considered a zoonotic disease, but reports of disease in humans in contact with infected horses are rare.
- Numerous reports of accidental infection of veterinarians with *B. abortus* from strain 19 vaccine.
- Infection in humans may result in subclinical, acute, localized, or chronic disease or relapsing infection.
- Acute disease is characterized by malaise, chills, sweats, fatigue, weakness, fever, myalgia, weight loss, and arthralgia.
- Localized infection may occur at almost any site.
- Chronic infection is characterized by persistent fatigue, malaise, and depression.
- Relapse may occur after apparent successful antimicrobial treatment. Relapse may occur as long as 2 years after initial treatment.

GEOGRAPHY AND SEASONALITY

- It has been reported in horses worldwide, but *B. abortus* has been effectively eradicated from several European countries, Japan, and Israel.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- *B. abortus* infections are more common than *B. suis* infections.
- *B. abortus* is associated with:
  - Septic supraspinous bursitis
  - Atlantal bursitis
  - Other bursal infections
  - Septic arthritis
  - Vertebral osteomyelitis
  - Rarely, abortion
- *B. suis* has been isolated from:
  - Septic bursitis
  - Aborted equine fetuses
  - The internal organs of one mare with no clinical signs of disease

HISTORY, CHIEF COMPLAINT

- Most affected horses have a history of exposure to cattle.
- Many seropositive horses show no recognizable clinical signs.
- The onset of clinical signs may be sudden or insidious.
- Lethargy and general stiffness in movement are seen.
- Pain, heat, and swelling of the withers or poll that may progress to obvious external fistulation or exudate.
- Rarely, the chief complaint may be abortion.

ElibeVet.com

- Lameness may be the primary complaint with some infections.

PHYSICAL EXAM FINDINGS

- Pain, heat, and swelling of the withers or poll
- May progress to obvious external fistulation or exudate
- May be apparent healing, fibrosis, and refistulation as disease progresses
- Clinical signs of bursitis, tenosynovitis, arthritis, or osteomyelitis, depending on the site of infection
- Evidence of recent abortion (rare)

ETIOLOGY AND PATHOPHYSIOLOGY

- *Brucella* spp. are nonmotile, aerobic, intracellular gram-negative cocci or short rods that require complex media for growth in culture.
- Transmission may occur by ingestion, inhalation, or direct contact through skin abrasions or mucous membranes.
- The organism may be shed in equine feces and urine and in tissues from aborted equine fetuses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Bacterial infections and abscesses caused by other organisms

INITIAL DATABASE

- Complete blood count and serum biochemical profile to assess systemic health
- Culture of exudate sampled aseptically from deep within the initial site of infection

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate the causative bacteria.
- Facilitate healing of affected tissues.

ACUTE GENERAL TREATMENT

- Many *Brucella* spp. are sensitive to tetracyclines, chloramphenicol, streptomycin, and selected sulfonamides.
- Long-term treatment solely with antimicrobials is rarely effective.
- Lavage of draining tracts with antiseptic or antimicrobial solutions may be beneficial.
- Aggressive surgery to remove diseased tissue is recommended if possible.
- Postsurgical healing is often slow and may not be complete.
- Administration of *Brucella* vaccine may be an effective extralabel treatment for horses with *B. abortus* infection; however, SC administration of the vaccine is associated with severe local and systemic reactions, and IV vaccine administration resulted in death in three of four treated horses.

FIGURE 1 Chronic fistulous withers with multiple tracts in horse infected with *Brucella abortus*. (From Sellon DC, Long MT: *Equine infectious diseases*. St Louis, 2007, Saunders.)

CHRONIC TREATMENT

All horses with brucellosis require chronic treatment as outlined above.

POSSIBLE COMPLICATIONS

Even with aggressive surgical and antimicrobial treatment, recovery may not be complete.

PROGNOSIS AND OUTCOME

Prognosis is guarded even with aggressive therapy, with the potential for poor and incomplete healing.

PEARLS & CONSIDERATIONS

COMMENTS

- In geographic areas with a low prevalence of *B. abortus* infection in cattle, *B. abortus* is rarely isolated from horses with fistulous withers.
- Although horses are a potential source of *B. abortus* infection for cattle, experimental infections indicate that horses do not excrete the organism in sufficient numbers to efficiently infect cattle in close contact.
- Horses with fistulous withers that are seropositive to *B. abortus* are significantly more likely than seronegative horses with fistulous withers to have radiographic evidence of osteomyelitis of underlying dorsal spinous processes.
- Confirmation of diagnosis by bacterial culture may be difficult because other bacteria are frequently found in exudates and may overgrow *B. abortus*. Culture of aspirates from deep inside lesions or from affected tissues collected at surgery or necropsy is indicated to attempt confirmation of the diagnosis.

FIGURE 2 Severe postsurgical lesions and exudation in horse with fistulous withers. (From Sellon DC, Long MT: *Equine infectious diseases*. St Louis, 2007, Saunders.)

PREVENTION

- Avoid comingling of horses with seropositive cattle.
- Use properly fitted saddles and harnesses to minimize trauma to the withers and poll.
- Effective parasite control programs to eliminate *Onchocerca* spp. and control fly populations may also be beneficial.

EDITORS: **MAUREEN T. LONG** and **DEBRA C. SELLON**

Bufo Toad Toxicosis

BASIC INFORMATION

DEFINITION

Exposure to *Bufo* spp. toads may result in the acute onset of severe cardiovascular and neurologic signs.

SYNONYM(S)

Cane, giant, or marine toad (*Bufo marinus*), Colorado River toad (*Bufo alvarius*)

EPIDEMIOLOGY

RISK FACTORS Most cases in the literature describing *Bufo* toad intoxications involve dogs and cats rather than horses and other large domestic animals. Although young or curious horses might mouth *Bufo* toads, a more likely route of exposure for most horses is the contamination of food or water sources by live or dead toads.

GEOGRAPHY AND SEASONALITY

- *Bufo* toads are primarily found in Florida, Texas, Colorado, Arizona, and Hawaii.
- These toads breed during warmer, wetter months and tend to hibernate during the colder, dryer months, making wintertime exposures less likely. Toads appear to be most active around dusk and at night and after rainstorms.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Oral contact with a *Bufo* toad is rapidly followed by hypersalivation, tachypnea, and disorientation. Severe exposures may progress to seizures, collapse, and cardiac arrhythmias.

PHYSICAL EXAM FINDINGS

- In addition to hypersalivation, hyperemic oral mucous membranes may also be observed.
- Horses should be examined for cardiovascular and neurologic abnormalities. Neurologic abnormalities reported in dogs include seizures, stupor, ataxia, nystagmus, opisthotonos, and extensor rigidity.

ETIOLOGY AND PATHOPHYSIOLOGY

- Many biologically active compounds, including dopamine, epinephrine, norepinephrine, serotonin, bufotenine, bufagenins, bufotoxins, and indolealkylamines, are secreted from the toad's large parotid glands. These compounds are readily absorbed across mucous membranes or through open wounds.
- Bufotenine is a pressor substance that may have hallucinogenic properties.
- Bufagenins and bufotoxins are cardiac glycosides that cross-react with digoxin, binding to and inhibiting Na/K-ATPase. These changes inhibit normal myocardial conduction and function.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other cardiac glycosides, including digoxin and digitoxin
- Seizure disorders
- Head trauma
- Other toxicoses: Metaldehyde, methylxanthines, oleander, anticholinesterase insecticides, hallucinogenic plants or mushrooms

INITIAL DATABASE

The initial examination should include determination of heart rate, thoracic auscultation, and evaluation of perfusion. Diagnosis of *Bufo* toad toxicity typically relies on the presence of compatible clinical signs and a history of exposure to toads.

ADVANCED OR CONFIRMATORY TESTING

- Horses with significant cardiac or neurologic abnormalities should have at least an initial electrocardiographic evaluation.
- When available, polyclonal (but not monoclonal) digoxin immunoassays may assist in confirming exposure, although results do not appear to correlate well with clinical effects.
- Some diagnostic laboratories may also be able to identify toad toxins from gastrointestinal contents and other samples using gas or liquid chromatography/mass spectrometry.

TREATMENT

THERAPEUTIC GOAL(S)

- Decontaminate the oral cavity.
- Control seizure activity.
- Evaluate and correct cardiac arrhythmias.
- Provide general supportive care.

ACUTE GENERAL TREATMENT

- Initially, the oral cavity should be flushed with copious amounts of water.
- If present, seizures should be controlled with diazepam.
- Crystalloid electrolyte solutions can be given intravenously.
- The cardiac status should be evaluated and treated symptomatically.
- Severely affected animals may benefit from digoxin-specific Fab fragments. Although used successfully in humans, this treatment has not been thoroughly evaluated in animals.

POSSIBLE COMPLICATIONS

Hyperkalemia may develop and require treatment. Administration of calcium should be avoided.

RECOMMENDED MONITORING

Careful cardiac monitoring is indicated, and hyperthermia may occur as a sequela of seizure activity.

PROGNOSIS AND OUTCOME

Many animals can fully recover with early intervention and treatment.

PEARLS & CONSIDERATIONS

There is also good evidence that *Bufo* toads' eggs are toxic and could be another potential source of exposure for horses.

AUTHOR: **LISA A. MURPHY**
EDITOR: **CYNTHIA L. GASKILL**

Burns

BASIC INFORMATION

DEFINITION

A lesion caused by contact with heat or fire

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Barn fires are one of the most common causes of burn in horses of any age.
- Horses housed in at-risk barns (no fire detection or protection systems) are more predisposed to burn injury.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Burns are classified by the depth of the injury:
  - First-degree burns involve only the most superficial layers of the epidermis. These burns are painful and are characterized by erythema, edema, and desquamation of the superficial layers of the skin. The germinal layer of the epidermis is spared, and these burns heal without complication.
  - Second-degree burns involve the epidermis and may be superficial or deep.
    - Superficial second-degree burns involve the stratum corneum, stratum granulosum, and a few cells of the basal layer. Tactile and pain receptors remain intact. Because the basal layers remain relatively uninjured, superficial second-degree burns heal rapidly with minimal scarring, within 14 to 17 days.
    - Deep second-degree burns involve all layers of the epidermis, including the basal layers. These burns are characterized by erythema and edema at the epidermal-dermal junction, necrosis of the epidermis, accumulation of white blood cells at the basal layer of the burn, eschar (slough produced by a thermal burn) formation, and minimal pain. The only germinal cells spared are those within the ducts of sweat glands and hair follicles. Deep second-degree wounds may heal spontaneously in 3 to 4 weeks if care is taken to prevent further dermal ischemia that may lead to full-thickness necrosis. In general, deep second-degree wounds, unless grafted, heal with extensive scarring.
  - Third-degree burns are characterized by loss of the epidermal and dermal components, including the adnexa (Figure 1). The wounds range in color from white to black. There is fluid loss and a marked cellular response at the margins and deeper tissue, eschar formation, lack of pain, shock, wound infection, and possible bacteremia and septicemia. Healing is by contraction and epithelialization from the wound margins or acceptance of an autograft. These burns are frequently complicated by infection.
  - Fourth-degree burns involve all of the skin and underlying muscle, bone, ligaments, fat, and fascia.

HISTORY, CHIEF COMPLAINT Burn injury to the horse of various depths, usually the result of barn fire and falling asphalt shingles on the dorsum

PHYSICAL EXAM FINDINGS

- Because heat is slow to dissipate from burn wounds, it is often difficult to accurately evaluate the amount of tissue damage in the early phase of injury. Whereas the extent of the burn depends on the size of the area exposed, the severity relates to the maximum temperature the tissue attains and the duration of overheating. This explains why skin injury often extends beyond the original burn.
- Burns are most commonly seen on the back and face.
  - Erythema, pain, vesicles, and singed hair are present depending on the extent of the injury.
  - Increases in heart and respiratory rates are present in association with abnormal discoloration of mucous membranes.
  - The burned horse may have blepharospasm, epiphora, or both, signifying corneal damage.
  - Coughing may indicate smoke inhalation, and a fever signals or confirms a systemic response.
  - Whereas the percentage of total body surface area involved usually correlates with death, the depth of the burn determines morbidity.

ETIOLOGY AND PATHOPHYSIOLOGY

- After severe burns, a dramatic cardiovascular effect termed *burn shock* occurs, which resembles hypovolemic shock. A dramatic increase in local and systemic capillary permeability occurs as a result of heat and the release of cytokines, prostaglandins, nitric oxide, vasoactive leukotrienes, serotonin,

FIGURE 1 Third-degree burn of the dorsal gluteal region incurred during a barn fire caused by hot asphalt roof shingles falling on the horse. The central burn area is surrounded by deep and superficial second-degree burns.

ElibeVet.com

histamine, and oxygen radicals. Local tissue damage results from massive protein coagulation and cellular death.
- Inhalation injury is a common sequela of closed-space fires and develops through three mechanisms: direct thermal injury, carbon monoxide poisoning, and chemical insult. Direct thermal injury causes edema and obstruction of the upper airway, but because of the efficient heat exchange capacity of the nasopharynx and oropharynx, superheated air is cooled before entering the lower respiratory tract.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Chemical burn injury

INITIAL DATABASE

- Complete blood count
- Serum chemistry panel
- Serial arterial blood gas analyses
- Upper airway endoscopy

ADVANCED OR CONFIRMATORY TESTING

- Thoracic radiographs
- Transtracheal washes for cytology and culture

TREATMENT

THERAPEUTIC GOAL(S)

Cardiovascular support to avoid circulatory collapse from burn shock in patients with greater than 15% of the total body surface area affected

ACUTE GENERAL TREATMENT

- Isotonic fluids should be given at a rate of 2 to 4 mL/kg body weight for each percentage of body surface area burned. Give a half dose in the first 24 hours and the other half the next day.
  - Fluid resuscitation is best titrated to maintain a stable and adequate blood pressure.
  - If there has been smoke or heat inhalation injury, crystalloids should be limited to the amount that normalizes circulatory volume and blood pressure.
- Two to 10 L of plasma is an effective albumin source as well as an exogenous source of antithrombin III for coagulopathies.
  - Flunixin meglumine (0.25–1.0 mg/kg q12–24h IV) and pentoxifylline (8.0 mg/kg q12h IV) are effective analgesics and improve blood flow in the small capillary networks.
- Dimethyl sulfoxide (DMSO) (1 g/kg, diluted to <20% IV) for the first 24 hours may decrease inflammation and pulmonary edema.
- Dexamethasone may be administered once at 0.5 mg/kg IV if pulmonary edema is present and is unresponsive to DMSO.

CHRONIC TREATMENT

- First-degree burns:
  - Are generally not life threatening and are simply managed.
  - Topical therapy in the form of cool compresses, cold-water baths, and wound coverings may provide relief.
  - Pain control may be accomplished with nonsteroidal antiinflammatory drugs or narcotics.
- Second degree burns:
  - Are associated with vesicles and blisters.
  - These vesicles should be left intact for the first 24 to 36 hours after formation because blister fluid provides protection from infection, and the presence of a blister is less painful than the denuded exposed surface.
  - After this interval, the blister is partially excised, and an antibacterial dressing is applied to the wound or an eschar is allowed to form.
- Third-degree burns:
  - May be difficult to manage.
  - Destruction of the dermis leaves a primary collagenous structure called an eschar.
  - Dry exposure is a treatment method that operates under the principle that bacteria do not thrive on a dry surface.
    - The goals of therapy are to keep the wound dry and protected from mechanical trauma.
    - Heat and water loss from the uncovered wound, however, are a disadvantage.
    - The eschar is covered with silver sulfadiazine in a 1% water miscible cream twice daily.
  - The exposed bed can then be grafted or allowed to contract.

DRUG INTERACTIONS

- Povidone-iodine causes some patient discomfort.
  - Its hyperosmolality causes severe hypernatremia and acidosis because of water loss such that it should not be used on extensive burns where systematic absorption is likely.
  - Immune system depression has also been reported in humans.
- Gentamicin is excellent for serious gram-negative infections but should be used only in selected cases because resistance can develop, and it may be nephrotoxic in patients with renal problems.
- Neomycin, bacitracin, and polymixin B
  - Generally associated with the rapid development of bacterial resistance and systemic toxicity
  - Not recommended for routine use in long-term wound care

POSSIBLE COMPLICATIONS

- Systemic antibiotics do not favorably influence wound healing, fever, or mortality, and they may encourage the emergence of resistant microorganisms.
- Many burned equine patients are pruritic, and measures must be taken to prevent self-mutilation of the wound.
- Reserpine may be effective in decreasing the urge to scratch by successfully breaking the itch-scratch cycle.

PROGNOSIS AND OUTCOME

Delayed healing and poor epithelialization and complications of second intention healing may limit return of the animal to previous uses.

PEARLS & CONSIDERATIONS

COMMENTS

- Extensive thermal injuries in horses may be difficult to manage.
- The large surface of the burn dramatically increases the potential for loss of fluids, electrolytes, and calories.

ElibeVet.com

Candidiasis

BASIC INFORMATION

DEFINITION

Candida spp. are opportunistic fungal pathogens that can cause a variety of localized and systemic infections in neonatal and adult horses that have been immunocompromised for any reason.

SYNONYM(S)

Thrush

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Horses with genetic conditions leading to immune compromise (eg, severe combined immunodeficiency of Arabians) are at increased risk.

RISK FACTORS

- Prolonged broad-spectrum antibiotic therapy
- Disruption of cutaneous or mucosal barriers by burns, surgery, cytotoxic agents, or trauma
- Any immune deficiency or immunosuppression produced by genetic defects, disease states such as sepsis, or administration of drugs such as glucocorticoids
- Low birth weight, premature foals
- Long-term placement of indwelling IV or urinary catheters or endotracheal tubes
- Prolonged parenteral nutrition

CONTAGION AND ZOONOSIS Although humans may develop a variety of infections from *Candida* spp., infection acquired from handling affected horses is probably unlikely unless the person is immunocompromised.

ASSOCIATED CONDITIONS AND DISORDERS Any other condition associated with immune deficiency

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Oral candidiasis or thrush
- Systemic candidiasis with variable organ localization
- Endometritis

HISTORY, CHIEF COMPLAINT History and chief complaint vary depending on the risk factors present, the reason for immunocompromise, and the site of infection.

PHYSICAL EXAM FINDINGS

- Physical examination findings vary depending on the risk factors present, the reason for immunocompromise, and the site of infection.
- Oral candidiasis (thrush) manifests as white plaques on the oral mucosa and tongue.
- Systemic candidiasis may present with nonspecific signs of fever or with signs related to the site of infection of the infection (eg, arthritis, meningitis, omphalophlebitis, pneumonia).
- Mares with uterine candidiasis may present with vaginal discharge or failure to conceive.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Candida* is acquired as part of the normal flora as neonates pass through the birth canal.
- It colonizes the mucosal and mucocutaneous surfaces of the gastrointestinal, respiratory, and genitourinary tracts.
- Under most circumstances, overgrowth of *Candida* spp. is inhibited by normal microflora.
- Opportunistic infections occur when immune defenses are altered by disease or various interventional strategies.
- Mucocutaneous forms such as thrush are often related to defects in cell-mediated immunity; systemic spread is more likely to be associated with neutropenia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other bacterial or fungal infection

INITIAL DATABASE

- Complete blood count and serum biochemical profile to assess systemic health and identify possible sites of infection or reasons for immunocompromise
- Cytologic evaluation or culture of appropriate clinical samples (eg, blood, synovial fluid, cerebrospinal fluid, scrapings from mucosal surfaces)

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate infection.
- Resolve underlying reasons for immunodeficiency.

ACUTE GENERAL TREATMENT

- Treat any underlying diseases and discontinue administration of immune suppressive medications.
- Antifungal therapy with fluconazole as a loading dose of 8 mg/kg PO followed by 4 mg/kg q12–24h
- Resistant strains may be treated with itraconazole at 3–6 mg/kg PO.
- Intrauterine infections (endometritis) may be treated with large-volume uterine flush followed by intrauterine infusion of nystatin (0.5–2.5 million units), clotrimazole (500–700 mg), fluconazole (100 mg), or miconazole (200 mg) in a small volume of solution.
- Supportive care should be provided as appropriate depending on the site of infection and underlying disease processes.

PROGNOSIS AND OUTCOME

Prognosis is guarded because many cases are complicated by serious underlying immunosuppressive conditions.

PEARLS & CONSIDERATIONS

- Treatment of septic arthritis caused by *Candida* spp. must be aggressive and include successive joint lavage and arthroscopic flush procedures to facilitate physical removal of accumulated fibrin.
- Patients with systemic candidiasis may have embolic colonization and microabscess formation in lung, kidneys, joints, eyes, liver, brain, or myocardium.

ElibeVet.com

Cardiac Failure

BASIC INFORMATION

DEFINITION

Clinical syndrome resulting from an acute or chronic impairment of cardiac function characterized by a reduction in cardiac output, inadequate perfusion of vital organs, heightened neurohumoral activity, renal sodium and fluid retention, and accumulation of fluid in tissues and body cavities

SYNONYM(S)

- Acute heart failure
- Chronic heart failure
- Congestive heart failure (CHF)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- May occur at any age.
  - The majority of affected patients are older horses with severe valvular heart disease.
  - Foals and younger horses may develop heart failure secondary to congenital malformations.

ASSOCIATED CONDITIONS AND DISORDERS

- Heart failure develops in foals and adult horses as a sequela to severe cardiac disease.
- Underlying conditions include congenital malformations, valvular heart disease, pericardial disease, myocardial disease, rupture of large vessels, severe pulmonary disease, or chronic cardiac arrhythmias.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- May be acute (eg, chordal rupture, bacterial endocarditis) or chronic (eg, degenerative valve disease)
- Early heart failure: May be subclinical at rest. Signs may include poor performance and delayed recovery after exercise.
- Acute or advanced chronic heart failure: Clinical signs are evident at rest. Even in chronic disease, sudden onset of clinical signs is common.
- CHF is characterized by volume overload, elevation of venous pressures, and fluid accumulation in tissues and in body cavities.
- CHF is uncommon in horses.
- Left ventricular failure is characterized by pulmonary venous congestion and pulmonary edema. Slowly progressive left heart disease often goes unnoticed until the right heart fails in response to chronic pulmonary hypertension (PH), leading to biventricular failure.
- Right ventricular and biventricular failure are characterized by systemic venous congestion, ventral edema, and effusion in body cavities.

HISTORY, CHIEF COMPLAINT

- Clinical signs may be subtle and depend on the stage of disease and the underlying cause.
- Early complaints: Poor performance, exercise intolerance, and delayed recovery after exercise.
- Advanced disease may lead to anxiety, weight loss, lethargy, tachypnea, cough, foamy nasal discharge, ventral edema, distension of the jugular veins, weakness, ataxia, syncope, or collapse.

PHYSICAL EXAM FINDINGS

- Early heart failure: May be unremarkable
- Advanced heart failure: Tachycardia, weak arterial pulses, pale mucous membranes, prolonged capillary refill time, and cool extremities. Cardiac cachexia (weight loss or loss of muscle mass) may also be seen.
- Cardiac auscultation may reveal:
  - Cardiac murmurs
  - Irregular cardiac rhythm
  - Muffled heart sounds or friction rubs, indicating pericardial disease
  - A loud third heart sound, indicating a severe increase in filling pressures
  - A prominent or split second heart sound, indicating PH
- Left ventricular failure: Tachypnea, increased respiratory effort, dyspnea, cough, nasal discharge, and abnormal lung sounds (crackles, wheezes) on auscultation. The pulmonary edema of pure left-sided congestive heart failure is frequently misdiagnosed as pneumonia, especially in foals with congenital heart disease.
- Right ventricular or biventricular heart failure: Distension of superficial veins; jugular venous pulsation; and generalized ventral, preputial, and pectoral edema. Isolated limb edema and ventral edema in the absence of generalized venous distension are not consistent with CHF.
- Fever may indicate an inflammatory or infectious process such as endocarditis, valvulitis, pericarditis, or myocarditis.

ETIOLOGY AND PATHOPHYSIOLOGY

- May result from any structural or functional heart disease.
- The pathophysiology is complex and affects many body systems.
- Exact mechanisms have not been extensively studied in horses but are likely similar to those reported in other species.
- The failing heart is characterized by:
  - Poor myocardial contractility
  - Decreased preload reserve (diminished response to volume loading)
  - Increased sensitivity to ventricular afterload (wall tension, primarily determined by ventricular geometry and systemic blood pressures)
- Systolic failure occurs because of reduced cardiac pump function.
- Diastolic failure occurs because of impaired cardiac relaxation and ventricular filling.
- Impairment of ventricular filling and reduction of cardiac pump function results in inadequate perfusion of vital organs.
- Inadequate organ perfusion leads to an activation of multiple neurohumoral pathways, including:
  - Sympathetic nervous system
  - Renin-angiotensin-aldosterone system
  - Other hormones, including vasopressin (antidiuretic hormone), endothelin, and natriuretic peptides
- Initially, neurohumoral activation is compensatory and beneficial. An increase in heart rate, contractility, and circulating blood volume allow support of cardiac pump function, and arteriolar vasoconstriction results in redistribution of blood flow to vital organs.
- With disease progression, the compensatory capacity of the cardiovascular system is exceeded, leading to development of overt congestive heart failure. Chronic neurohumoral activation results in exacerbation of clinical signs and heart failure.
  - Sodium and water retention contribute to volume overload, resulting in organ congestion.
  - Catecholamines exert proarrhythmic effects, promote myocardial remodeling, and are toxic to myocytes.
  - Aldosterone causes endothelial dysfunction and myocardial fibrosis.
  - Proinflammatory cytokines contribute to weight loss and apoptotic cell loss in myocardial tissues.
- Strenuous work, anemia, fever, or pregnancy increase the demands for cardiac output and may precipitate heart failure in a compensated patient.
- Development of atrial fibrillation in a horse with underlying structural disease may also cause sudden deterioration in a compensated patient.
- Left-sided heart failure: The left ventricle undergoes remodeling, leading

ElibeVet.com

to dilation and hypertrophy, with decreased myocardial perfusion and potential myocardial ischemia. Ventricular dilation may result in worsening of mitral regurgitation, exacerbating pulmonary congestion.
- Chronic left-sided CHF in horses causes interstitial lung edema, remodeling of the pulmonary vasculature, and PH.
- PH leads to dilation of the pulmonary artery and development of pulmonic and tricuspid regurgitation (see "Pulmonary Hypertension" in this section).
- Biventricular failure may result from chronic right ventricular overload.
- In severe (but rare) cases, rupture of the dilated pulmonary artery is possible.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other systemic diseases resulting in fever, weight loss, and tachycardia.
- For left-sided failure: Other causes of respiratory distress such as acute respiratory distress syndrome, recurrent airway obstruction, or severe pneumonia or pleuropneumonia.
- For right-sided heart failure: Other causes of venous distension and edema such as a mediastinal or thoracic mass or other space-occupying masses.
- Causes of left-sided or biventricular failure include:
  - Mitral regurgitation: Severe degenerative valve disease, valvulitis, bacterial endocarditis, chordal rupture (see "Mitral/Tricuspid Regurgitation" and "Endocarditis, Infective" in this section)
  - Aortic regurgitation: Severe degenerative valve disease, valvulitis, bacterial endocarditis, rupture or fenestration of aortic valve leaflet (see "Aortic/Pulmonic Regurgitation, Acquired" in this section)
  - Myocardial disease: Dilated cardiomyopathy, ionophore toxicity, white muscle disease, myocarditis, myocardial ischemia, myocardial necrosis (see "Myocarditis" and "Cardiomyopathy" in this section)
  - Vascular rupture (see "Aortocardiac Fistula" in this section)
  - Chronic tachyarrhythmia
  - Congenital heart disease: Ventricular septal defect, patent ductus arteriosus, and other malformations (see "Congenital Heart Disease" in this section and "Comments" below)
- Causes of right-sided failure include:
  - Tricuspid or pulmonary valve lesions: severe degenerative valve disease, valvulitis, bacterial endocarditis, chordal rupture (see "Mitral/Tricuspid Regurgitation" and "Endocarditis, Infective" in this section)
  - Pericardial disease: Pericardial effusion, constrictive pericarditis (see "Pericardial Disease" in this section)
  - Severe primary lung disease or pulmonary vascular disease, leading to PH (cor pulmonale)
  - Congenital heart disease: Tricuspid valve atresia, atrial septal defect, and other malformations (see "Congenital Heart Disease" in this section)
- The most common cause of CHF in horses is valvular heart disease, often complicated by atrial fibrillation.
- Biventricular failure often occurs because of progression of left-sided heart disease to CHF.

INITIAL DATABASE

- Thorough medical history, including current use, athletic condition, and exercise capacity
- Complete physical examination, including careful assessment of mucous membranes, palpation of peripheral pulses, and inspection of venous filling; cardiac auscultation; thoracic auscultation; thoracic percussion; and observation of edema and body condition

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography:
  - Detection of underlying structural heart disease
  - Identification of abnormal blood flow patterns (eg, valvular insufficiencies, shunts)
  - Detection of cardiomegaly and volume overload
  - Evaluation of myocardial function
  - Diagnosis of PH
- Electrocardiography:
  - Assessment of cardiac rhythm disturbances
  - Atrial fibrillation is commonly seen in association with CHF
  - Other arrhythmias such as supraventricular or ventricular premature depolarizations or supraventricular or ventricular tachycardia may also occur
- Thoracic radiography:
  - To identify pulmonary edema and evaluate response to treatment.
  - Limited in its ability to demonstrate mild forms of congestion.
  - Clinical signs do not always correlate with radiographic findings.
  - Mild congestion may be characterized by an interstitial pattern and pulmonary venous congestion.
  - Acute heart failure and severe congestion are characterized by an alveolar pattern and air bronchograms; the cardiac silhouette may be rounded or enlarged, and pleural effusion may be identified.
- Thoracic and abdominal ultrasonography: to identify pleural effusion, ascites, and hepatic congestion
- Complete blood count and plasma fibrinogen concentration: Diagnosis of underlying inflammatory conditions such as endocarditis, valvulitis, pericarditis, or myocarditis
- Serum biochemistry profile:
  - To assess the severity of renal compromise (prerenal or renal azotemia)
  - To identify serum electrolyte disturbances
  - To assess the degree of hepatic damage secondary to congestion
- Blood or plasma lactate concentration to assess peripheral perfusion deficiencies
- Cardiac troponin I (cTnI) or cardiac troponin T (cTnT): Sensitive and specific markers of myocardial cell damage (see "Troponins, Cardiac" in Section IV)
- Blood culture and susceptibility testing: mandatory with suspected bacterial endocarditis (see "Endocarditis, Infective" in this section)
- Ultrasound-guided pericardiocentesis, cytologic evaluation and culture and sensitivity testing: In cases with pericardial effusion (see "Pericardiocentesis" in Section II)
- Exercise testing
  - In horses with early heart failure that are subclinical at rest
  - To document exercise intolerance and poor performance
- Blood pressure monitoring (direct or indirect): To assess the degree of hypotension or response to treatment
- Intracardiac and pulmonary vascular pressure measurements:
  - Cardiac chamber pressure, pulmonary artery pressure, capillary wedge pressure
  - To document PH and increased filling pressures
  - Invasive procedure that is rarely performed in clinical practice

TREATMENT

THERAPEUTIC GOAL(S)

- General goals:
  - Reduction of congestion and edema
  - Improvement of cardiac output and tissue perfusion
  - Inhibition of deleterious neurohumoral activation
- If possible, treat the underlying condition
  - Pericardiocentesis and drainage of pericardial effusion

ElibeVet.com

- Antimicrobial therapy in bacterial endocarditis
- Antiarrhythmics to control chronic tachyarrhythmias
- Addressing treatable causes of myocarditis or cardiomyopathy

ACUTE GENERAL TREATMENT

- Acute heart failure or acute worsening of chronic heart failure:
  - Diuretics (eg, furosemide): 0.5 to 3.0 mg/kg SC, IM, or IV q8–12h or as a bolus of 0.12 mg/kg IV followed by a constant rate infusion (CRI) at a rate of 0.12 mg/kg/hr; doses should be adjusted as needed to produce a diuretic effect.
  - Positive inotropes (eg, dobutamine): CRI at doses of 1 to 5 µg/kg/min, uptitrated to effect or until development of adverse reactions (eg, arrhythmias, tachycardia, extreme anxiety). Administer 2 to 4 µg/kg/min.
  - Intranasal oxygen
- Vasodilators:
  - Used to reduce pulmonary congestion, lower ventricular afterload, and improve tissue perfusion
  - Hydralazine (arterial dilator; 0.5–1.5 mg/kg PO q12h), nitroglycerin (venodilator), milrinone (inotropic vasodilator)
  - Data on efficacy and safety of these drugs in horses with heart failure are lacking
- Cardiac tamponade:
  - Requires a different approach.
  - Initial management includes pericardiocentesis and drainage of the effusion (see "Pericardiocentesis" in Section II).
  - IV fluid administration (as opposed to diuresis) may be necessary to ensure adequate volume loading of the ventricles.
- Life-threatening tachyarrhythmias:
  - May require immediate antiarrhythmic treatment after careful consideration of potential adverse effects (see "Antiarrhythmic Drugs" in Section VI)
  - Criteria for immediate antiarrhythmic treatment include:
    - Severe hemodynamic compromise
    - Sustained heart rates greater than 100 to 120 beats/min
    - Presence of multiforme ventricular complexes or R-on-T phenomenon (when the succeeding QRS complex is essentially continuous with the preceding T wave, increasing the likelihood of inducing ventricular fibrillation)

CHRONIC TREATMENT

- In clinical practice, therapy is often limited to furosemide and digoxin.
  - Furosemide (0.5–2.0 mg/kg SC, IM, or IV q8–12h, titrated to effect), to alleviate volume overload, congestion, and edema.
  - Digoxin (0.011 mg/kg q12h PO, titrated to effect) to increase myocardial contractility and to slow ventricular response rate in patients with rapid atrial fibrillation.
  - Oral potassium supplementation to prevent the occurrence of furosemide-induced hypokalemia that could potentiate the toxic effects of digoxin.
- Angiotensin-converting enzyme (ACE) inhibitors:
  - Decrease renal sodium and water reabsorption, reduce volume overload, counteract the development of diuretic resistance, cause vasodilation with a decrease in myocardial oxygen demand, and are considered to be cardioprotective by decreasing myocardial remodeling and fibrosis.
  - Enalapril (0.5 mg/kg PO q12h), ramipril (0.05 mg/kg PO q24h), and quinapril (0.25 mg/kg PO q24h) have been used in horses.
  - The pharmacology of ACE inhibitors in horses has not been fully investigated, and the efficacy for prophylaxis and treatment of heart failure is unknown.
- β-adrenergic inhibitors, aldosterone antagonists, or inodilators such as pimobendan are commonly used in humans and in dogs with CHF. The use of these agents in the treatment of heart failure has not been investigated in horses to date.
- Pericardectomy: Potential treatment option in horses with severe constrictive pericarditis
- Long-term IV, broad-spectrum antibiotic treatment:
  - Indicated for bacterial endocarditis or infective pericarditis.
  - The antibiotic choice should be adapted based on the results of bacterial culture and susceptibility testing.
- Antiarrhythmics:
  - Lidocaine, magnesium sulphate, procainamide, quinidine, propafenone, phenytoin, and diltiazem
  - Used for treatment of severe arrhythmias after careful consideration of the benefits and potential risks of treatment

DRUG INTERACTIONS

- Simultaneous administration of quinidine and digoxin increases the steady-state serum concentration of digoxin and may promote toxic concentrations because of the narrow therapeutic window.
- Furosemide is potassium wasting, which can potentiate the toxic effects of digoxin.

POSSIBLE COMPLICATIONS

- Furosemide (long-term administration): Hyponatremia, hypokalemia, hypomagnesemia, and metabolic alkalosis
- Positive inotropes: Dose-dependent tachycardia, ventricular arrhythmias, and vasoconstriction leading to hypertension and increases in ventricular afterload
- Digoxin: Depression, anorexia, colic, diarrhea, sinus bradycardia, atrioventricular block, as well as supraventricular and ventricular arrhythmias (eg, bigeminy)
- ACE inhibitors: Cough, impairment of renal function, hyperkalemia, and hypotension
- Vasodilators: Severe hypotension, reflex tachycardia, and weakness
- Antiarrhythmics: Proarrhythmic, cardiodepressant, and hypotensive effects

RECOMMENDED MONITORING

- Clinical monitoring: Periodic reevaluation of mentation and behavior, heart rate, respiratory rate and effort, mucous membranes, peripheral arterial pulses, jugular veins, lung sounds, ventral edema, and exercise capacity.
- Monitoring for signs of adverse drug effects.
- Furosemide, dobutamine, and digoxin should be titrated to effect; improved perfusion, decreased edema, reduced respiratory effort and respiratory rate, decreased heart rate and increased exercise capacity indicate clinical efficacy.
- Serum digoxin concentrations:
  - Periodic monitoring required because of the marked interindividual pharmacokinetic variation
  - Recommended digoxin peak (1–2 hours) and trough (12 hours) concentrations at steady state: 0.8 to 2.0 ng/mL (1.0–2.6 nmol/L)
- Electrocardiographic changes: monitored to detect potential proarrhythmic effects of dobutamine and digoxin
- Serum electrolyte concentrations and serum creatinine concentration:
  - Periodic monitoring is advisable during diuretic therapy to avoid electrolyte disturbances and prerenal azotemia.
  - Important because renal dysfunction may affect digoxin excretion and abnormalities in serum sodium, potassium, magnesium, and calcium concentrations may alter the sensitivity to digoxin.

ElibeVet.com

PROGNOSIS AND OUTCOME

- Usually, management of CHF is only effective in the short and medium term (2 to 6 months).
- The prognosis is usually guarded to poor when irreversible structural heart disease is the cause of CHF. Euthanasia is often elected because of the poor prognosis at the time of diagnosis.
- The prognosis may be fair for horses with potentially reversible diseases such as pericarditis, myocarditis, acute myocardial ischemia, or sustained ventricular tachycardia.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinical detection of CHF should prompt the veterinarian to perform a complete cardiovascular workup to identify the cause of heart failure.
- At the time of detection of CHF, the underlying cardiac disease is usually advanced and severe.
- Treatment options are limited in horses. The appropriate treatment may vary depending on the underlying cause.
- The prognosis is guarded to poor in most cases. Selected horses with a potentially reversible cause may have a fair prognosis.

CLIENT EDUCATION

- Congestive heart failure is a serious, life-threatening condition resulting from severe heart disease.
- Immediate treatment or euthanasia is required at the time of diagnosis.
- Treatment is usually only effective in the short and medium term (maximum, 2–6 months), and the prognosis is usually guarded to poor.
- Horses with CHF should not be worked or ridden. There may be a risk of syncope (collapse) or sudden death because of severe ventricular arrhythmia or pulmonary artery rupture.
- Breeding of animals with controlled CHF may be possible under close supervision through the veterinarian. However, pregnancy may trigger sudden deterioration of a compensated condition, and breeding could trigger pulmonary artery rupture in a stallion.

Cardiomyopathy

BASIC INFORMATION

DEFINITION

A myocardial disease process resulting in decreased myocardial function. In horses, this often results in dilation and decreased contractility, which can lead to congestive heart failure, arrhythmias, or both. Myocarditis is often a precursor to cardiomyopathy.

SYNONYM(S)

Dilated cardiomyopathy

EPIDEMIOLOGY

RISK FACTORS Any cause of myocarditis that does not completely resolve has the potential to progress to cardiomyopathy (see "Myocarditis" in this section).

GEOGRAPHY AND SEASONALITY Cardiomyopathy associated with selenium deficiency is most common in young horses (see "Myocarditis" in this section).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Acute, subacute, and chronic: These subtypes have not been well characterized in horses.

HISTORY, CHIEF COMPLAINT

- Exercise intolerance
- Signs of left-sided heart failure: Tachypnea, dyspnea, cough, nostril flare, weakness
- Signs of right-sided heart failure: Jugular pulses, jugular distension, edema, abdominal distension
- Syncope, sudden death

PHYSICAL EXAM FINDINGS

- Tachycardia, arrhythmias, gallop rhythm
- Cardiac murmurs
- Tachypnea, dyspnea, nostril flare, cough
- Exercise intolerance
- Weak pulses, jugular pulses, jugular distention, ventral (pectoral) edema
- Abdominal distension
- Syncope
- Nonspecific signs include weight loss (cardiac cachexia), depression, anorexia, weakness

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes of myocarditis that become chronic may progress to cardiomyopathy.
- Most often leads to decreased systolic function and chamber dilation, with subsequent arrhythmias.
- Arrhythmogenic right ventricular cardiomyopathy is also seen in horses, rarely.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- For exercise intolerance, lethargy, weakness, weight loss: Abnormalities in respiratory, neuromuscular, gastrointestinal systems
- For arrhythmias: Arrhythmias secondary to severe valvular or congenital heart disease with cardiac enlargement; systemic disease; electrolyte abnormalities
- For heart failure: Primary valvular, pericardial, or congenital heart disease
- For respiratory signs: Primary pulmonary or pleural disease

ElibEVet.com

INITIAL DATABASE

- The complete blood count may be normal or may show characteristics of concurrent disease.
- Chemistry panel: Changes consistent with passive congestion from right-sided heart failure (increased liver enzymes) or changes consistent with organ dysfunction caused by decreased cardiac output (azotemia). Elevations in creatine kinase in horses with selenium deficiency may be seen. Elevations in lactate associated with poor tissue perfusion may be seen.
- Thoracic radiography: Evidence of pulmonary edema (interstitial or alveolar pattern may be seen), cardiomegaly, pleural effusion.
- Electrocardiogram (ECG): Sinus tachycardia with any additional arrhythmias.
- Echocardiogram: Will show evidence of dilated cardiomyopathy, including dilated atria and ventricles possibly with thin walls, decreased systolic function (low fractional shortening), spontaneous contrast indicating a low flow state, and distended pulmonary artery suggesting pulmonary hypertension. The left ventricle will appear hypokinetic, with an increased septal–E point separation. Doppler evaluation may show valvular regurgitation. There may be evidence of infiltrative cardiomyopathy (thick walls, heteroechogenicity of myocardium) (Figure 1).
- Cardiac troponin I: Likely elevated in cases of cardiomyopathy associated with active myocardial necrosis.

ADVANCED OR CONFIRMATORY TESTING

- Evaluation of pasture for toxic plants and feed for ionophore antimicrobials
- Blood selenium concentrations
- Pursuit of heavy metal exposure
- Pursuit of potential infectious cause, as for myocarditis (see "Myocarditis" in this section)

TREATMENT

THERAPEUTIC GOAL(S)

- Resolve congestive heart failure (address fluid retention, provide inotropic support, and control arrhythmias)
- Improve quality of life
- Treat underlying disease

ACUTE GENERAL TREATMENT

- Arrhythmias: Treat life-threatening arrhythmias with antiarrhythmics drugs (AAD).
- Congestive heart failure: Furosemide (1–2 mg/kg IV q12h or as needed), positive inotropes (eg, dobutamine), and vasodilators (eg, hydralazine) (see "Cardiac Failure" in this section).
- Intranasal oxygen supplementation.
- Minimize stress.
- Suspect recent intoxication: remove all suspected contaminated feed, and remove the horse from the pasture. Administer activated charcoal or mineral oil via nasogastric intubation.
- Suspect monensin intoxication: administer high levels of vitamin E and selenium to stabilize cell membranes.
- Address mineral deficiencies, such as selenium and vitamin E supplementation.

CHRONIC TREATMENT

- Arrhythmias: AAD can be given orally if necessary to treat persistent ventricular arrhythmias. It is contraindicated to convert atrial fibrillation (AF) to sinus rhythm when it is associated with dilated cardiomyopathy and congestive heart failure, but rate control to slow the ventricular response, if excessive, is critical. Drugs such as quinidine are negative inotropes, hypotensive agents, and vagolytic (increase ventricular rate), all of which are detrimental in heart failure. AF alone is unlikely to result in the horse's death and will not cause significant progression of heart failure.
- Diuretics: Furosemide as needed to control edema. It is not well absorbed in horses orally, so it is best if given SC, IM, or IV (see "Cardiac Failure" in this section).
- Digoxin as a positive inotrope: The initial dose is 0.011 mg/kg PO q12h; this may need to be adjusted based on therapeutic drug monitoring of peak and trough serum concentrations (therapeutic range, 0.5–2.0 ng/mL) and clinical signs. Renal function and electrolytes should also be monitored closely. Decreased renal function will increase digoxin levels, potentially into the toxic range, and hypokalemia may precipitate digoxin toxicity. Horses receiving furosemide are more likely to become hypokalemic, particularly if anorectic, and may require potassium supplementation (see "Cardiac Failure" in this section).
- Angiotensin-converting enzyme (ACE) inhibitors such as enalapril (0.5–1.0 mg/kg q12h PO), although this is not well absorbed orally in horses and does not result in significant decrease in ACE activity (see "Cardiac Failure" in this section).
- Strict stall rest for as long as clinical signs remain (a minimum of 2 months).
- Supplement with selenium and vitamin E, if indicated.
- Treat the primary disease process.
- Provide supportive care to improve quality of life.

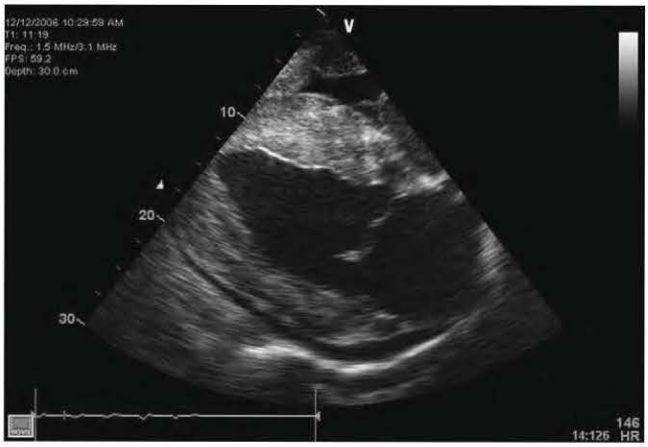

FIGURE 1 Right-sided parasternal longitudinal four-chamber echocardiographic view of a horse with cardiomyopathy secondary to monensin intoxication. Note the thick heteroechoic myocardial walls from active inflammation and the mild pericardial effusion. Systolic function was significantly decreased. This scan was acquired at 1.5 MHz and a depth of 30 cm.

DRUG INTERACTIONS

- Digoxin should not be used in cases of monensin intoxication because both increase intracellular calcium; this may enhance myocardial cell death, leading to arrhythmias.
- Furosemide treatment may lead to hypokalemia, which may lead to arrhythmias and potentiate digoxin toxicity. Serum potassium concentrations should be monitored and supplemented orally as needed.
- Corticosteroids should only be used after active infections have been ruled out.

POSSIBLE COMPLICATIONS

- Any AAD can be proarrhythmic and have other cardiovascular side effects such as hypotension.

ElibeVet.com

- Sudden death (fatal arrhythmia).
- Dilated cardiomyopathy will likely progress to congestive heart failure unless it is mild or discovered early.

RECOMMENDED MONITORING

- Initial monitoring:
  - Arrhythmias: Continuous ECG monitoring using radiotelemetry (particularly if arrhythmia is being treated).
  - Serum lactate concentrations may be used as an indicator of tissue perfusion.
  - Central venous pressure monitoring may be used to assess preload and cardiac function.
  - Cardiac catheterization will show severe increases in right ventricular and pulmonary artery systolic, mean, and diastolic pressures in cases nearing heart failure.
  - Cardiac output monitoring will show decreased cardiac output.
- Chronic monitoring:
  - Horse should have activity level, appetite, attitude, heart rate, respiratory rate and effort, and edema monitored by the owner after discharge. Any changes in these may indicate a progression of disease.
  - Repeat echocardiograms should be performed every 3 to 6 months after discharge or sooner if any of the above clinical signs are noted by the owner. These should continue until normal echocardiograms are seen.
  - 24-hour continuous ECG (Holter) monitoring should be performed intermittently after discharge or if the above clinical signs are noted.
  - If clinical and echocardiographic abnormalities resolve, the horse must have an exercising electrocardiogram performed before it is determined if the horse is safe to ride. Significant arrhythmias occurring during exercise may lead to syncope or collapse and injury or death to the rider or horse.
  - Cardiac troponin I may reflect changes in the degree of myocardial cell injury or necrosis and may be monitored intermittently.
  - Renal parameters and electrolyte status should be monitored at home, particularly if the horse is on chronic furosemide and digoxin therapy.
  - Therapeutic drug monitoring of digoxin levels should be done until the horse is stable. This should be repeated if any change in status such as anorexia, diarrhea, depression, or colic or changes in heart rate occur.

PROGNOSIS AND OUTCOME

- Prognosis is guarded to poor in most situations because it is often not recognized until disease is fairly advanced. Treatment is usually palliative and aimed at increasing the comfort level and lifespan of the horse.
- If the cause is recognized early and can be removed (eg, early removal of monensin, early recognition of selenium deficiency), the prognosis may be fair.

PEARLS & CONSIDERATIONS

COMMENTS

- In cases of monensin intoxication, the initial echocardiogram has prognostic value.
- Horses with normal left ventricular function have an excellent prognosis for life and performance.
- Horses with mild systolic dysfunction have a good prognosis for life and a fair prognosis for performance.
- Horses with significant systolic dysfunction have a poor prognosis for life and performance.

PREVENTION

- Monensin intoxication: use a reputable feed supplier, preferably one that does not mix equine feed in the same location as poultry or steer feed.
- Plant intoxications: know the content of pastures on which horses are kept.
- Selenium deficiency: know the status of soil and pastures.

CLIENT EDUCATION

- Horses with dilated cardiomyopathy leading to chamber enlargement and pulmonary hypertension are at risk for collapse or sudden death secondary to fatal arrhythmias or pulmonary artery rupture (rare).
- These horses should never be ridden because of this risk.

Cardiotoxic Plants

BASIC INFORMATION

DEFINITION

Cardiac disease subsequent to exposure to toxic plants

SYNONYM(S)

- Oleander poisoning (*Nerium oleander*)
- Summer pheasant's eye poisoning (*Adonis aestivalis*)
- Grayanotoxin intoxication (*Azalea* spp., *Rhododendron* spp; see "Rhododendron Toxicosis" in this section.)
- Yew poisoning (*Taxus* spp; see "*Taxus* Toxicosis" in this section.)
- Avocado poisoning (*Persea* spp.)
- Cardiac glycoside intoxication (*N. oleander, Digitalis* spp., *Asclepias* spp.)

EPIDEMIOLOGY

RISK FACTORS

- Fresh cardiotoxic plants have low palatability. Animals are more likely to ingest dried cardiotoxic plant material.
- Plant trimmings present the most common source for oleander and yew poisoning.
- Contamination of hay or hay cubes with cardiotoxic plants is a great risk.
- The Guatemalan race of avocados and the Fuerte hybrid are reportedly toxic. The Mexican race has low toxicity.

GEOGRAPHY AND SEASONALITY

- Oleander exposure is a year-round risk. Oleander poisoning is common

ElibeVet.com

FIGURE 1 Oleander leaf (*top*) and eucalyptus leaf (*bottom*).

FIGURE 2 Oleander leaf in stomach contents.

in horses, especially in California, Arizona, and Texas. Ingestion of dried oleander clippings often causes poisoning.
- Summer pheasant's eye has been limited to some northern California counties.
- Grayanotoxin-containing plants have the highest toxin concentrations in the leaves.
- Ingestion of yew clippings is the most common cause for poisonings with *Taxus* spp. All species of *Taxus*, including *T. baccata* (English yew), *T. cuspidata* (Japanese yew), and *T. brevifolia* (Pacific or Western yew), are considered toxic.
- Avocado is extensively cultivated in California and Florida but can also be found as an ornamental in the Gulf Coast areas. Avocado leaves are especially toxic.
- Some cardiotoxic plants are most abundant in the spring and summer, depending on the location

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Acute cardiotoxicity subsequent to exposure to cardiotoxic plants.
- Acute death from ingestion of oleander, yew, summer pheasant's eye, avocado, or azaleas. Animals are often found dead.
- Cardiac changes include bradyarrhythmias, tachyarrhythmias, atrioventricular (AV) blocks, ectopic beats, and gallop rhythms.

HISTORY, CHIEF COMPLAINT
- Clinical signs of colic are often seen within hours of exposure.
- Other clinical signs include weakness, tremors, excessive salivation, incoordination, dyspnea, and sometimes convulsions. Progression of signs may be rapid.
- Animals exposed to oleander may be anorectic for several days.

PHYSICAL EXAM FINDINGS
- Oleander: Irregular fast pulse with tachycardia, ventricular arrhythmias, or gallop rhythms; anorexia and colic; occasionally diarrhea
- Summer pheasant's eye: Gastrointestinal (GI) stasis, feed refusal, dyspnea, and cardiac arrhythmias
- Grayanotoxins: Depression, salivation, abdominal pain, possibly diarrhea; in severe cases: recumbency, seizures, tachycardia, tachypnea, and pyrexia
- Yew: Incoordination, nervousness, difficulty in breathing, bradycardia, diarrhea, and convulsions. Sudden death is often all that is seen.
- Avocado: Subcutaneous edema of the head and chest, submandibular edema, respiratory dyspnea, and cardiac arrhythmias

ETIOLOGY AND PATHOPHYSIOLOGY
- Oleander contains cardiotoxic glycosides, such as oleandrin. Cardiac glycosides inhibit Na^+/K^+ ATPase, which leads to increased intracellular Ca^{2+} concentrations and a subsequent positive inotropic effect. In addition, direct effects on the sympathetic nervous system are seen.
- Summer pheasant's eye contains cardiotoxic glycosides.
- Grayanotoxins, found in azaleas and rhododendrons, are diterpenes that bind to sodium channels in excitable cell membranes (skeletal and myocardial muscle, nerves, and central nervous system). Excitable cells are maintained in a state of depolarization. Additionally, increased intracellular sodium results in an exchange with extracellular calcium, which affects the control of transmitter release.
- Yews contain taxine alkaloids (such as taxine A and B) that are inotropic and change AV conduction. Yews also contain ephedrine, nitriles, and irritant oils that are likely to be responsible for colic and diarrhea.
- Avocado contains persin, but the exact mechanism of toxic action is not known.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Toxic plants that can cause sudden death, such as poison hemlock, water hemlock, tree tobacco, lupine
- Monensin and other ionophore antibiotics
- Cyanide poisoning
- Organophosphorus or carbamate intoxication
- Acute intestinal disease
- Myocarditis
- Endocarditis

INITIAL DATABASE
- Serum chemistry changes are often limited.
- In horses with oleander poisoning, azotemia may be present.
- Myocardial damage may lead to hyperkalemia and elevated lactate dehydrogenase, creatinine kinase, aspartate aminotransferase, and cardiac troponin I.

ADVANCED OR CONFIRMATORY TESTING
- Visual and microscopic examination of stomach or intestinal contents for plant fragments often aids in the diagnosis.
- Postmortem lesions, such as reddening of the mucosa of the GI tract and congestion of organs, are generally nonspecific.
  - Horses with oleander poisoning may have fluid in the pericardium and body cavities, endocardial hemorrhages, and multifocal myocardial degeneration and necrosis.
  - *Taxus* poisoning may result in mild to moderate endocardial hemorrhages.

ElibeVet.com

- Avocado-poisoned horses may have fluid accumulation in the pericardial sac and in the thoracic and abdominal cavities, edema of the gallbladder and perirenal tissues, and a flabby, pale heart.
- Confirmatory testing is often needed to reach an accurate diagnosis of cardiotoxic plant intoxication.
  - Oleander: Detection of oleandrin and other cardiac glycosides in serum, urine, stomach, cecal or colon contents, liver, and myocardium; detection of oleandrin in hay or other source material
  - Summer pheasant's eye: Detection of the aglycone strophanthidin in source material or stomach, cecal, or colon contents
  - Grayanotoxins: Grayanotoxin detection in source material or stomach, cecal, or colon contents
  - Yew: Taxine alkaloid detection in source material or stomach, cecal, or colon contents
  - Avocado: Confirmatory testing not available

TREATMENT

THERAPEUTIC GOAL(S)

- There is no specific antidote for plant cardiotoxins. The recommended treatment of exposed animals is symptomatic and supportive and should include administration of IV fluids and antiarrhythmics.
- Adsorption of toxins with activated charcoal is recommended; multidose activated charcoal is beneficial in oleander intoxications.
- Atropine may be given in cases of severe bradycardia.

ACUTE GENERAL TREATMENT

- Oleander: Activated charcoal is the adsorbent of choice in horses with oleander toxicosis.
- Cardiac effects are best treated after careful cardiac evaluation. Atropine and propranolol have been used successfully.
- Digoxin-specific Fab antibody fragments have been effective in cross-reacting with cardiac glycosides in oleander, but Fab antibodies have not been studied in horses and dosages are empirical.
- Avocado: If edema is present in avocado poisoning, administration of diuretics is recommended.

POSSIBLE COMPLICATIONS

- In many cases, the rapid onset of acute intoxication does not allow timely therapeutic intervention, so mortality rates are high.
- Potassium should not be administered in fluids if hyperkalemia is present.

RECOMMENDED MONITORING

Close monitoring of serum electrolytes and electrocardiogram

PROGNOSIS AND OUTCOME

- Horses are often found dead after exposure to cardiotoxic plants.
- Progression of animals with cardiotoxic plant poisoning is rapid, and treatment is often too late.
- In horses with oleander and yew intoxications, the prognosis is poor.
- If treatment is initiated promptly after the onset of clinical signs, the prognosis is fair.
- Animals that survive the acute poisoning may have myocardial damage and may be more prone to stress.

PEARLS & CONSIDERATIONS

COMMENTS

- Cardiotoxic plants can be deadly if they are grazed upon or unintentionally incorporated into hay or baleage. The ability to recognize the presence of poisonous plants in hay or forage may help prevent additional animal poisonings.
- Oleander is cultivated widely in the southern United States and is most commonly associated with plant poisonings in horses.
- The treatment of most cardiotoxic plants intoxications is nonspecific. Awareness of poisonous plants growing in a certain geographic region and their associated clinical signs are instrumental in making a diagnosis and initiating treatment.
- Proper and rapid diagnostic workup of suspect cardiotoxic plant poisonings is necessary to prevent additional exposures.

PREVENTION

- Recognize cardiotoxic plants of concern in the geographic location and prevent access by horses.
- Provide adequate forage to limit ingestion of toxic plants.

CLIENT EDUCATION

- If poisonous weed contamination is suspected, hay should be tested before feeding.
- Oleander poisoning in horses is common and often lethal. Oleander plants should be removed from the environment of horses.

Cataracts

BASIC INFORMATION

DEFINITION

Cataracts are opacities of the eye's crystalline lens or lens capsule.

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Horses prone to developing recurrent uveitis are at risk for developing cataracts.

RISK FACTORS

- Any type of ocular trauma
- Chronic or recurrent uveitis

ASSOCIATED CONDITIONS AND DISORDERS

- Chronic or recurrent uveitis
- Ocular trauma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Diseases of the equine lens may be congenital

ElibeVet.com

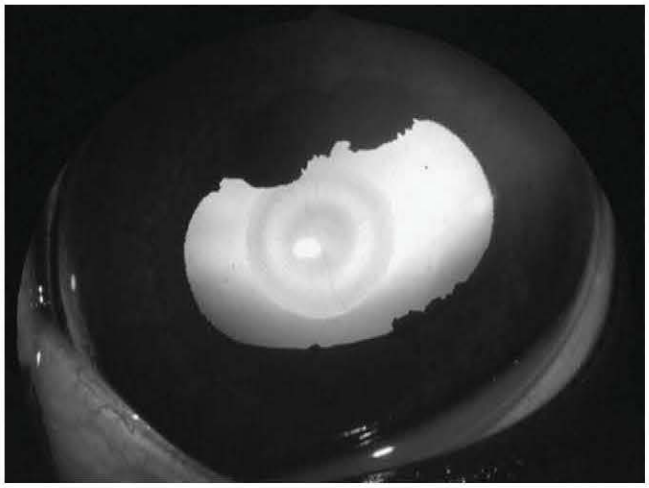

FIGURE 1 Equine congenital nuclear cataract.

FIGURE 2 Diffuse mature cataract in an adult horse.

or acquired and generally involve malformation, malposition, or lens opacity (cataract). The most common and significant lens disorder is cataract formation.

HISTORY, CHIEF COMPLAINT Cataracts are the most common congenital ocular anomaly in horses, and development of cataracts in adult horses is a common cause of vision loss, with or without associated uveitis.

PHYSICAL EXAM FINDINGS

- Cataracts are classified according to age at onset (congenital, juvenile, senile), cause (e.g., hereditary; secondary to uveitis, trauma, metabolic disease), or location within the lens (anterior polar, anterior subcapsular, anterior cortical, equatorial, peripheral cortical, nuclear, posterior cortical, posterior subcapsular, and posterior polar).
- Congenital cataracts may be unilateral or bilateral, and they may be focal or diffuse (Figures 1 and 2). Focal opacities involving the anterior or posterior suture lines are often nonprogressive, but progression does occur in some cases. A nuclear cataract may appear as a ringlike opacity, a hollow sphere, or a solid opacity in the center (nucleus) of the affected lens. These cataracts rarely progress and often decrease in size relative to total lens size as new layers of normal cortical fiber are produced throughout life. The location, density, and size of a focal cataract determine its effect on vision.

ETIOLOGY AND PATHOPHYSIOLOGY Aqueous humor, which acts to supply metabolic needs of intraocular structures, is produced constantly by the ciliary body of the equine eye. In uveitis, the aqueous humor is altered, which affects the lens metabolism. Abnormal lens metabolism results in cataract formation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic uveitis
- Lens rupture caused by penetrating ocular trauma
- Nuclear sclerosis
- Lens luxation

INITIAL DATABASE

A thorough and complete ophthalmic examination with mydriasis should be done to help differentiate the cause of the cataracts and to rule out other causes of ocular opacity such as keratitis.

ADVANCED OR CONFIRMATORY TESTING

If cataract surgery is being considered, an ocular ultrasound and electroretinogram should be considered to determine if the remainder of the eye is healthy.

TREATMENT

THERAPEUTIC GOAL(S)

- Prevent progression of cataracts
- Improve visual function

ACUTE GENERAL TREATMENT

- Control ocular inflammation with use of topical and systemic antiinflammatory medications.
- Cataract dissolving medications have not been demonstrated to be effective in any animal, including horses.

CHRONIC TREATMENT

Equine cataract surgery: Phacoemulsification and aspiration of cataracts in horses through a small corneal incision with intraocular lens implantation are becoming routine procedures.

POSSIBLE COMPLICATIONS

Vision loss is common because the disease is progressive. Both eyes are at risk and should be monitored.

RECOMMENDED MONITORING

Examine monthly to determine lens progression.

PROGNOSIS AND OUTCOME

- Prognosis is guarded for saving vision.
- Cataract surgery has a success rate of more than 80%.

PEARLS & CONSIDERATIONS

COMMENTS

- Both eyes are at risk and should be monitored.
- Photographing the eye with the pupil dilated will help monitor cataract progression.

PREVENTION

- Minimizing ocular and corneal trauma may help prevent the development of ocular inflammation.
- Use of a quality fly mask is recommended.
- Feeding hay on the ground is recommended to minimize ocular trauma.

Cecal Impaction

BASIC INFORMATION

DEFINITION

Distension of the cecum with feed material or fluid (or both) associated with mechanical or functional obstruction to flow of ingesta

EPIDEMIOLOGY

SPECIES, AGE, SEX It appears that older horses (>15 years in one study) are predisposed to cecal impaction. Cecal impaction in hospitalized patients may not have the same age predisposition.

GENETICS AND BREED PREDISPOSITION One report indicated predisposition in Arabians, Appaloosas, and Morgans. Other studies have not reported any breed predisposition.

RISK FACTORS Proposed risk factors have included:

- Dietary factors: Poor-quality or coarse roughage, Bermuda grass hay
- Poor dentition
- Decreased water consumption
- Parasitism: Parasite-induced thromboembolism, tapeworm (*Anoplocephala perfoliata*) infestation
- Change in exercise: Lack of exercise with use of nonsteroidal antiinflammatory drugs (NSAIDs)
- Hospitalization with or without surgery and anesthesia, frequently for nongastrointestinal (GI) disease (especially musculoskeletal problems)

GEOGRAPHY AND SEASONALITY There has been some suggestion that horses in regions with Bermuda grass hay are predisposed. No seasonality has been established.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Cecal impactions are frequently divided into two types: impaction with firm ingesta causing a mechanical obstruction and distension with fluid ingesta without any apparent mechanical obstruction. Motility dysfunction has been proposed in horses with distension with fluid ingesta.

HISTORY, CHIEF COMPLAINT

- Horses with cecal impactions often show signs of mild colic (lying down, flank watching) for several days to weeks. Horses with fluid cecal impaction or dysfunction may have acute and increased signs of pain.
- Decreased appetite is one of the first clinical signs in many horses with cecal impactions. Horses frequently have decreased fecal output or changes in fecal consistency (soft or firm small fecal balls). Historical findings may indicate any of the risk factors identified in the epidemiology section.
- It is important to note that cecal perforation may occur in horses with cecal impaction with little to no signs of colic (see "Cecal Perforation" in this section).

PHYSICAL EXAM FINDINGS

- Physical examination in horses with cecal impaction often reveals vital signs within normal limits with the exception of tachycardia during episodes of colic. Horses with fluid cecal impaction or dysfunction may have more pronounced tachycardia.
- Affected horses frequently have decreased borborygmi. Horses with fluid cecal impaction or dysfunction may show signs of endotoxemia.
- If perforation occurs, clinical signs will worsen rapidly (see "Cecal Perforation" in this section).

ETIOLOGY AND PATHOPHYSIOLOGY

- Impaction with dry, firm feed material may have a similar pathogenesis to large colon impactions (see "Large Colon Impaction" in this section). Risk factors described above may affect motility, particle size of feed material, and water content of ingesta, resulting in accumulation of dry, firm feed material in the cecum.
- Motility dysfunction has been proposed in horses with distension with fluid ingesta. Anesthesia, NSAID administration, diet changes, and parasites (especially tapeworms) have been proposed to alter GI motility. Administration of NSAIDs may mask the mild clinical signs associated with cecal impactions and contribute to ulceration and predispose to cecal perforation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild abdominal pain are simple or nonstrangulating obstructions of the GI tract such as feed or sand impaction of the large colon, enterolithiasis, large colon displacements, large intestinal intraluminal obstructions, tympany, small colon impactions, and ileal impactions.
- Other causes of a firm, digesta-filled viscus in the right dorsal abdomen include feed or sand impaction of the large colon, right dorsal colon impaction with a right dorsal displacement, nonstrangulating infarction of the cecum, and cecocecal or cecocolic intussusception.

INITIAL DATABASE

- Examination per rectum is the most useful diagnostic test for cecal impactions. Early in the course of the disease or if impaction is restricted to the cupula, the most significant finding on examination per rectum will be a tight, sometimes thickened ventral band of the cecum (coursing from the right caudodorsal abdomen craniоventrally). As impaction of the body and base of the cecum progresses, the round cecal base is palpable in the right caudodorsal abdomen. Differentiation of the cecum from the colon can be difficult. If the distended structure is the cecum, the examiner should not be able to pass his or her hand over the impaction dorsally because the cecum is attached to the dorsal body wall. As the disease progresses, the colon empties, and the cecum becomes heavier. This may result in inability to diagnose the cecal impaction during examination per rectum. Careful evaluation of the thickness of the cecal wall and the texture of the contents may help differentiate between the two types of impaction (firm ingesta causing mechanical obstruction versus fluid ingesta associated with dysfunction).
- Nasogastric reflux is uncommon.
- Bloodwork is generally normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
- Abdominal fluid analysis is generally within normal limits. Horses with fluid cecal impaction or dysfunction may have elevation in total protein. It is important to remember that intestinal compromise may occur with little to no change in peritoneal fluid with cecal disease.

TREATMENT

THERAPEUTIC GOAL(S)

Passage or removal of impacted ingesta

ACUTE GENERAL TREATMENT

- Treatment of cecal impactions remains controversial. The controversy is associated with the risk of rupture without warning of worsening clinical signs and the difficulty in appropriately identifying which type of impaction is

ElibEVet.com

present to better judge the likelihood of resolution with medical treatment and the risk of recurrence. Horses with fluid cecal impaction or dysfunction are believed to be less likely to respond to medical management and are at risk for continued dysfunction after resolution, resulting in some surgeons electing to perform bypass procedures during surgery.

- Medical management of cecal impactions is similar to medical treatment of large colon impactions. Horses should be held off feed. IV and oral fluid administration is combined with laxatives or cathartics such as mineral oil; $MgSO_4$, dioctyl sodium sulfosuccinate, and psyllium have been recommended. Judicious administration of analgesics (flunixin meglumine most commonly) may be helpful. Careful monitoring with repeated physical and rectal examinations is important to ensure that analgesics are not masking progression of the disease and the need for surgery. The administration of prokinetics has been suggested by some clinicians, but the safety and efficacy are unknown.
- Surgical treatment is recommended in cases with marked signs of colic at presentation, very firm ingesta or fluid ingesta, signs of systemic compromise, increasing signs of colic during treatment, or lack of improvement or progression of impaction during medical treatment. Typhlotomy with evacuation of the contents is the mainstay of surgical treatment. A surgeon may elect to perform a bypass procedure (complete or incomplete jejunocolic or ileocolic anastomosis) in cases of recurrent cecal impaction or fluid cecal impaction or dysfunction.
- Refeeding after resolution of cecal impaction should be done slowly and monitored closely with repeat examination per rectum to identify any recurrence of impaction.

POSSIBLE COMPLICATIONS

The two most important complications associated with cecal impaction are cecal perforation (see "Cecal Perforation" in this section) and recurrence of impaction. Cecal perforation has been reported in 25% to 57% of cases with cecal impaction. Reported recurrence rates range from 13% to 29%.

FIGURE 1 Cecal impaction as identified at exploratory laparotomy; distension by fluid and gas secondary to cecal dysfunction.

PROGNOSIS AND OUTCOME

Reported success rates for cecal impactions are quite variable. Most recent reports indicate that both medical and surgical treatment may result in successful outcomes with up to 90% survival. However, when discussing prognosis with owners, it is important to address the significant risks of perforation and recurrence.

PEARLS & CONSIDERATIONS

COMMENTS

- Cecal impaction should be considered as a differential diagnosis in horses with mild signs of colic, decreased appetite, and changes in fecal production.
- Horses hospitalized for non-GI diseases may be predisposed to cecal impaction.
- Early identification and close monitoring are required for successful treatment of cecal impaction.

PREVENTION

Hospitalized horses should be monitored closely for any change in attitude, appetite, or fecal production. Handwalking may stimulate GI motility in horses on stall rest.

Cecal Intussusception

BASIC INFORMATION

DEFINITION

Invagination of the apex of the cecum into the body of the cecum (cecocecal intussusception) or through the cecocolic orifice into the right ventral colon (cecocolic intussusception)

EPIDEMIOLOGY

SPECIES, AGE, SEX Increased incidence has been reported in young (<3 years old) horses, although it can occur in all ages.

ElibEVet.com

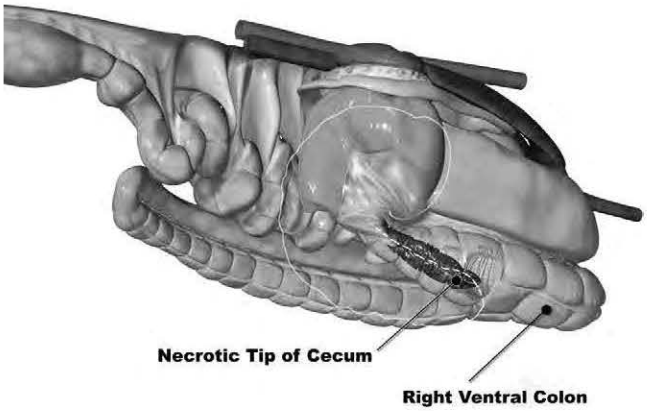

FIGURE 1 Diagram demonstrating cecocolic intussusception. (Courtesy The Glass Horse Equine Colic CD.)

FIGURE 2 Transcutaneous ultrasonogram (4 MHz) of the right ventral abdomen showing the typical bull's eye appearance of a cecal intussusception.

FIGURE 3 Cecocecal intussusception at exploratory laparotomy.

FIGURE 4 Cecocolic intussusception at exploratory laparotomy. The mucosal surface of the necrotic tip of the intussuscepted cecal apex is visible through a colotomy of the right ventral colon. Several tapeworms are present on the mucosa.

GENETICS AND BREED PREDISPOSITION Increased incidence has been reported in Standardbreds.

RISK FACTORS A number of risk factors have been proposed. Proposed infectious risk factors include abscessation of the cecal wall and infection with *Salmonella* spp., *Emeria leuckarti*, *Strongylus vulgaris*, cyathostomins, or *Anoplocephala perfoliata*. Other possible risk factors include dietary changes and use of organophosphates or parasympathomimetic drugs.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cecal intussusceptions can be separated into cecocecal and cecocolic intussusception.
- There appear to be three forms of cecal intussusception: acute (requiring immediate surgical intervention), subacute (clinical signs persisting 3–8 days), and chronic (clinical signs persisting 6–120 days). Acute is the most common form followed by subacute and then chronic. Whereas cecocolic intussusception is more likely to result in ischemia of the apex of the cecum and an acute presentation, cecocecal intussusception is more likely to result in partial obstruction without ischemia and result in a more chronic presentation.

HISTORY, CHIEF COMPLAINT Clinical signs are variable depending on the degree of obstruction and intestinal compromise. Horses with the acute form have rapid onset of moderate to severe abdominal pain. Horses with the subacute form have intermittent mild to moderate signs of colic and soft feces or diarrhea. Horses with the chronic form have a history of intermittent mild abdominal pain, scant feces, and weight loss.

PHYSICAL EXAM FINDINGS Physical examination findings also depend on the degree of obstruction and intestinal viability. As ischemia and obstruction worsens, signs of progressive tachycardia and cardiovascular compromise (eg, prolonged capillary refill time, decreased jugular refill, cold extremities) occur. Fever is common in horses with the chronic form of cecal intussusception.

ETIOLOGY AND PATHOPHYSIOLOGY The most likely cause of cecal intussusception is abnormal motility associated with the proposed risk factors discussed in the etiology section.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of abdominal pain include feed or sand impaction of

ElibVet.com

the large colon, enterolithiasis, large colon displacements, large intestinal intraluminal obstructions, tympany, small colon impactions, and ileal impactions.
- Other causes of a firm viscus in the right dorsal abdomen include feed or sand impaction of the large colon, right dorsal colon impaction with a right dorsal displacement, nonstrangulating infarction of the cecum, and cecal impaction.
- Other causes of change in fecal production and character include infectious and sand colitis and cecal impactions.
- Other causes of abdominal pain associated with fever include infectious and sand colitis and small colon impactions.

INITIAL DATABASE

- Examination per rectum may be within normal limits or reveal an abnormality in palpation of the cecum. The abnormal findings vary and include a firm, edematous viscus in the right dorsal abdomen, malpositioning of the cecum, and inability to palpate the cecum.
- Nasogastric reflux is uncommon because the small intestine is generally not obstructed.
- Bloodwork varies with the degree of intestinal compromise. Progressive dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein) and metabolic acidosis may occur with worsening ischemia.
- Because the damaged intestine is sequestered from the abdomen, abdominocentesis is insensitive for cecal intussusception and may be normal even with ischemic bowel. Elevations in nucleated cell count, total protein, and color (serosanguinous) may occur over time with increased severity.
- Abdominal ultrasonography of the cecum and right dorsal colon may reveal a bull's-eye pattern of bowel within bowel typical of an intussusception.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduction of the intussusception with resection of ischemic bowel as necessary
- Supportive care

ACUTE GENERAL TREATMENT

Exploratory celiotomy is required to treat cecal intussusception. Cecocecal intussusceptions are easier to reduce than cecocolic intussusceptions. Reduction of cecocolic intussusceptions may require an enterotomy into the right dorsal colon with or without resection of damaged cecum within the colon before reduction.

CHRONIC TREATMENT

If *A. perfoliata* or *A. cyathostomin* larvae are identified at the time of surgery, appropriate deworming is recommended.

PROGNOSIS AND OUTCOME

The prognosis appears good if resection of the damaged portion of the cecum is possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Cecal intussusception is an uncommon cause of abdominal pain in horses.
- Acute, subacute, and chronic forms of the disease occur. Clinical signs and diagnostic findings are variable depending on the form of the disease and the severity of obstruction and intestinal compromise.
- Prognosis is good with surgical treatment.

Cecal Perforation

BASIC INFORMATION

DEFINITION

Loss of integrity of the cecal wall associated with leakage of intestinal contents into the abdomen

SYNONYM(S)

Cecal rupture

EPIDEMIOLOGY

SPECIES, AGE, SEX

- In one form of cecal perforation, the disease occurs solely in broodmares at the time of parturition.
- In other forms of cecal perforation, there is no known age or sex predisposition.

RISK FACTORS In broodmares with cecal perforation at the time of parturition, dystocia appears to be a risk factor. In other forms of cecal perforation, risk factors including hospitalization, nonsteroidal antiinflammatory drug (NSAID) administration, and anesthesia have been identified.

ASSOCIATED CONDITIONS AND DISORDERS Cecal perforation has been reported in association with infestation with *Anoplocephala perfoliata.*

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Cecal perforation occurs in several forms:

- Cecal perforation has been identified in broodmares at the time of parturition with no evidence of cecal outflow obstruction or dysfunction.
- Cecal perforation occurs in 25% to 57% of horses with cecal impaction.
- Cecal perforation has been reported in horses hospitalized for nongastrointestinal (GI) disease without evidence of cecal impaction with feed. However, it is important to note that horses with fluid cecal impactions or dysfunction may not show signs of colic before perforation and would not have evidence of impaction with feed at the time of necropsy.
- Cecal perforation has been reported with infestation with *A. perfoliata.*

HISTORY, CHIEF COMPLAINT Broodmares with cecal perforation may show signs of abdominal pain shortly after parturition. In general, horses with cecal perforation show signs referable to endotoxemia. Owners may note pain, muscle fasciculations, and sweating. Sudden collapse and death are also possible.

ElibeVet.com

FIGURE 1 Cecal perforation identified at exploratory laparotomy.

PHYSICAL EXAM FINDINGS Horses with cecal perforation are in endotoxemic shock. Typical findings on physical examination include tachycardia, tachypnea, toxic mucous membranes, prolonged capillary refill time, cold extremities, and poor pulse quality.

ETIOLOGY AND PATHOPHYSIOLOGY

- The proposed pathophysiology for broodmares with periparturient cecal perforation is cecal distension caused by altered motility that ruptures because of increased abdominal pressure during parturition.
- The pathophysiology of cecal perforation in hospitalized horses administered NSAIDs may be related to ulceration or masking clinical signs of fluid cecal impaction or dysfunction.
- The pathophysiology of cecal perforation associated with *A. perfoliata* is unknown.
- The pathophysiology of cecal perforation secondary to cecal impaction is discussed in "Cecal Impaction" in this section.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of endotoxemia include colitis, typhlitis, enteritis, large colon volvulus, and nonstrangulating infarction of the large colon or cecum.
- Other causes of septic peritonitis include gastric rupture and idiopathic peritonitis.

INITIAL DATABASE

- Examination per rectum is consistent with pneumoperitoneum. In cases of pneumoperitoneum, the rectum will tightly surround the arm during palpation, and as the person performing palpation moves his or her arm, there is a floating sensation. Additional findings on examination per rectum may include roughening of the surface of the intestines caused by ingesta and fibrin formation and crepitus over the cecum associated with perforation.
- Nasogastric reflux may occur because of ileus secondary to endotoxemia and peritonitis.
- Bloodwork is consistent with endotoxemic shock, including hemoconcentration, leukopenia caused by a neutropenia with a left shift, azotemia, and hyperlactatemia.
- Abdominal fluid reveals a mixed population of intracellular bacteria and plant material. Intracellular bacteria ensure that the fluid is not the result of enterocentesis. Ultrasound guidance during collection of abdominal fluid may help prevent enterocentesis.
- Abdominal ultrasonography reveals increased abdominal fluid. The fluid has a mixed echogenicity and may have hyperechoic, shadowing gas bubbles.

TREATMENT

THERAPEUTIC GOAL(S)

Relieve suffering

ACUTE GENERAL TREATMENT

There is no viable treatment for gross fecal contamination of the abdomen secondary to cecal perforation. Horses should be humanely euthanized.

PROGNOSIS AND OUTCOME

For humane reasons, horses should be euthanized.

PEARLS & CONSIDERATIONS

COMMENTS

- Cecal perforation should be considered as a differential diagnosis in horses with signs of severe endotoxemic shock and septic peritonitis.
- Broodmares at the time of parturition and hospitalized horses may be at increased risk.

PREVENTION

- Hospitalized horses should be monitored closely for any change in attitude, appetite, and fecal production. Handwalking may stimulate GI motility in horses on stall rest.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

ElibeVet.com

Cecal Tympany

BASIC INFORMATION

DEFINITION
Accumulation of gas in the cecum

SYNONYM(S)
Cecal dilation

CLINICAL PRESENTATION
DISEASE FORMS/SUBTYPES Cecal tympany can be separated into primary and secondary subtypes. Cecal tympany occurs most commonly secondary to obstructions of the large colon such as feed or sand impactions, large colon displacements, large colon tympany, and large colon intraluminal obstructions. The history, clinical signs, diagnostic findings, treatment, and prognosis for cecal tympany secondary to nonstrangulating obstructions of the large colon are related to the primary disease (see entries on respective conditions). This entry focuses on the less common primary cecal tympany.

HISTORY, CHIEF COMPLAINT Abdominal pain and distension (primarily right sided)

PHYSICAL EXAM FINDINGS
- Cardiovascular parameters are generally stable. Elevations of heart rate may be associated with pain, abdominal distension, decreased or absent borborygmi, and signs of mild dehydration.
- Uncommonly, severe distension may result in compromise to the cardiovascular and respiratory systems.

ETIOLOGY AND PATHOPHYSIOLOGY Overproduction of gas because of diet changes, changes in bacterial flora, or alterations in motility resulting in decreased passage of gas through the cecum may result in increased gas accumulation in the cecum.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Other causes of mild to moderate abdominal pain are simple or nonstrangulating obstructions of the gastrointestinal tract such as feed or sand impaction of the large colon, enterolithiasis, large colon displacements, large intestinal intraluminal obstructions, cecal impaction, small colon impactions, and ileal impactions.
- Other causes of cecal distension on examination per rectum include typhlitis; nonstrangulating infarction of the cecum; and nonstrangulating obstructions of the large colon, such as feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large colon volvulus, and other intraluminal obstructions resulting in secondary distension of the cecum.

INITIAL DATABASE
- Examination per rectum reveals a variable degree, possibly severe, of gas distension of the cecum.
- Nasogastric reflux is uncommon.
- Bloodwork may be normal or consistent with mild dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
- Abdominal fluid analysis is within normal limits.

TREATMENT

THERAPEUTIC GOAL(S)
- Pain management
- Supportive care

ACUTE GENERAL TREATMENT
- Withhold feed.
- Most horses with cecal tympany have a good response to analgesics (flunixin meglumine, α_2 agonists, butorphanol). Analgesics minimize sympathetic inhibition of motility.
- Some horses may benefit from IV fluids to support cardiovascular status and treat any dehydration.
- Trocarization of the cecum (right flank) can relieve pain from cecal tympany. Because of the potential for complications (peritonitis, abscess formation), clinicians should choose the patient carefully. Before performing trocarization, the clinician should take into account the cardiovascular status of the horse and the potential for referral and surgery.

RECOMMENDED MONITORING
- During treatment, horses should be monitored for signs of unrelenting pain, nasogastric reflux, progressive abdominal distension, and systemic deterioration (increasing heart rate, cardiovascular compromise).
- Progression of signs may indicate an inability to resolve the gas distension medically or that the cecal tympany is secondary to a primary large intestinal disease. Surgical exploration may be required.

PROGNOSIS AND OUTCOME

Prognosis is excellent.

PEARLS & CONSIDERATIONS

- Primary cecal tympany is an uncommon cause of colic.
- Cecal tympany occurs more frequently secondary to disease of the large colon.

FIGURE 1 Cecal tympany (secondary to colon displacement) identified at exploratory laparotomy.

Cecal Volvulus

BASIC INFORMATION

DEFINITION

Rotation of the cecum around the mesenteric axis (which is also the long axis of the cecum)

SYNONYM(S)

Cecal torsion

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS Cecal volvulus has been associated with congenital abnormalities of the cecocolic fold and dorsal body wall attachments of the cecum.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Cecal volvulus can be separated into primary and secondary subtypes. Cecal volvulus occurs most commonly secondary to large colon volvulus. The history, clinical signs, diagnostic findings, treatment, and prognosis for cecal volvulus secondary to large colon volvulus are consistent with a large colon volvulus (see "Large Colon Volvulus"). This entry focuses on the less common primary cecal volvulus.

HISTORY, CHIEF COMPLAINT Horses with cecal volvulus present with acute, severe signs of colic.

PHYSICAL EXAM FINDINGS Physical examination findings depend on the duration and degree of cecal compromise and distension. Early in the disease, physical examination may reveal tachycardia and decreased or absent borborygmi. As ischemia and distension progress, cardiovascular compromise and endotoxemia will occur. Signs of endotoxemia or hypovolemia on physical examination may include hyperemic or toxic mucous membranes, prolonged or increased capillary refill time, poor pulse quality, cold extremities, and decreased jugular refill.

ETIOLOGY AND PATHOPHYSIOLOGY

- As noted above, cecal volvulus may be associated with abnormalities of the cecocolic ligament or dorsal body wall attachments of the cecum. These abnormalities allow an increased range of motion of the cecum, resulting in a greater potential for rotation.
- In cases in which no congenital abnormality is identified, the etiology of cecal volvulus is unknown. As with large colon volvulus, it is possible that changes in motility or distension are the cause of the volvulus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of severe colic include large colon volvulus; severe colitis; and strangulating lesions of the small intestine such as small intestinal volvulus, epiploic foramen entrapment, and strangulating lipoma.
- Other causes of cecal distension on examination per rectum include cecal tympany, typhlitis; nonstrangulating infarction of the cecum; and nonstrangulating obstructions of the large colon resulting in secondary distension of the cecum such as feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large colon volvulus, and other intraluminal obstructions.
- Other causes of endotoxemia include colitis, typhlitis, enteritis, and nonstrangulating infarction of the large colon or cecum.

INITIAL DATABASE

- Findings on examination per rectum are nonspecific. A variable degree of cecal distension may be palpable.
- Nasogastric reflux is unlikely.
- Bloodwork will vary depending on the degree of cardiovascular compromise and endotoxemia. Progressive increase in packed cell volume, decrease in total protein, and leukopenia caused by neutropenia with a left shift indicate increased severity of systemic compromise. Hyperlactatemia is associated with poor perfusion and ischemia of the strangulated region.
- Increases in abdominal fluid total protein or nucleated cell count are possible.
- Thickening of the wall of the cecum may be evident on ultrasonography of the right paralumbar fossa. However, the severity of pain may make ultrasound evaluation difficult, and it is unnecessary to make the decision that surgery is required.
- Surgical exploration is often required for diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Correction of volvulus and resection of compromised cecum as necessary
- Supportive care

ACUTE GENERAL TREATMENT

- If cardiovascular compromise is present, rapid fluid resuscitation should be performed before anesthesia.
- At surgery, the volvulus is corrected, and the viability of the cecum is assessed. All nonviable tissue should be resected. Complete typhlectomy is possible but requires a rib resection.

POSSIBLE COMPLICATIONS

If cecal volvulus is associated with a congenital abnormality of the cecocolic ligament or the dorsal body wall attachments of the cecum, recurrence is possible.

PROGNOSIS AND OUTCOME

- Prognosis is likely related to the severity of compromise and the amount of cecum involved.
- One report indicated a 60% survival after partial typhlectomy.

PEARLS & CONSIDERATIONS

- Primary cecal volvulus is an uncommon cause of abdominal pain in horses.
- Affected horses show signs of acute, severe pain with progressive cardiovascular collapse and endotoxemia.

Cecum: Nonstrangulating Infarction

BASIC INFORMATION

DEFINITION

Loss of blood supply to the cecum not associated with strangulation

EPIDEMIOLOGY

RISK FACTORS High parasite load and inappropriate deworming programs may predispose to infestation with *Strongylus vulgaris* or larval cyathostomins.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Affected horses may have mild signs of colic that progress over approximately 24 hours (most commonly reported) or acute, severe abdominal pain. Horses may also have a history of diarrhea.

PHYSICAL EXAM FINDINGS Physical examination findings vary depending on the amount of cecum affected and the severity of vascular compromise. Variable tachycardia, tachypnea, and fever are associated with pain and endotoxemia. Cardiovascular collapse and endotoxemic shock may occur with hyperemic or toxic mucous membranes, prolonged or decreased capillary refill time, poor pulse quality, cold extremities, and decreased jugular refill.

ETIOLOGY AND PATHOPHYSIOLOGY

- One proposed cause is verminous arteritis associated with *S. vulgaris* infestation (see "Large Colon: Nonstrangulating Infarction" in this section).
- Multifocal infarction secondary to infestation with larval cyathostomins has also been proposed as a cause.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of colic include feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large intestinal intraluminal obstructions, small colon impactions, ileal impactions, strangulating small intestinal obstructions, large colon volvulus, and colitis.
- Other causes of a firm viscus in the right dorsal abdomen include feed or sand impaction of the large colon, right dorsal colon impaction with a right dorsal displacement, cecal intussusception, and cecal impaction.
- Other causes of endotoxemia include colitis and large colon volvulus.
- Other causes of peritonitis include idiopathic gastrointestinal (GI) rupture and other strangulating GI lesions such as small intestinal or large colon volvulus.
- Other causes of change in fecal production and character include infectious and sand colitis and cecal impactions.

INITIAL DATABASE

- Examination per rectum may be within normal limits or may reveal a firm viscus in the right dorsal abdomen.
- Nasogastric reflux is not expected.
- Findings on routine blood work are variable. Chronic parasitism may be associated with anemia, hypoalbuminemia (if associated with protein-losing enteropathy), or hyperglobulinemia (if associated with chronic inflammation). Endotoxemia is frequently accompanied by leukopenia, specifically neutropenia with left shift.
- Abdominal fluid is frequently consistent with peritonitis with changes in color (serosanguinous), increased total nucleated cell count, and increased total protein.
- If the ischemic region is edematous, abdominal ultrasonography may reveal a thickened, hypoechoic bowel wall.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove ischemic bowel.
- Provide supportive care.

ACUTE GENERAL TREATMENT

Depending on the amount of the cecum that is affected, surgical resection may be curative. Although total typhlectomy has been described, it does not appear necessary in most cases.

CHRONIC TREATMENT

Affected horses should be placed on a good deworming program.

POSSIBLE COMPLICATIONS

If the condition is progressive, additional portions of the cecum may become necrotic after surgical resection is performed.

PROGNOSIS AND OUTCOME

- Prognosis appears good with partial typhlectomy in the limited number of cases reported in the literature.
- It is likely that prognosis would decrease when total typhlectomy is required.

PEARLS & CONSIDERATIONS

COMMENTS

- Nonstrangulating infarction of the cecum is an uncommon cause of colic in horses.
- Nonstrangulating infarction may be associated with verminous arteritis or multifocal infarction caused by larval cyathostomins.

PREVENTION

- Appropriate deworming may decrease the potential for nonstrangulating infarction of the cecum associated with *S. vulgaris* and larval cyathostomins.

ElibeVet.com

Cerebellar Diseases

BASIC INFORMATION

DEFINITION

- The cerebellum provides regulation of range, rate, and strength of skeletal movement, as well as coordination of balance and posture. Diseases of the cerebellum often have profound effects on posture and gait but fortunately are rare in horses.
- Diseases of the equine cerebellum include cerebellar abiotrophy and degeneration; congenital brain malformation (Dandy-Walker–like syndrome); developmental diseases (eg, cerebellar hypoplasia, cerebellar dysplasia, cerebellar hypoplasia with internal hydrocephalus); infection caused by *Sarcocystis neurona*, *Streptococcus equi* subsp. *equi*, equine herpesvirus type 1, or *Halicephalobus gingivalis*; and miscellaneous conditions (eg, Gomen disease, cerebellar herniation, methyl mercurial poisoning, hematoma of the fourth ventricle reported in two Thoroughbred foals). Most of the diseases are very rare, and interested readers are referred to literature describing the specific diseases.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cerebellar abiotrophy and degeneration
  - Abiotrophy: Arabian, Gotland pony, and Oldenburg horse breeds; degeneration: Thoroughbred and Paso Fino horses
  - Clinical signs develop between the time of birth and 6 months of age. Foals are often born without abnormalities and develop the disease later.
- Dandy-Walker syndrome
  - Thoroughbred and Arabian horses
  - Foals are born with signs of the defect

GENETICS AND BREED PREDISPOSITION

- Cerebellar abiotrophy and degeneration: This is a genetic neurologic disease with a recessive mode of inheritance, meaning that a horse can carry the disease gene but not be affected by the disease. Arabian and part-Arabian horses are affected most frequently. Cerebellar abiotrophy in Oldenburg horses is progressively fatal with histologic lesions similar to those of Arabian foals. The disease is not usually fatal in Arabian foals.

RISK FACTORS A high degree of inbreeding of affected Arabian foals has been shown on pedigree analysis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Cerebellar abiotrophy and degeneration: Affected foals appear normal at birth but develop intentional head tremor (vertical or horizontal) and a lack of balance equilibrium (ataxia) at around 6 weeks of age.
- Dandy-Walker syndrome: Difficulty rising, seizures shortly after birth in Arabian or Thoroughbred foals

PHYSICAL EXAM FINDINGS

- Cerebellar abiotrophy and degeneration: Clinical signs include ataxia, wide-based stance and gait, dysmetria, spasticity, and intentional head tremor. Nystagmus is almost never reported. Mentation is not affected. A menace reflex is often diminished or absent. Gait abnormalities are generally symmetric and can be exacerbated with blindfolding or by having the foal travel over obstacles. The signs vary in severity.
- Dandy-Walker syndrome
  - Foals are often abnormal from birth, with seizures, difficulty rising, ataxia, nystagmus, and absent suckle reflex.
  - Excessively domed forehead.
  - Aggression and difficulties in training can be seen as the foal ages.

ETIOLOGY AND PATHOPHYSIOLOGY Cerebellar abiotrophy and degeneration is a genetic condition with a recessive mode of inheritance.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cranial malformations
- Congenital spinal malformations (atlantoaxial malformation and stenotic myelopathy)
- Inflammation or infection of the cerebellum
- Trauma

INITIAL DATABASE

- Cerebellar abiotrophy and degeneration
  - Antemortem diagnosis is based on history and clinical signs in appropriate breeds.
  - Completed blood count and serum biochemistries are normal.
  - Cerebrospinal fluid analysis: Elevated creatine kinase activity (6.6–62 IU/µL; normal, 0–8 IU/µL); associated with neural necrosis or degeneration. Total protein is elevated (226 mg/dL; normal, 0–180 mg/dL), but this elevation is not specific for cerebellar abiotrophy.
  - Electroencephalographic (EEG) abnormalities may be observed; this is primarily useful to exclude seizure disorders as the cause of tremors (ie, EEG would likely be normal in the case of seizure disorders).
  - Skull and cervical radiographs are unremarkable.
- Dandy-Walker syndrome: Diagnosis is made using computed tomography or on postmortem examination.

ADVANCED OR CONFIRMATORY TESTING

- Ancillary testing is of limited value.
- Although the clinical signs are distinctive, the only definitive confirmation for a diagnosis of cerebellar abiotrophy is to examine the brain histologically after euthanasia.

TREATMENT

THERAPEUTIC GOAL(S)

Cerebellar diseases are untreatable.

PROGNOSIS AND OUTCOME

In general, the prognosis is considered poor. For foals with cerebellar abiotrophy, signs may progress until the foal reaches maturity. Rarely, signs may eventually mildly improve or stabilize.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- Cerebellar abiotrophy and degeneration
  - Breeding between two carrier horses will produce an affected foal 25% of the time.
  - At the time of this writing, research to identify the defective gene and create a DNA-based test is ongoing at University of California, Davis Veterinary Genetics Laboratory. Interested readers are advised to go to the following websites to learn if the test is available at the current time:

AUTHOR: **NICOLE H. PASSLER**

EDITOR: **STEPHEN M. REED**

Cervix, Defects of

BASIC INFORMATION

DEFINITION

Cervical defects in mares may be caused by congenital, traumatic, or aging processes and may include malformations, muscle defects (healed cervical lacerations), adhesions, or failure to dilate due to fibrosis.

EPIDEMIOLOGY

SPECIES, AGE, SEX Mares of any age may present with a cervical problem, but the average age that most mares are diagnosed with cervical defects is approximately 13 years of age; these mares are most often pluriparous.

GENETICS AND BREED PREDISPOSITION These defects may be seen in any breed, but Thoroughbreds appear to be overrepresented in the literature.

RISK FACTORS

- Middle-aged (older than 12 years of age), pluriparous mares are predisposed to muscle defects and cervical adhesions.
- Middle-aged (older than 12 years of age), maiden mares, and donor mares that have not carried a foal in 3 or more years are predisposed to a cervix that fails to dilate.
- History of previous foaling (eutocia or dystocia), abortion, stillbirth, or the birthing of foals with congenital musculoskeletal abnormalities
- Rarely, congenital or breeding injuries

ASSOCIATED CONDITIONS AND DISORDERS Persistent or chronic endometrial infections, inability to conceive, early embryonic death, ascending placentitis, abortion, failure for the cervix to dilate at time of parturition, septic foals, maladjustment syndrome in neonates

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cervical muscle defect or healed cervical lacerations
- Cervical adhesion
- Cervical fibrosis
- Cervical malformation

HISTORY, CHIEF COMPLAINT Mares with cervical defects are generally middle-aged, pluriparous mares that have been diagnosed with chronic, persistent endometrial infections and the inability to conceive and carry a foal to term.

PHYSICAL EXAM FINDINGS

- The physical examination results are often normal. Transrectal palpation and ultrasound examination of the reproductive tract may reveal evidence of uterine fluid and edema associated with an inflammatory response but may be normal.
- Digital examination of the cervix is necessary to assess for muscle defects in the external os, cervical body, or internal os of the cervix as well as intraluminal or extraluminal adhesions or cervical fibrosis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cervical muscle defects and adhesions are generally associated with trauma to the cervix during foaling and occasionally may be seen after natural mating or iatrogenically induced with aggressive cervical manipulation.
- Cervical fibrosis may be caused by trauma or aging changes.
- Cervical malformation is generally a congenital condition but may be secondary to cervical trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Persistent or chronic endometrial infection
- Endometrial or periglandular fibrosis
- Ascending placentitis (pregnancy)

INITIAL DATABASE

- Good reproductive history
- Transrectal palpation and ultrasonography
- Vaginal speculum examination
- Digital examination of the cervix

ADVANCED OR CONFIRMATORY TESTING

- Although digital examination of the cervix is generally the gold standard test to diagnose a cervical defect, the following tests should be considered to determine if the mare is a good candidate for surgery or if she should be treated for an endometrial infection before surgical intervention.
  - Endometrial culture
  - Endometrial cytology
  - Endometrial biopsy

TREATMENT

THERAPEUTIC GOAL(S)

Improve integrity of the cervix, thus improving the fertility of the mare.

ACUTE GENERAL TREATMENT

Acute treatment of cervical lacerations is based on decreasing inflammation with nonsteroidal antiinflammatory drugs and the incidence of infection with systemic antibiotics. Surgical intervention is not attempted until the tissue has healed.

CHRONIC TREATMENT

- Surgical intervention for the correction of the incompetent cervix is the gold standard treatment for cervical muscle defects and adhesions.
- Cervical fibrosis may be treated with prostaglandin E_2 topical creams 1 to 2 hours before breeding to allow for optimal cervical dilatation and then a postbreeding uterine lavage 4 to 6 hours after mating to promote uterine clearance and decrease intraluminal uterine debris. Ecbolics such as oxytocin and prostaglandin $F_{2\alpha}$ may assist in uterine clearance as well.
- Surgical treatment for cervical fibrosis and malformation is rarely beneficial.

POSSIBLE COMPLICATIONS

Minimal

ElibEVet.com

RECOMMENDED MONITORING

- Postsurgical correction of the cervix should not be manipulated for 2 to 4 weeks to allow the incision(s) to heal.
- Incisional adhesions may occur and should be bluntly dissected. The use of glucocorticoid creams or hyaluronic suppositories may be useful in decreasing adhesion formation after surgery.

PROGNOSIS AND OUTCOME

- To optimize fertility, expedient diagnosis and surgical treatment are indicated. Mares diagnosed within 24 months of cervical injury may have a 67% postoperative rate of fertility. Those diagnosed and surgically repaired beyond the 24-month window have a significant decrease in fertility to 41%.
- Recurrence rate of cervical defects after surgical intervention is approximately 20%.

Cervical Vertebral Stenotic Myelopathy

BASIC INFORMATION

DEFINITION

Cervical vertebral stenotic myelopathy (CVM, CVSM, CSM, CVCM) is characterized by compression of the spinal cord in the cervical region at the site of two adjacent vertebrae. Compression of the spinal cord results in chronic or repetitive trauma with blockage of normal conduction pathways, axon damage, and eventual loss with resulting signs of weakness and ataxia.

SYNONYM(S)

Wobbler, CVM, CSM, CVSM, CVCM

EPIDEMIOLOGY

- Horses affected with CVSM often present at a young age (younger than age 2 years), although some horses may not be identified until 5 years or older.
- Some investigators suggest bony malformation may be a result of developmental abnormalities such as osteochondrosis affecting the articular process joints of the cervical vertebral column with subsequent instability and hypertrophy of the soft tissues such as the ligamentum flavum and other support structures associated with the vertebral column.
- Osteochondrosis is a disturbance in endochondral ossification in rapidly growing animal species and humans. Diet appears to be a factor in this condition as well as in other developmental orthopedic problems affecting the appendicular skeleton of horses.
- The higher incidence in Thoroughbreds and a few other breeds suggests an inherited basis, although characterization of the mode of inheritance has not been completed to date. In addition to diet and a role of genetic predisposition, gender, rate of growth, endocrine dysfunction, and biomechanical stress have also been incriminated.

SPECIES, AGE, SEX The condition appears more often in males than in females, although it affects both genders. The age of affected horses is generally younger than 2 years of age, although it may present at a later time.

GENETICS AND BREED PREDISPOSITION Because the problem has a higher incidence in Thoroughbred horses, a genetic predisposition is suspected, although an exact mode of inheritance has not been identified.

RISK FACTORS

- Important risk factors are described above; however, a very important factor appears to be diet. In some studies, the incidence of osteochondrosis affecting the vertebral articular process joints of the cervical vertebrae was nearly six times as frequent in foals born to mares fed and foals raised on diets lower in copper than in a similar group fed a diet much higher in copper.
- Other important factors are the glycemic index of the diet, the gender of the foals, trauma, and the rate of growth.

GEOGRAPHY AND SEASONALITY This condition is recognized worldwide, and horses may present at any time during their lives, although many animals are recognized during periods of growth. The condition often consists of episodes of ataxia, which often appear most obvious after a period of rapid growth after a period of quiescence.

ASSOCIATED CONDITIONS AND DISORDERS Horses affected with CVSM often have concurrent signs of developmental orthopedic conditions affecting the appendicular skeleton such as osteochondritis dissecans of some long bones of the horse along with evidence of epiphysitis and physitis of some long bones.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- This condition is observed as a developmental disease in which malformation and malarticulation of cervical vertebrae result in compression of the spinal cord. The condition appears to be multifactorial, and the higher incidence in Thoroughbred horses suggests a genetic predisposition.
- The observation of the problem most often in young growing horses, male more often than female, that are fed high-carbohydrate diets that may be deficient in copper or contain excess zinc supports the idea of a multifactorial cause for this condition.
- The second group of affected horses are generally older and have osteoarthritic enlargements of the articular processes.

HISTORY, CHIEF COMPLAINT

- Ataxia (often symmetrical)
- Paresis
- Hypometria
- Dysmetria of all limbs with signs usually most severe in the pelvic limbs
- In a few cases, signs may progress to recumbency.
- Cases may be either acute or insidious, but in many horses, the signs often appear episodic with intermittent

ElibeVet.com

worsening of signs followed by periods of improvement.

PHYSICAL EXAM FINDINGS

- Ataxia, paresis (often symmetrical), or both, which are a result of upper motor neuron and general proprioceptive tract damage as a result of spinal cord compression. Damage to these tracts results in ataxia, incoordination, and weakness along with inappropriate limb rigidity.
- The horse should be evaluated by careful observation of the gait while walking on a nonslippery surface as well as while walking in circles and walking on a slope or other maneuvers to help demonstrate the presence of signs in all limbs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Clinical signs result from compression of the spinal cord as a result of vertebral canal stenosis.
- Canal stenosis may result from elongation of the dorsal laminae (vertebral arch) with a relative shortening of the vertebral body.
- This may contribute to vertebral instability with either lordotic or kyphotic deviations of the vertebrae along with flare of the caudal epiphysis of the vertebral body.
- Degenerative osteoarthritis of the articular process joints
- Vertebrae will be narrowed from dorsal to ventral at the cranial and caudal orifice of the vertebral foramen.
- Soft tissue changes such as hypertrophy of the ligamentum flavum, thickening of the joint capsules, or synovial cyst formation may also result in or contribute to spinal cord compression.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine degenerative myelopathy
- Equine herpesvirus-1 myelopathy
- Equine protozoal myeloencephalitis
- Spinal cord trauma
- Cervical vertebral osteoarthropathy

INITIAL DATABASE

- Neurologic examination
- Cervical vertebral radiographs
- Cervical vertebral myelography (Figure 1)
- Cerebrospinal fluid (CSF) analysis for cytologic evaluation
- Serum and CSF testing for equine protozoal encephalomyelitis

ADVANCED OR CONFIRMATORY TESTING

- Radiography of the cervical vertebrae
- Myelographic examination of the cervical vertebrae (see Figure 1)
- CSF analysis and cytology

FIGURE 1 Lateral view myelogram of the cranial half of the cervical vertebrae illustrating a compressive lesion at C3–C4.

- Postmortem examination with histopathologic evaluation.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduction of central nervous system (CNS) inflammation
- Ventral stabilization to stop spinal cord compression
- Supportive care until the horse can improve neurologic function

ACUTE GENERAL TREATMENT

- Corticosteroids: Dexamethasone (0.05–0.2 mg/kg IV q12–24h) or methylprednisolone sodium succinate (1.0–2.5 mg/kg IV q6h). The dose and interval depend on the severity of the clinical signs.
- Flunixin meglumine: 1.1 mg/kg IV q12–24h
- Dimethyl sulfoxide (0.5–1.0 g/kg IV q12–24h) must be diluted to a 10% solution or less in an isotonic balanced electrolyte solution.
- Surgical correction using ventral stabilization at the affected site(s)

CHRONIC TREATMENT

- In young horses (younger than 1 year of age and preferably younger than 6 months of age) may try dietary management to affect the rate of growth and vertebral canal development.
- Antiinflammatory medications such as flunixin meglumine (0.5–1.1 mg/kg PO q12–24h), phenylbutazone (1–2 mg/kg PO q12–24h), prednisolone (0.5–1.0 mg/kg PO q12–24h), or dexamethasone (0.05–0.2 mg/kg PO q12–24h) as needed for CNS inflammation.
- Horses that are unable to stand or get up on their own need to be placed into a sling periodically.

RECOMMENDED MONITORING

Periodic repeat neurologic examinations to assess response to therapy

PROGNOSIS AND OUTCOME

- The overall prognosis for complete recovery is guarded.
- Horses that survive may have permanent neurologic deficits.

PEARLS & CONSIDERATIONS

COMMENTS

- Cervical vertebral radiography is very helpful to determine whether a horse has a narrow vertebral canal.
- Myelography is recommended before attempting surgical correction.
- CSF testing is strongly indicated to eliminate other causes of spinal ataxia.

PREVENTION

- Careful observation of young, growing horses for signs of ataxia
- Use of cervical vertebral radiography at an early age to evaluate the canal diameter
- Careful attention to diet in young, growing foals

CLIENT EDUCATION

- Make clients aware of important risk factors as well as the important diagnostic tests essential for diagnosis of canal stenosis.

Choanal Atresia

BASIC INFORMATION

DEFINITION

Choanal atresia is a congenital abnormality resulting in unilateral or bilateral obstruction of the choanae. Choanal atresia is caused by failure of the bucconasal membrane to rupture. The obstruction can be membranous or fibrocartilaginous.

EPIDEMIOLOGY

SPECIES, AGE, SEX There is no known breed or sex predilection, although most of the reported cases have been in Standardbreds. Foals with choanal atresia are diagnosed at birth if the case is bilateral. Horses with unilateral choanal atresia may not be diagnosed until they are placed into training.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Foals affected with bilateral choanal atresia are unable to breathe at birth and present with acute respiratory distress. Foals with bilateral choanal atresia usually die unless an emergency tracheotomy or orotracheal intubation is performed. Placement of the hands over the nares reveals no air movement from the nares.
- Unilateral choanal atresia may not be clinically evident until the horse is placed into athletic training. Affected horses make a respiratory noise and develop exercise intolerance. An additional abnormality is failure to pass a nasogastric tube on the affected side(s).

PHYSICAL EXAM FINDINGS

- The diagnosis of choanal atresia is suspected based on clinical signs of nasal obstruction or severe dyspnea in foals at birth. Evaluation of airflow from the nares reveals no air movement from the affected side(s).
- Endoscopy is the best method to confirm choanal atresia. Endoscopic findings compatible with choanal atresia include failure to pass the endoscope into the nasopharynx and the presence of a sheet of tissue at the caudal aspect of the junction between the ethmoid turbinates, nasal septum, and caudal nasal conchae. Because of the obstructing membrane, the nasopharynx cannot be visualized.

ETIOLOGY AND PATHOPHYSIOLOGY

- Choanal atresia results from failure of the bucconasal membrane to separate from the primitive buccal or oral cavity from the nasal pits during embryologic development.
- This membrane can be complete, consisting of bone or fibrocartilage, or membranous. In horses, the majority of affected cases are membranous.
- Bilateral choanal atresia results in dyspnea at birth and may result in death if an emergency tracheotomy is not performed.
- Unilateral choanal atresia is typically not diagnosed until the horse is placed into training and is not life threatening.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Epiglottic entrapment
- Epiglottitis
- Dorsal displacement of the soft palate
- Epiglottic retroversion
- Rostral displacement of the palatopharyngeal arch
- Laryngeal hemiplegia
- Arytenoid chondritis
- Tracheal collapse
- Nasal passage obstruction

INITIAL DATABASE

- Physical examination: Subjective evaluation of airflow from each nasal passage. Unilaterally affected horses have no airflow from the affected side. Foals with bilateral choanal atresia are dyspneic.
- Endoscopy: Endoscopic examination reveals an obstructing membrane between the caudal aspect of the nasal septum, ventral aspect of the ethmoid turbinates, and nasal conchae. No nasopharyngeal structures can be visualized through the membrane.
- Radiography: Contrast radiography with contrast media being instilled into the affected nasal passage can highlight the obstructing membrane with no communication between the nasal passage and nasopharynx.

TREATMENT

THERAPEUTIC GOAL(S)

- Foals with bilateral choanal atresia must have an emergency tracheotomy as soon as possible after birth. Alternatively, if moribund, the foal can be intubated orally.
- After the tracheotomy, treatment options can be discussed with the owner.
- Horses with unilateral choanal atresia require surgical creation of a new opening via the obstructing membrane from the nasal passage into the nasopharynx.
- The problem with either of the surgical techniques is after resection or ablation of the obstructing membrane, stricture of the new opening is common and should be expected to occur to some degree. To help minimize the chances for stricture, the choanae should be stented for 2 to 3 weeks. The authors currently recommend ablation of the obstructing membrane with a noncontact, diode laser (50 W). After the choanae has been opened with the noncontact laser, the new opening is stented with a shortened nasotracheal tube for at least 2 to 3 weeks.

ACUTE GENERAL TREATMENT

- Few cases of choanal atresia have been reported in the veterinary literature. This makes treatment recommendations difficult because of the lack of experience with the condition.
- There are basically two methods of surgical management: Resection of the membrane through unilateral or bilateral nasal osteoplastic flaps and ablation of the membrane with a diode or Nd:YAG surgical laser.

ElibVet.com

- When using osteoplastic nasal bone flaps, the margins of the membrane are resected to establish an opening between the nasal passage and nasopharynx. In horses with a small nasal passage, resection of turbinates and the caudal aspect of the nasal septum may be considered to ensure an adequate airway.
- Standing laser ablation of the obstructing membrane can be performed with a noncontact, diode laser. Personal experience has shown that the noncontact laser ablation has several advantages over contact laser techniques. These advantages include less hemorrhage and a larger opening secondary to latent thermal necrosis at the margins of the laser ablation. The minimum power setting for this application is 50 W, with the laser fiber being discharged for 3 seconds and off for 1 second.

- Regardless of the surgical technique used, the newly created opening should be stented with a shortened nasotracheal tube for a minimum of 2 to 3 weeks. Postoperative stricture is not unusual after surgical ablation, and owners should be apprised of this potential complication.
- Some horses may require follow-up surgical procedures to ensure an adequate airway diameter. These procedures may include repeat laser ablation or incision of strictured opening or partial resection of the nasal septum with an osteoplastic flap. Radial incisions at the stricture in conjunction with bougienage have also been successful.

POSSIBLE COMPLICATIONS

The most significant complication after surgical correction of choanal atresia is stricture of the new opening.

RECOMMENDED MONITORING

Surgically treated horses should be monitored with endoscopy at 1- to 2-month intervals after surgical correction. This is done in an effort to address stricture if it occurs.

PROGNOSIS AND OUTCOME

- The prognosis for choanal atresia is poor unless the new choanal opening remains patent.
- Horses with unilateral choanal atresia may be successfully treated and return to athletic activity.
- However, the majority of horses with choanal atresia have a guarded prognosis for athletic activity, especially racing.
- Horses with small nasal passages and problems with stricture of the choana after surgery have a guarded prognosis.

PEARLS & CONSIDERATIONS

- Standing noncontact laser surgical ablation of the obstructing membrane is preferred over contact techniques.
- Stenting of the newly created opening is very important to maintain the patency of the new opening.
- The stricture can be resolved with follow-up surgical procedures if necessary.

Cholangiohepatitis, Chronic, and Biliary Fibrosis

BASIC INFORMATION

DEFINITION

Cholangiohepatitis is an inflammatory process of the walls of the bile ducts and the adjacent liver parenchyma. A bacterial infection (primary or secondary) is a common component of cholangiohepatitis, which frequently presents with biliary stasis and sometimes cholelithiasis. With chronicity, ongoing inflammation triggers the onset and progression of liver fibrosis.

EPIDEMIOLOGY

RISK FACTORS

- Gastroduodenal ulcers and duodenal strictures in foals.
- Anterior enteritis in adult horses.
- Enterocolitis.
- Cholelithiasis.
- In a case series of cholangiohepatitis in horses, broodmares were overrepresented, but the low number of subjects in the study did not allow making an association. In human medicine, pregnancy (and particularly the cholestatic effect of estrogens) is suspected to predispose to biliary tract diseases.
- Sepsis in neonatal foals.

ASSOCIATED CONDITIONS AND DISORDERS

- The form of chronic active hepatitis characterized by neutrophilic infiltration, cholangitis, and cholestasis is consistent with chronic cholangiohepatitis.
- Cholelithiasis, defined by the presence of calculi within the biliary ducts, is commonly accompanied by cholangiohepatitis and biliary fibrosis.
- Bacterial hepatitis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most commonly subtle and gradual in onset
- Manifestation of clinical signs can be acute

HISTORY, CHIEF COMPLAINT Depressed mentation, inappetence, weight loss, signs of abdominal discomfort, loose stools

PHYSICAL EXAM FINDINGS

- Fever.
- Icterus.
- Dehydration.
- Colic or diarrhea may be directly related to cholangiohepatitis or may be secondary to an underlying gastrointestinal disease.
- Signs of hepatic failure (photosensitization, mucosal petechiation, hepatic encephalopathy) are less commonly present.

ElibVet.com

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common isolates are enteric bacteria:
  - Gram negative: *Salmonella* spp., *Escherichia coli, Enterobacter* spp., *Citrobacter* spp., *Actinobacillus* spp.
  - Anaerobes: *Bacteroides* spp.
- Hypotheses of pathogenesis:
  - Bacterial infection ascends the bile ducts from the lumen of the small intestine and is secondary to any condition that is associated with cholestasis (eg, right dorsal colon displacement, anterior enteritis, enterocolitis, duodenal stricture in foals).
  - Bacterial translocation of intestinal microorganisms into the blood stream drained by the portal vein with secondary bacterial infection of the portal triad and cholangitis.
  - Cholelithiasis: Bilirubin precipitates with calcium, forming calcium bilirubinate, with secondary bile stasis, cholangitis, and bacterial infection. However, it is more likely that choleliths may be a consequence, rather than a cause, of chronic cholangiohepatitis.
  - Hematogenous spread secondary to septicemia in neonatal foals.
  - With any form of chronic cholangiohepatitis, hepatic fibrosis may ensue and progress.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Biliary obstruction secondary to acute or chronic colon displacement
- Cholelithiasis
- Bacterial hepatitis
- Chronic active hepatitis
- Chronic megalocytic hepatopathy
- Biliary atresia in neonates
- Hepatic neoplasia
- Amyloidosis
- Liver parasites

INITIAL DATABASE

- Packed cell volume: Normal or increased because of hemoconcentration or erythrocytosis induced by liver disease
- Total protein concentration: Normal or increased (hyperglobulinemia)
- White blood cell count: Normal or increased
- Fibrinogen concentration: Normal or increased
- Sorbitol dehydrogenase (SDH) and aspartate aminotransferase (AST) activity: Normal or increased
- Gamma glutamyltransferase (GGT) and alkaline phosphatase (ALP) activity: Moderately to markedly increased
- Total bilirubin: Increased
- Direct (conjugated) fraction: >25% of total bilirubin
- Serum bile acids concentration: Increased; may be normal

ADVANCED OR CONFIRMATORY TESTING

- Plasma ammonia may be increased.
- Clotting profile: prothrombin time and activated partial thromboplastin time may be increased.
- Transabdominal ultrasonographic examination of the liver (see "Diagnostic Imaging of the Liver" in Section II):
  - Liver size may be increased.
  - Increased liver parenchyma echogenicity, localized or generalized.
  - Lack of homogenicity in the ultrasonographic appearance of the liver parenchyma.
  - Biliary distension.
  - Hyperechoic "sludge-like" material within the biliary tract.
  - Hyperechoic shadow-casting foci within the bile ducts are consistent with choleliths.
- Transabdominal ultrasonographic examination of the abdomen may reveal increased peritoneal fluid volume.
- Abdominocentesis may be consistent with a transudate or nonseptic inflammation.
- Ultrasound-guided liver biopsy:
  - Histopathology
    - Suppurative inflammation characterized by neutrophils infiltrating the lumen of the bile ducts, the biliary walls, and the liver parenchyma (most pronounced in the portal area)
    - Hepatocellular degeneration, necrosis, or both
    - Biliary hyperplasia
    - Fibrosis may be incipient in early stages and more pronounced in chronic cases, up to the point of connecting one portal triad to another (bridging fibrosis)
  - Bacterial culture of liver tissue: gram-negative enteric bacteria most commonly cultured

TREATMENT

THERAPEUTIC GOAL(S)

The goal of medical therapy is treatment of the underlying bacterial infection. Supportive care and dietary manipulation may be required to maintain hydration and provide nutrition while minimizing liver workload.

ACUTE GENERAL TREATMENT

- IV fluids if the horse is febrile and dehydrated.
- Flunixin meglumine (1.1 mg/kg IV) to control signs of abdominal pain or pyrexia.
- Long-term antimicrobial therapy.
  - Potentiated sulfonamides, ceftiofur, penicillin and gentamicin, enrofloxacin, ampicillin, or chloramphenicol.
  - Metronidazole may be added for improved anaerobic coverage.
- Antimicrobial therapy should be administered until GGT and ALP activity has normalized for 2 to 4 weeks.

CHRONIC TREATMENT

- Dimethylsulfoxide 1 g/kg IV (diluted in a 5% solution in fluids) q24h for 5 to 7 days may act as a solvent for calcium bilirubinate calculi.
- Surgical procedures (manual lithotripsy or choledocholithomy) have been reported to successfully treat complete biliary obstruction in horses with persistent signs.

ADDITIONAL TREATMENTS

- Also see treatment for "Hepatic Encephalopathy."
- S-adenosylmethionine (SAMe): 5 g PO q24h; the bioavailability of crushed pills is questionable in horses.

PREVENTION OF LIVER FIBROSIS

- Pentoxifylline: 8–16 mg/kg PO q8–12h
- Colchicine: 0.03 mg/kg PO q24h; there have been anecdotal reports of presumed toxicity

POSSIBLE COMPLICATIONS

- Diarrhea
- Peritonitis

RECOMMENDED MONITORING

- GGT or ALP activity
- Serum bile acids concentration
- Repeat liver biopsy

PROGNOSIS AND OUTCOME

- Good prognosis with early diagnosis and treatment of bacterial infection and suppurative hepatitis
- Guarded to poor prognosis with biliary fibrosis
- Typically a grave prognosis when bridging fibrosis is present

PEARLS & CONSIDERATIONS

A transient increase in serum GGT may be observed in the initial phase of medical treatment, possibly consistent with response to

ElibVet.com

therapy and biliary epithelium regeneration and hyperplasia.

AUTHOR: **ALESSANDRA PELLEGRINI-MASINI**

EDITOR: **MICHELLE HENRY BARTON**

Cholelithiasis

BASIC INFORMATION

DEFINITION

A cholelith is a calculi that develops anywhere within the biliary tree and includes hepatoliths (within intrahepatic ducts) and choledocholiths (within the common bile duct). Cholelithis are usually composed of bile pigments, bile acids, calcium, and cholesterol.

SYNONYM(S)

Bile stones

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Broodmares may be at greater risk
- Middle age (6–15 years)

RISK FACTORS

- Cholangiohepatitis
- Any condition resulting in cholestasis.
- Pregnancy may be a risk factor.

ASSOCIATED CONDITIONS AND DISORDERS Clinical signs of cholelithiasis may be indistinguishable from other liver disorders, including cholangiohepatitis, chronic megalocytic hepatopathy, clover toxicity, chronic active hepatitis, hepatic abscessation, and hepatic neoplasia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic: Intermittent weight loss, anorexia, colic, fever, icterus
- Acute: Hepatoencephalopathy, fever, colic

HISTORY, CHIEF COMPLAINT Owners may observe intermittent colic, weight loss, anorexia, depression, icterus, or fever.

PHYSICAL EXAM FINDINGS Icterus, fever, low-grade colic, photosensitization, hepatoencephalopathy, petechiae (rarely).

ETIOLOGY AND PATHOPHYSIOLOGY

- The exact mechanism is unknown.
- Excreted conjugated bilirubin becomes unconjugated bilirubin and combines with calcium to form calcium bilirubinate, which precipitates, resulting in cholelith formation.
- Often associated with ascending cholangitis or cholangiohepatitis, especially with gram-negative enteric bacteria.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cholangiohepatitis
- Chronic megalocytic hepatopathy
- Chronic active hepatitis
- Clover toxicity
- Hepatic abscess
- Hepatic neoplasia

INITIAL DATABASE

- Leukocytosis characterized by neutrophilia
- Hyperfibrinogenemia
- Gamma glutamyltransferase (GGT) activity: Increased
- Alkaline phosphatase (ALP) activity: Increased
- Serum bile acids concentration: Increased
- Total bilirubin concentration: Increased
- Direct bilirubin concentration: Increased, usually >25% of total
- Sorbitol dehydrogenase (SDH) activity: Variable degree of increase
- Hyperglobulinemia
- Bilirubinuria

ADVANCED OR CONFIRMATORY TESTING

- Coagulation times, particularly prothrombin time, may be prolonged.
- Blood ammonia concentration may be increased.
- Ultrasonography: Increased echogenicity of hepatic parenchyma, hepatomegaly, distended bile ducts. Cholelithis typically appear as hyperechoic foci and may cast anacoustic shadows (see "Diagnostic Imaging of the Liver" in Section II).
- Liver biopsy: Periportal fibrosis, biliary hyperplasia, bile stasis, concentric fibrosis around intrahepatic bile ducts, cholangitis
- Liver culture: Gram-negative enteric bacteria are often isolated.

TREATMENT

THERAPEUTIC GOAL(S)

- With medical treatment, the clinical signs may resolve. Choledocholiths may be amenable to surgical removal.

ACUTE GENERAL TREATMENT

- IV fluids may be required in animals that are febrile and dehydrated.
- Antiinflammatory drugs: Flunixin meglumine (1.1 mg/kg PO q12h).
- Nutritional support: Low-protein diet with high content of branched-chain amino acids.
- See treatment for "Hepatic Encephalopathy" in this section.

CHRONIC TREATMENT

- Nutritional support
- Antiinflammatory drugs
- Antifibrotic agents: pentoxifylline (8–16 mg/kg PO q8–12h)
- Dimethyl sulfoxide has been shown to dissolve calcium bilirubinate stones in humans.
- Long-term antimicrobial therapy as guided by liver culture (enrofloxacin, 5.0–7.5 mg/kg PO q24h; trimethoprim-sulfa, 20–30 mg/kg PO q12h; procaine penicillin G, 22,000 U/kg IM q12h) and gentamicin (6.6 mg/kg IM q24h); ceftiofur (2.2–4.4 mg/kg IM q12h); ampicillin (20 mg/kg IV q6–8h); chloramphenicol (50 mg/kg PO q6h)
- Surgical exploration is the only way to confirm obstruction of the common bile duct. Choledocholiths may be removed by external manual pressure to crush the stones, with subsequent dislodgement into the duodenum. Choledocholithotripsy and choledochotomy have been performed in horses.

POSSIBLE COMPLICATIONS

Hepatic encephalopathy, photosensitivity dermatitis, rupture of the common bile duct and fatal bile peritonitis, hepatic fibrosis

ElibeVet.com

RECOMMENDED MONITORING

- Monitor liver enzymes every 2 to 3 weeks until GGT returns to within normal limits.
- Serial liver biopsies (q2–3mo).

PROGNOSIS AND OUTCOME

Guarded to good prognosis, depending on the degree of hepatic fibrosis and success of cholelith removal

PEARLS & CONSIDERATIONS

- It has been recommended to continue antimicrobial therapy until GGT activity returns to normal and there is complete resolution of clinical and laboratory evidence of inflammation.
- Horses with recurrent colic or signs of hepatic disease should be considered as candidates for exploratory celiotomy to rule out obstruction of the common bile duct.

AUTHOR: **HEIDI BANSE**

EDITOR: **MICHELLE HENRY BARTON**

Cleft Palate

BASIC INFORMATION

DEFINITION

A congenital defect resulting in the partial or complete failure of closure of the palatal folds in early embryologic development

SYNONYM(S)

Palatoschisis

EPIDEMIOLOGY

RISK FACTORS Influence of teratogens, genetic factors, and malnutrition around the forty-seventh day of gestation

ASSOCIATED CONDITIONS AND DISORDERS

- As with other congenital diseases, concurrent congenital malformations or defects may be present.
- Most often, coughing or aspiration of milk develops soon after birth and may lead to life-threatening aspiration pneumonia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The extent of clinical signs depends on the size of the defect and ranges from mild to severe.
- Both the soft and the hard palates may be involved. If the defect is small and only involves the caudal aspect of the soft palate, clinical signs may be mild and aspiration pneumonia may not be obvious for several weeks (if left untreated). These foals may eventually grow more slowly than healthy foals and appear unthrifty.
- Foals with a larger defect in the soft palate or with a cleft hard palate develop much more severe signs within days, prompting the owners to consult a veterinarian immediately.

HISTORY, CHIEF COMPLAINT Owners may observe milk running out of both nostrils immediately after nursing. Affected foals show signs of aspiration of milk (coughing, dyspnea) and may be weak and lethargic.

PHYSICAL EXAM FINDINGS

- Milk draining from both nostrils after nursing, coughing, dyspnea
- Later, signs of aspiration pneumonia and possibly fever

ETIOLOGY AND PATHOPHYSIOLOGY

- Not yet completely understood.
- Closure of the palatal folds occurs around the forty-seventh day of gestation.
- Genetic, nutritional, and teratogenic factors that are present around this time may be responsible for the development of a cleft palate.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of aspiration in newborn foals, such as:
  - Fourth branchial arch anomaly
  - Epiglottic entrapment
  - Esophageal inclusion cyst
  - Pharyngeal dysfunction

INITIAL DATABASE

- Drainage of milk from both nostrils after nursing in a newborn foal.
- Coughing
- Dyspnea
- Observation of the cleft palate by oral examination (most often only possible with a hard palate defect).
- Digital palpation (hard or possibly soft palate defect).
- Diagnosis is confirmed, and the extent of the defect may be described by endoscopy. The epiglottis is positioned between the two edges of the soft palate and appears to be "dropped down" in the oropharynx.

ADVANCED OR CONFIRMATORY TESTING

If the defect involves only the caudal part of the soft palate, the epiglottis may still cover the cleft. Swallowing should be initiated during the endoscopic examination to be able to visualize the caudal aspect of the soft palate.

TREATMENT

THERAPEUTIC GOAL(S)

- Prevention of further aspiration.
- Surgical reconstruction (palatoplasty) of the palate as a salvage procedure.
- Treatment attempts should not be done if more than 20% of palatal tissue is missing.

ACUTE GENERAL TREATMENT

- Because no medical treatment option exists, the foal should be stabilized with supportive therapy and the signs of aspiration should be treated to decrease the risk for general anesthesia.
  - Broad-spectrum antimicrobial agents
  - Nonsteroidal antiinflammatory drugs (NSAIDs)
  - IV fluids if needed
  - Parenteral nutrition
- The ultimate treatment is the surgical reconstruction of the palate by mandibular symphysiotomy, laryngotomy, or pharyngotomy, or transoral reconstruction (endoscopic assisted). Broad-spectrum antimicrobial agents, NSAIDs, and enteral nutrition via a nasogastric tube or parenteral nutrition should be continued postoperatively as needed.

ElibVet.com

POSSIBLE COMPLICATIONS

- Dehiscence of the repair (partial or complete) is common.
- The severity of already established aspiration pneumonia can be life ending.

RECOMMENDED MONITORING

- If the repaired defect was small, an alternative way of feeding (nasogastric tube, parenteral nutrition) may not be necessary. In these rare cases, recurrence of clinical signs (milk drainage from the nose after nursing, coughing) must be monitored.
- If the foal is not allowed to nurse after surgery, the integrity of the repair should be monitored endoscopically.
- Signs of aspiration pneumonia should be monitored in both cases (endoscopy, lung auscultation, chest radiography, leukocyte counts, and fibrinogen).

PROGNOSIS AND OUTCOME

- The prognosis depends on the size and symmetry of the defect.
- If the defect involves both the hard and the soft palate, the prognosis decreases significantly (<20%).
- Even in the best-case scenario (ie, minimal tissue loss and a defect on the midline), successful repair may not exceed 50%.
- Because cleft palate repair is considered a salvage procedure, a successful outcome is reached when the animal can eat, swallow, and breathe normally.

PEARLS & CONSIDERATIONS

COMMENTS

- Repair of a cleft palate is a surgical procedure with a high failure rate. This may be because of the congenital nature of the defect. The surgeon must adapt tissue that has never been joined together before. Unlike tissue that was separated by trauma, a cleft palate represents a defect that may not only be repaired with considerable tension along the suture line, but the direction of the muscle fibers is changed. The muscle fibers of the levator veli palatini muscle in foals with a cleft palate do not insert at midline but rather at the caudal aspect of the hard palate. If possible, this false insertion should be severed and attempts should be undertaken to reconstruct the so-called *levator sling*.
- Horses with even small defects should be treated because chronic aspiration of milk and later other food material will decrease the quality of life of the affected animal to an extent that may not be tolerable.
- The only alternative to surgical treatment of a cleft palate is euthanasia.

CLIENT EDUCATION

- Clients must understand that cleft palate is a severe, potentially life-threatening disease that should not be left untreated.
- Palatoplasty is a salvage procedure, and the animal may never become an athlete.
- Horses that are successfully treated should be excluded from the gene pool because the disease is congenital in nature.

AUTHOR: **KARSTEN VELDE**

EDITOR: **ERIC J. PARENTE**

Clostridiosis, Enteric

BASIC INFORMATION

DEFINITION

Enteric disease caused by infection with clostridial species, primarily *Clostridium perfringens* and *Clostridium difficile*

SYNONYM(S)

- Necrotizing enterocolitis (typically associated with *C. perfringens*)
- Pseudomembraneous colitis (typically associated with *C. difficile*)

EPIDEMIOLOGY

RISK FACTORS Antimicrobial use

CONTAGION AND ZOONOSIS

- Occurrence is often sporadic, but outbreaks have been described on farms and in veterinary hospitals. Therefore isolation of affected horses and use of barrier precautions, such as dedicated clothes and gloves, are recommended.
- Both *C. perfringens* and *C. difficile* are recognized enteropathogens in humans. Although direct transmission between horses and humans has not been documented, horses should be treated as if infectious and control measures implemented (barrier precautions, hand hygiene, disinfectants).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Variable signs depending on several factors, including the region of the gastrointestinal (GI) tract that is affected
- Acute colitis most common
- Proximal enteritis

HISTORY, CHIEF COMPLAINT

- Diarrhea is the most common complaint
- Colic
- Occasionally, sudden death

PHYSICAL EXAM FINDINGS

- Colitis
  - Diarrhea
  - Anorexia, pyrexia
  - Variable degrees of dehydration, toxemia, colic
- Cases that involve only the small intestine or cecum may exhibit similar signs without diarrhea.
- Cases that involve the proximal small intestine may present with significant reflux.

ETIOLOGY AND PATHOPHYSIOLOGY

- Gram-positive, anaerobic bacteria in the genus *Clostridium*, primarily *C. difficile* and *C. perfringens*.
- Transmission is by ingestion; disease is caused by the proliferation of toxigenic strains in the intestinal tract.
- Toxin production results in enterocolitis.
- *C. difficile*: primarily toxin A (enterotoxin) and toxin B (cytotoxin).
  - Approximately 13% of equine isolates do not produce any toxin and are nonpathogenic; most pathogenic isolates produce both toxin A and B.
  - Age influences colonization rates: subclinical carriage of *C. difficile* has been reported in 29% of foals younger than 14 days of age but in

ElibεVet.com

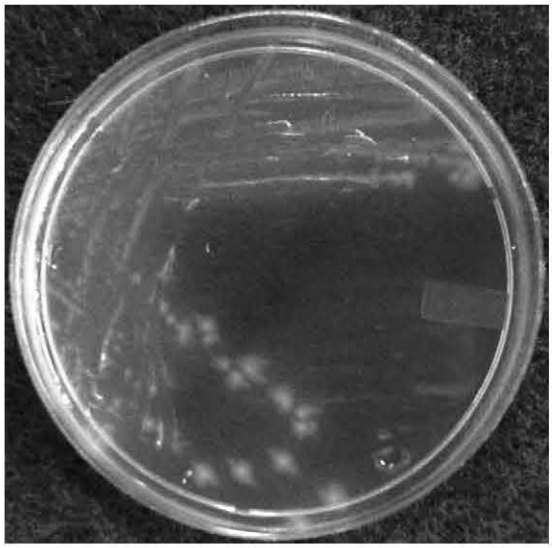

FIGURE 1 Colony morphology of *Clostridium difficile* on a cycloserine-cefoxitin fructose agar, a selective and differential culture medium used for isoluation of *C. difficile*. (From Sellon DC, Long MT: *Equine infectious diseases*. St. Louis, Saunders, 2007.)

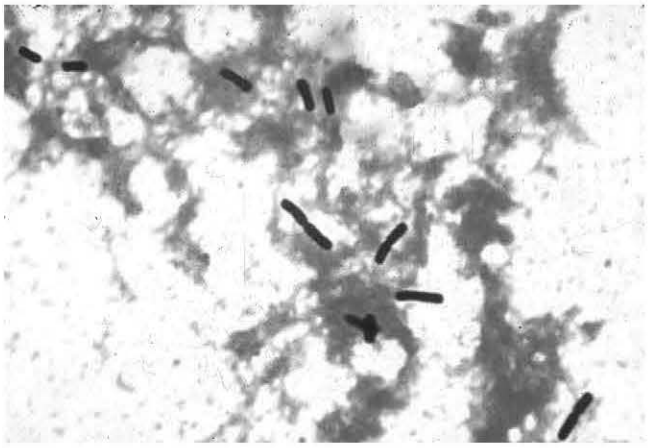

FIGURE 3 Gram stain appearance of *Clostridium perfringens*, demonstrating the characteristic appearance of short, thick, gram-positive rods. (From Sellon DC, Long MT: *Equine infectious diseases*. St. Louis, Saunders, 2007.)

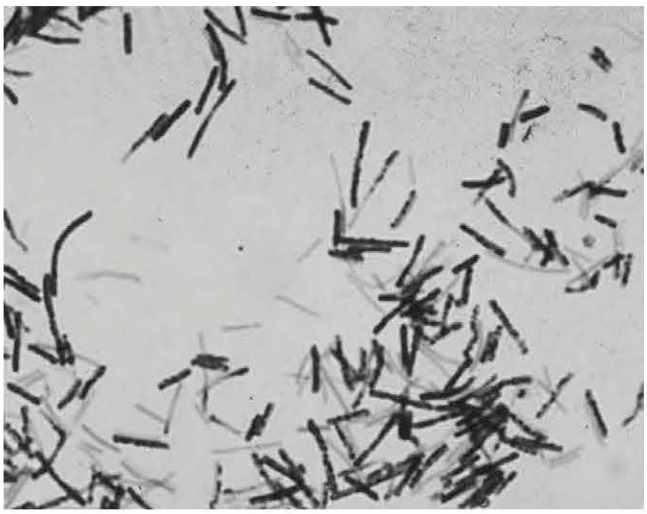

FIGURE 2 Gram stain morphology of *Clostridium difficile*. Note the long, thin rods. The variable staining appearance may be encountered in cultures over 48 hours or longer. (From Sellon DC, Long MT: *Equine infectious diseases*. St. Louis, Saunders, 2007.)

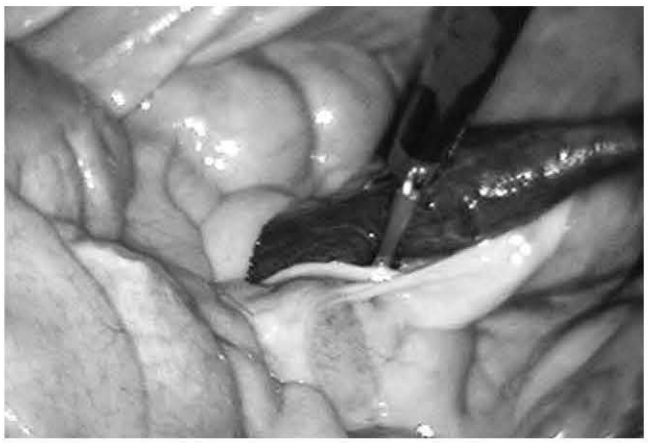

FIGURE 4 *Clostridium difficile* colitis. Note the widespread petechial and ecchymotic hemorrhages consistent with disseminated intravascular coagulation. (From Sellon DC, Long MT: *Equine infectious diseases*. St. Louis, Saunders, 2007.)

less than 1% of older foals and normal adults.

- *C. perfringens*: classified into different types based on the pattern of toxin production; β-2 toxin and enterotoxin may be the most important clinically.
  - A normal inhabitant of the equine GI tract found in 19% to 35% of broodmares and more than 90% of 3-day-old foals
  - Type A: predominant type in normal horses and horses with diarrhea
  - Type C: has been associated with severe enterocolitis, especially in foals
  - Limited reports of disease associated with types B and D

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Salmonellosis
- *Neorickettsia risticii* (Potomac horse fever)
- Cantharidin toxicity
- Parasitism
- *Aeromonas*, *Campylobacter*, and *Lawsonia* spp.
- Other antibiotic-associated diarrhea
- Sand
- Thromboembolic disease
- Anaphylaxis
- Undiagnosed colitis
- Additional differentials in foals
  - Rotavirus, coronavirus
  - Foal heat diarrhea
  - Cryptosporidiosis
  - Associated with septicemia
  - Secondary lactose intolerance

INITIAL DATABASE

- Clinicopathologic abnormalities: nonspecific; consistent with dehydration and endotoxemia from diarrhea and mucosal damage
  - Leukopenia, neutropenia
  - Elevated packed cell volume (PCV), variable total protein (TP); hypoproteinemia often develops
  - Acid-base and electrolyte abnormalities consistent with diarrhea
- Although clostridial diarrhea in neonatal foals is not generally associated with failure of passive transfer, it is

ElibeVet.com

recommended to evaluate affected foals for antibody concentration and the presence of septicemia.
- Abdominal ultrasonography may reveal ileus or a thickened intestinal wall; occasionally, intramural gas is seen (may also be seen radiographically in foals).

ADVANCED OR CONFIRMATORY TESTING

- Culture: not diagnostic by itself because of the presence of nonpathogenic isolates and the presence in some normal horses, especially with *C. perfringens*; culture samples should be handled anaerobically.
- *C. difficile* toxin detection in feces (toxins stable in refrigerated or frozen samples)
  - Cell cytotoxicity assay (toxin B): Considered the gold standard but not available in some laboratories
  - Enzyme immunoassays (EIA) to detect toxin A or B: Rapid and frequently used, but sensitivity and specificity in horses are not well established
  - Polymerase chain reaction for toxin genes after culture
- *C. perfringens*
  - Genotyping of isolates to determine the strain and, identify specific toxin genes
  - Detection of toxin in feces: Commercial EIA for enterotoxin; sensitivity and specificity in horses are not known

TREATMENT

THERAPEUTIC GOAL(S)

- Resolution of enterocolitis
- Maintenance of physiologic homeostasis of water and electrolyte balance
- Amelioration of clinical effects of systemic inflammatory response syndrome

ACUTE GENERAL TREATMENT

- Specific antimicrobial therapy: Drug choice is most often based on historical information because antimicrobial sensitivity testing for *Clostridium* spp. is not routine in many laboratories. However, antimicrobial resistance has been documented in *Clostridium* spp., and sensitivity testing is recommended in refractory cases.
  - Metronidazole (15 mg/kg PO q8h): Generally considered the drug of choice; resistance has been identified infrequently
  - Vancomycin has been used in cases with metronidazole resistance; consider use carefully because of the importance of vancomycin in the treatment of resistant bacteria in human medicine
  - Zinc bacitracin is effective against *C. perfringens* but resistance is common in *C. difficile*
- Di-tri-octahedral smectite (BioSponge, Platinum Performance, Belton, CA.) adsorbs clostridial toxins and endotoxin in vitro.
- *Saccharomyces boulardii* (25 g PO q12h) may be useful in the management of horses with acute enterocolitis.
- Supportive care for diarrhea
  - Treatment for dehydration and electrolyte and acid-base abnormalities
  - Treatment for associated systemic inflammatory response syndrome (endotoxemia).
  - Broad-spectrum systemic antibiotic therapy in horses with colitis is controversial.
    - Sometimes used to prophylactically control potential bacteremia from translocation of bacteria across the damaged intestinal mucosa.
    - If diarrhea developed while the horse is on antibiotics, discontinuing or changing those antibiotics is suggested.

POSSIBLE COMPLICATIONS

- Laminitis
- Thrombophlebitis
- Peritonitis

RECOMMENDED MONITORING

- Attitude, vital parameters, diarrhea
- PCV, TP
- Hydration status, renal function
- Acid-base and electrolyte abnormalities

PROGNOSIS AND OUTCOME

- Prognosis is variable depending on the strain and host factors.
- A mortality rate of up to 42% has been reported with *C. difficile*; prognosis may be worse in adults than foals.
- Prognosis is guarded in foals with *C. perfringens*, especially type C; the mortality rate is approximately 50%.

PEARLS & CONSIDERATIONS

COMMENTS

Enteric clostridiosis is an important cause of enterocolitis in horses, accounting for approximately 40% of cases in some studies.

PREVENTION

- Careful use of antimicrobials.
- Clostridial spores are often present in the environment; good management practices, including regular cleaning and disinfection of stalls and equipment, will limit the environmental burden.
- There is no approved vaccine for horses. Anecdotally, vaccines approved in other species for the prevention of *C. perfringens*–associated disease have been used in horses; no data currently support their use.

CLIENT EDUCATION

Clients should be made aware of the risk of antibiotic-associated diarrhea and should be counseled to call their veterinarian if diarrhea occurs.

ElibeVet.com

Clover Toxicosis

BASIC INFORMATION

DEFINITION

Clover toxicity is caused by ingestion of alsike clover (*Trifolium hybridum*) or red clover (*Trifolium pratense*), resulting in signs of photosensitivity and liver failure.

SYNONYM(S)

- Dew poisoning
- Trifoliosis
- Big liver disease

EPIDEMIOLOGY

RISK FACTORS Consumption of pasture or hay containing alsike or red clover

GEOGRAPHY AND SEASONALITY

- Found mainly in Canada and the northwestern United States
- Most cases occur from April to November
- Associated with a wet spring

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Photosensitization
- Chronic hepatic disease
- Chronic wasting and failure to thrive

HISTORY, CHIEF COMPLAINT

- Owners may observe a necrotizing dermatitis primarily affecting white skin, weakness, weight loss, anorexia, ataxia, and behavior changes.
- History of consumption of alsike or red clover hay or pasture.

PHYSICAL EXAM FINDINGS Icterus, photosensitivity dermatitis, ulceration of mucous membranes, hepatic encephalopathy, weight loss

ETIOLOGY AND PATHOPHYSIOLOGY

- Alsike or red clover ingestion resulting in bile duct proliferation and perilobular (periportal) fibrosis.
- Photosensitization is the result of systemic accumulation of the chlorophyll metabolite phylloerythrin that is not removed by the diseased liver. Phylloerythrin is a photodynamic agent that absorbs ultraviolent radiation, particularly in unpigmented skin, leading to skin necrosis.
- Signs develop 2 to 4 weeks after ingestion.
- The exact toxin(s) are not known, although fungal infection of the clover with *Cymodothea trifolii* increases the risk of liver disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic megalocytic hepatopathy
- Aflatoxicosis
- Cholelithiasis
- Chronic active hepatitis
- Cholangiohepatitis
- Any cause of primary or secondary photosensitization

INITIAL DATABASE

- Complete blood count: Typically normal
- Gamma glutamyltransferase (GGT), alkaline phosphatase (ALP, aspartate aminotransferase (AST), and sorbitol dehydrogenase (SDH) activity: Increased
- Hyperglobulinemia: May be present if chronic
- Serum bile acids concentration: Increased
- Total bilirubin concentration: Increased
- Direct bilirubin concentration: Increased; often more than 25% of total
- Coagulation times: May be prolonged
- Plasma ammonia concentration: May be increased
- Urinalysis: Bilirubinuria

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography: Hepatomegaly or a small, difficult-to-find liver; distended bile ducts
- Liver biopsy: Periportal, centrolobular to perilobular fibrosis that typically spares the sinusoids; biliary hyperplasia, bile stasis, mild megalocytosis, and inflammatory cells may be present

TREATMENT

THERAPEUTIC GOAL(S)

Palliative

ACUTE GENERAL TREATMENT

- See treatment for "Hepatic Encephalopathy" in this section.
- For photosensitization, avoid sunlight. Topical or systemic antiinflammatory or antimicrobial agents (or both) may be necessary if skin lesions are severe.

CHRONIC TREATMENT

See treatment for "Hepatic Encephalopathy" in this section.

POSSIBLE COMPLICATIONS

Hepatic encephalopathy, photosensitivity dermatitis

RECOMMENDED MONITORING

- Monitor GGT activity and serum bile acid concentrations.
- Perform serial liver biopsies.

PROGNOSIS AND OUTCOME

Fair to grave, depending on the degree of hepatic fibrosis

PEARLS & CONSIDERATIONS

COMMENTS

A diet with 20% alsike clover hay has been associated with disease.

PREVENTION

Ensure clover hay is less than 20% of the diet (avoid completely if possible).

CLIENT EDUCATION

Remove the source of alsike clover (herbicidal treatment and reseed pasture; provide new source of hay)

SUGGESTED READING

Nation NP: Alsike clover poisoning: a review. *Can Vet J* 30:410, 1989.

EDITOR: **MICHELLE HENRY BARTON**

ElibeVet.com

Coccidioidomycosis

BASIC INFORMATION

DEFINITION

A systemic fungal infection of equids and other mammals that may result in pneumonia, osteomyelitis, mastitis, abortion, or superficial or internal abscessation.

EPIDEMIOLOGY

CONTAGION AND ZOONOSIS

- Horses and humans acquire disease by inhalation of arthroconidia or rarely through the skin.
- Horse-to-horse and horse-to-human transmission is very rare. However, there is one report of a veterinarian developing fatal disease after attending the necropsy of a horse with disseminated coccidioidomycosis.

GEOGRAPHY AND SEASONALITY

- Indigenous to the southwestern and western United States and areas of Mexico, Central America, and South America between 40 degrees south latitude and 40 degrees north latitude
- Areas with significant problems often have hot, dry summers with relatively mild winters and moderate rainfall.
- Cases are most common in late summer and fall.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Respiratory disease is common because infection is usually acquired by inhalation.
- Systemic dissemination may occur, leading to disease in a variety of locations.
- Cutaneous inoculation may cause localized subcutaneous infection.

HISTORY, CHIEF COMPLAINT

- Fever, weight loss
- Signs reflecting an internal site of infection
  - Respiratory tract infection: Increased respiratory rate, cough, dyspnea
  - Osteomyelitis: Pain, lameness, neurologic signs
  - Abdominal infection: Colic
  - Subcutaneous infection: Abscess, chronic draining tracts
  - Respiratory tract: Abortion, placentitis

PHYSICAL EXAM FINDINGS Vary to reflect the site of infection

ETIOLOGY AND PATHOPHYSIOLOGY

- *Coccidioides immitis* is a diphasic, pleomorphic mold and fungus.
- The saprobic phase is found in nature and in culture.
  - Hyphae differentiate into chains of arthroconidia (spores).
  - Mammalian infection occurs by inhalation of arthroconidia.
- Inside the host, arthroconidia transform to spherules, which release endospores to form more spherules.
- Spherules and endospores induce a neutrophil and macrophage response with development of suppurative-granulomatous lesions.
- Growth elicits host antibody response to chitinase enzyme that is released as spherules mature and release endospores.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Respiratory infection
  - Bacterial pneumonia, pleuropneumonia
  - Other fungal pneumonias
  - Pulmonary abscess
  - Interstitial pneumonia
  - Pulmonary nodular fibrosis (equine herpesvirus-5)
- Systemic infection
  - Abdominal abscess
  - Strangles (*Streptococcus equi* subsp. *equi*)
  - Pigeon fever (*Corynebacterium pseudotuberculosis*)
  - Other bacterial or fungal forms of osteomyelitis
  - Abortion secondary to bacterial or fungal endometritis, nocardioform infection, leptospirosis
- Cutaneous infection
  - Subcutaneous bacterial or fungal abscesses
  - Sporotrichosis
  - *Corynebacterium pseudotuberculosis*

INITIAL DATABASE

- Mild to moderate anemia
- Leukocytosis caused by mature neutrophilia
- Hyperfibrinogenemia
- Hyperglobulinemia
- Monocytosis
- Thrombocytosis

ADVANCED OR CONFIRMATORY TESTING

- Imaging such as radiography or ultrasonography depending on the site of suspected infection
- Direct demonstration of organism in tracheobronchial aspirates, exudates, or tissues
- Culture of appropriate tissues, exudates, or tracheobronchial aspirates
- Serum antibody testing by immunodiffusion or enzyme immunoassay. Higher titers are seen in horses with disseminated disease or pneumonia with thoracic effusion compared with horses with abortion, bone involvement only, or cutaneous infection.

TREATMENT

THERAPEUTIC GOAL(S)

Eliminate infection through a combination of surgical and medical therapy.

ACUTE GENERAL TREATMENT

- Surgical removal of lesions if possible
- Preferred antifungal therapy may be fluconazole (10 mg/kg PO loading dose followed by 5 mg/kg PO q24h).
- Alternative antifungal medications include amphotericin B, ketoconazole, itraconazole, and voriconazole.

CHRONIC TREATMENT

Antifungal therapy may be required for months or years.

POSSIBLE COMPLICATIONS

Amphotericin B is nephrotoxic and irritating when administered IV and should be used with caution.

RECOMMENDED MONITORING

Increasing serum antibody titer generally indicates worsening disease.

PROGNOSIS AND OUTCOME

- Guarded prognosis; successful treatment may require considerable time and expense.
- Horses with higher titers may have a poorer prognosis.

PEARLS & CONSIDERATIONS

- Veterinarians practicing in areas where coccidioidomycosis occurs should be aware of this differential diagnosis for horses with evidence of chronic infection or inflammation.
- Rising titers in a horse with evidence of chronic infection or inflammation should be considered diagnostic of

ElibEVet.com

coccidioidomycosis even if the actual site of infection cannot be identified.

AUTHOR & EDITOR: **DEBRA C. SELLON**

Cocklebur Toxicosis

BASIC INFORMATION

DEFINITION

Cocklebur (*Xanthium* spp.) are common weeds throughout North America with the capability of causing acute liver failure in pigs, cattle, sheep, poultry, and occasionally horses. Pigs are most frequently affected.

SYNONYM(S)

There are three species of cocklebur: *Xanthium strumarium*, *Xanthium spinosum*, and *Xanthium ambrosioides*. Common names include ditch bur, sheep bur, bur thistle, and abrojo.

EPIDEMIOLOGY

RISK FACTORS

- Young animals
- Cocklebur seedlings in the spring

GEOGRAPHY AND SEASONALITY

- The most common cocklebur, *X. strumarium*, is found throughout North America.
- Poisoning in animals occurs most often in the spring and summer when growing conditions favor germination of the seedlings.
- The mature plants are prolific bur producers; consequently, massive numbers of seedlings may germinate at once, increasing the potential for poisoning to occur.
- Cocklebur are annual erect, branching plants up to 6 feet in height with a taproot. The leaves are large and simple and alternate with serrated edges. Flowers are produced in leaf axils or terminally on branches. Characteristic burs turn brown when mature (Figure 1).

ASSOCIATED CONDITIONS AND DISORDERS

- Cocklebur poisoning can mimic other hepatotoxins, including alsike clover and cyanobacteria toxin poisoning.
- Animals that survive acute cocklebur poisoning may develop chronic liver disease that may mimic pyrrolizidine alkaloid poisoning.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owners may observe acute onset of anorexia, depression, weakness, and colic.
- Death may be the only presenting sign.

PHYSICAL EXAM FINDINGS

- Anorexia, depression, weakness, ataxia, spasms of the cervical muscles, dyspnea, and convulsions may be observed.
- Death may occur within hours of the onset of signs.
- Animals that survive acute poisoning often develop signs of chronic liver disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cocklebur poisoning generally causes acute liver failure.
- Carboxyatractyloside, a sulfated diterpene glycoside, is the primary hepatotoxin. It primarily acts by inhibiting oxidative phosphorylation at the mitochondria.
- The two-leafed (cotyledonary) stage of the seedling poses the highest risk, with the highest toxin concentrations in the two cotyledons within the bur (0.46%).
- Ingestion of 0.75 to 3.0% of body weight of cotyledonary seedlings causes acute toxicity.
- As seedlings develop past the two-leafed stage, their toxicity rapidly decreases.
- Mature plants with multiple burs are toxic but are rarely palatable.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ingestion of Alsike clover, *Nolina texana*, *Agave lechuguilla*, *Phyllanthus abnormis*, and *Lantana camara*
- Ingestion of Klein grass
- Ingestion of plants containing pyrrolizidine alkaloids
- Ingestion of cyanobacteria (blue-green algae)
- Ingestion of gossypol

INITIAL DATABASE

- Blood glucose: Severe hypoglycemia
- Serum hepatic enzymes: Markedly elevated

ADVANCED OR CONFIRMATORY TESTING

- Assay for carboxyatractyloside in stomach contents, blood, urine, and aqueous humor
- Gross necropsy: Swollen liver, pulmonary edema, hydrothorax, hydropericardium

FIGURE 1 Cocklebur and two-leafed seedling (inset).

ElibEVet.com

- Histology: Severe diffuse centrilobular hepatocellular necrosis

TREATMENT

THERAPEUTIC GOAL(S)

Acute cocklebur poisoning is seldom treatable because of the acute nature of the toxicity.

ACUTE GENERAL TREATMENT

Early treatment with activated charcoal via a nasogastric tube may decrease absorption of the toxin.

CHRONIC TREATMENT

Supportive therapy

PROGNOSIS AND OUTCOME

Prognosis is poor as a result of diffuse hepatic necrosis.

PEARLS & CONSIDERATIONS

COMMENTS

Cocklebur poisoning in horses is rarely reported, but because of the invasiveness of the plants the potential for poisoning can be high. Germination of massive numbers of cocklebur seedlings in late summer in the muddy shores of ponds or flooded areas poses a high risk.

CLIENT EDUCATION

- Learn to recognize cocklebur plants and burs.
- Remove the plants before they produce seeds.
- Mechanically cultivate, mow, or use appropriate herbicides on the seedlings.

AUTHOR: **ANTHONY P. KNIGHT**

EDITOR: **CYNTHIA L. GASKILL**

Colitis, Antimicrobial Associated

BASIC INFORMATION

DEFINITION

Colitis or diarrhea that occurs during or shortly after administration of antimicrobial drugs

EPIDEMIOLOGY

RISK FACTORS

Antimicrobial administration:

- May occur with any antimicrobial drug but most often associated with:
  - Macrolides and lincosamides (erythromycin, clarithromycin, azithromycin, lincomycin, and clindamycin) in adult horses and foals older than 6 months of age
    - Diarrhea has also been reported in mares whose young foals were receiving erythromycin for treatment of *Rhodococcus equi* infection, presumably because of exposure to erythromycin in the foals' feces.
  - Trimethoprim-sulfamethoxazole
  - Ceftiofur
  - Metronidazole
  - Doxycycline or enrofloxacin, although development of diarrhea with these antimicrobials seems to have some regional specificity
- Changing from one class of antimicrobial to another or concurrent hospitalization, surgery, or gastrointestinal disease may increase the likelihood of development of antimicrobial-associated diarrhea.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Recent or ongoing antimicrobial administration
- Inappetence, colic, fever and diarrhea are most common, as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).

PHYSICAL EXAM FINDINGS As for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

ETIOLOGY AND PATHOPHYSIOLOGY

- Antimicrobial-associated diarrhea presumably results from alteration in the normal colonic bacterial flora, allowing overgrowth of or colonization with a pathogenic bacterial species.
- Overgrowth of toxin-producing *Clostridium difficile* strains has been documented in some horses with antimicrobial-associated colitis, although salmonellosis or diarrhea caused by an overgrowth of an unidentified pathogen may also occur.
- Infection with a pathogenic bacterial species results in damage to and disruption of the colonic mucosal barrier as for other causes of diarrhea (see "Colitis/Diarrhea, Acute" and "Diarrhea, Clostridial" in this section), resulting in fluid, electrolyte, and protein losses and diarrhea as well as signs of endotoxemia and colic.
- Clinical signs are typically, but not always, seen within 1 to 7 days of initiating antimicrobial therapy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

INITIAL DATABASE

As for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

ADVANCED OR CONFIRMATORY TESTING

A presumptive diagnosis of antimicrobial-associated diarrhea is made when a horse develops signs of acute colitis during antimicrobial therapy. However, testing for clostridial toxin production and *Salmonella* infection should be performed (see "Diarrhea, Clostridial" and "Salmonellosis" in this section).

TREATMENT

THERAPEUTIC GOAL(S)

- Provide supportive care.
- Promote reestablishment of normal colonic flora.

ElibeVet.com

ACUTE GENERAL TREATMENT

- Provide fluid and colloidal support, antiinflammatory and antiendotoxic therapy, and other supportive care as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).
- Current antimicrobial therapy should be discontinued and antimicrobials avoided even in severely leukopenic patients if at all possible, with the potential exception of:
  - Metronidazole (15–25 mg/kg PO or PR q8h), which is indicated if the horse was not on metronidazole when the signs developed or if clostridial toxins are detected in the feces.
- Dietary support is critical because provision of adequate roughage in the form of pasture, hay, or easily digestible fiber will aid in facilitating reestablishment of normal colonic flora. All efforts should be made to encourage the horse to eat and to stimulate its appetite.
- Other therapy, including probiotics (eg, *Saccharomyces boulardii*), or di-tri-octahedral smectite (Bio-Sponge), may be beneficial in antimicrobial-associated colitis as for other causes of colitis (see "Colitis/Diarrhea, Acute" and "Diarrhea, Clostridial" in this section).

POSSIBLE COMPLICATIONS

As for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

PROGNOSIS AND OUTCOME

- Fair to good with good clinical response to discontinuing antimicrobials and supportive care
- Guarded to poor with colitis associated with macrolide or lincosamide administration in adult horses (which is often rapidly fatal)

PEARLS & CONSIDERATIONS

- Even though *C. difficile* is considered to play a role in many cases of antimicrobial-associated colitis, some horses do develop diarrhea while taking metronidazole. In these cases, another pathogen (or potentially a metronidazole-resistant strain of *Clostridium* spp.) may be the cause of the diarrhea, so metronidazole should be discontinued and fecal testing for clostridial toxins performed.
- Vancomycin has been effective in treating metronidazole-resistant clostridial organisms in horses, although its use in veterinary medicine is controversial.

AUTHOR: **KELSEY A. HART**

EDITOR: **TIM MAIR**

Colitis/Diarrhea, Acute

BASIC INFORMATION

DEFINITION

Inflammation of the colon

EPIDEMIOLOGY

RISK FACTORS

- Stress: shipping, routine changes, illness, hospitalization
- Recent diet changes
- Recent antimicrobial administration
- Nonsteroidal antiinflammatory drug (NSAID) therapy

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Usually, the horse has a history of depression, fever, inappetence, and mild colic signs, with or without diarrhea, lasting hours to days.
- Occasionally, the horse has an acute onset of severe colic signs and rapid systemic deterioration in the absence of diarrhea. Rarely, in peracute cases, horses are simply found dead.

PHYSICAL EXAM FINDINGS

- Depression
- Variable signs of abdominal pain ranging from none to mild colic or inappetence to severe intractable colic
- Pyrexia
- Variable tachycardia (normal to 80–100 beats/min)
- Variable tachypnea
- Mucous membranes are often injected and may vary in color from bright pink to purple-gray.
- Capillary refill time may range from brisk (<1 second) in the early stages to dramatically prolonged (4–5 seconds) as severe dehydration and endotoxic or septic shock progress.
- There may be evidence of hypovolemia and poor peripheral perfusion (cold extremities, poor jugular refill) in severe cases.
- Hypermotile, "fluidy" gastrointestinal borborygmi
- Gross abdominal distension is occasionally present, especially in severe or peracute cases.
- Diarrhea may be absent or range from soft, formed feces to profuse, watery, or hemorrhagic diarrhea.
- Rectal examination
  - Should be performed in all horses with signs of colic or abdominal distension because concurrent colonic displacements or large or small colon impactions may occur in horses with colitis.
  - Edematous rectal mucosa and fluid colonic contents are often appreciated even when rectal findings are otherwise normal.

ETIOLOGY AND PATHOPHYSIOLOGY

- Initially, the colonic mucosal barrier is damaged focally or diffusely by one of the following:
  - Bacteria in the intestinal lumen, including:
    - Invasion of a primary pathogen (eg, *Salmonella, Neorickettsia risticii*)
    - Overgrowth of or toxin production from a potentially pathogenic organism normally present in low numbers (*Clostridium difficile* and *Clostridium perfringens*) caused by alterations in normal enteric flora associated with stress, dietary changes, or antimicrobial administration
  - Intestinal parasitic infection
  - Toxin ingestion (cantharidin)
  - Altered colonic mural perfusion and mucus production with NSAID therapy
  - Colonic sand accumulation
- Loss of the colonic mucosal barrier allows intraluminal bacteria and bacterial toxins (eg, endotoxin) to invade the colonic wall, stimulating mural inflammation and edema.

ElibeVet.com

- Bacteria and bacterial toxins are also then able to enter the intestinal lymphatic system and systemic circulation, resulting in clinical signs of endotoxemia and the systemic inflammatory response syndrome (fever, tachycardia, tachypnea, congested mucous membranes, and altered hemodynamic status and peripheral perfusion).
- In addition, the damaged mucosal barrier compromises colonic absorptive capacity, resulting in loss of water and electrolytes in the feces, and may permit loss of plasma proteins if the damage is severe.
- See sections "Cyathostominosis," "Salmonellosis," "Diarrhea, Clostridial," "Potomac Horse Fever," "Nonsteroidal Antiinflammatory Drug Toxicity," "Colitis, Antimicrobial Associated," "Colitis X," "Blister Beetles," and "Sand Enteropathy" in this section for more details.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Salmonellosis
- Clostridial diarrhea
- Potomac horse fever
- Cyathostominosis
- NSAID toxicity
- Antimicrobial-associated colitis
- Colitis X
- Cantharidin toxicity
- Sand enteropathy

INITIAL DATABASE

- Complete blood count
  - Leukopenia characterized by neutropenia with increased band neutrophils and toxic changes in neutrophils is typically seen.
  - The hematocrit varies with hydration status but may be markedly increased (>60%) in severe cases.
  - Thrombocytopenia is occasionally present in severe cases with concurrent disseminated intravascular coagulation.
- Serum biochemistry profile
  - Variable electrolyte derangements are common, with hypokalemia, hyponatremia, hypochloremia, and hypocalcemia most common.
  - Serum total protein concentration may be increased with dehydration or normal or low with enteric loss.
  - Variable azotemia is common and may be caused by prerenal or renal causes (or both).
  - Hyperlactatemia (>2 mmol/L) suggests impaired peripheral perfusion and tissue oxygenation caused by hypovolemia.
  - Metabolic acidosis is often present and may be associated with hyperlactatemia, bicarbonate loss in the feces, or both.
- Transabdominal ultrasonography
  - Fluid contents in the colon or cecum are often appreciated.
  - Colonic mural thickness may be increased (>5 mm) focally or diffusely.
- Peritoneal fluid analysis
  - Should be performed in horses that have persistent signs of colic, fever, or leukopenia because peritonitis resulting from translocation of intestinal bacteria or, less often, infarction of the colonic vasculature may occur in severe colitis.
  - In most horses with colitis, grossly normal-appearing peritoneal fluid with a normal nucleated cell count and mildly increased protein concentration (>2 g/dL) is observed.

ADVANCED OR CONFIRMATORY TESTING

- Diagnostic testing for specific causes of colitis in adult horses should include the following:
  - Fecal flotation for intestinal parasites
  - Fecal polymerase chain reaction (PCR) or culture for *Salmonella* spp.
  - Fecal Gram stain and fecal toxin assays for *C. perfringens* and *C. difficile* toxins
  - Serology or whole-blood PCR for Potomac horse fever
  - Fecal sedimentation and abdominal radiography for sand accumulation
  - Positive or negative urinanalysis for cantharidin
- See sections "Cyathostominosis," "Salmonellosis," "Diarrhea, Clostridial," "Potomac Horse Fever," "Sand Enteropathy," and "Blister Beetles" in this section for more details.

TREATMENT

THERAPEUTIC GOAL(S)

- Supportive care: fluid support, antiinflammatory therapy
- Specific therapy for certain causes

ACUTE GENERAL TREATMENT

- IV fluid therapy
  - Fluid resuscitation with hypertonic saline (2–4 mL/kg IV bolus) or hydroxyethyl starch (Hetastarch) (5–10 mL/kg IV bolus) is indicated in severely dehydrated patients.
  - This should be followed by isotonic balanced polyionic crystalloid fluids (eg, Normosol-R or Plasmalyte) at 50 to 150 mL/kg/day, depending on the degree of dehydration and ongoing losses in diarrhea.
  - Supplementation with potassium chloride (10–40 mEq/L with the rate not to exceed 0.05 mEq/kg/h), 23% calcium gluconate (1–2 mL/kg/day), or magnesium sulfate (20–25 g/450 kg/day) is often necessary to correct electrolyte derangements.
  - Administration of sodium bicarbonate may be necessary with severe metabolic acidosis (pH ≤7.1; serum bicarbonate concentration <15 mmol/L), but correction of dehydration often sufficiently corrects metabolic acidosis without the need for additional bicarbonate supplementation.
  - Colloidal support with equine plasma (20–40 mL/kg IV) or hydroxyethyl starch (5–10 mL/kg IV bolus q24–48h or 1 mL/kg/h IV continuous rate infusion [CRI]) is indicated in patients with hypoproteinemia. (Note: Patients with initially normal total protein concentrations may have hypoproteinemia after rehydration.)
  - Horses with colitis are particularly prone to thrombophlebitis. Long-term polyethylene IV catheters should be used and removed at the first sign of a problem with the catheter or vein.
- Antiinflammatory and analgesic therapy
  - Flunixin meglumine: 0.5 to 1.1 mg/kg IV q12h for colic; then decrease to 0.25 mg/kg IV q6–8h for antiinflammatory effects when signs of colic resolve. **Do not use in NSAID toxicity.**
  - Lidocaine: 1.3 mg/kg IV as a slow bolus; then 0.05 mg/kg/min IV CRI for persistent colic or as a primary analgesic in NSAID toxicity
  - Pentoxifylline: 8 mg/kg PO q8–12h (may decrease inflammatory cytokine production and may promote microvascular blood flow by rheologic and antiplatelet effects)
  - Dimethylsulfoxide (90% solution): 20 to 100 mg/kg diluted to less than 10% solution in IV fluids q12h for 1 to 3 days (may scavenge free radicals and limit oxidative injury)
- Antiendotoxic therapy
  - Equine plasma (2–4 L IV or more if hypoproteinemic, regular equine plasma, or hyperimmune plasma with antiendotoxin antibodies may be used) or hyperimmune antiendotoxin serum (Endoserum, 1–2 mL/kg diluted in 3–5 L isotonic fluids IV)
  - Polymyxin-B: 2000 to 6000 IU/kg (diluted in 500–1000 mL 0.9% saline) IV q12h for 1 to 3 days after the patient is hydrated and if renal function is adequate
- Laminitis prophylaxis
  - Placement of frog supports and maintenance in deep bedding should be initiated immediately.

ElibEVet.com

- Periodic or continuous maintenance in ice boots during initial therapy may be helpful in preventing laminitis, although this is not universally accepted.
- If signs of laminitis occur, treatment should be rapid and aggressive (see "Laminitis, Acute" in this section).

- Intestinal absorbents
  - Bio-Sponge (di-tri-octahedral smectite) has been shown to absorb clostridial toxins and may absorb other bacterial toxins as well.
  - Activated charcoal or bismuth subsalicylate (4.5 mL/kg by nasogastric tube q6–12h) may provide similar benefits, although there is less evidence to support their use.
- Diet and nutritional support
  - It is important to encourage appetite and provide adequate nutritional support to horses with colitis. In general, horses with colitis that maintain a good appetite generally have a better prognosis than persistently inappetent or anorectic horses.
  - Early on, minimize concentrates and provide adequate roughage with good-quality grass hay and access to fresh pasture or grass if at all possible.
  - If NSAID toxicity or protracted diarrhea is present, provide a low-residue, easily digestible fiber source such as a complete pelleted equine senior feed.
  - Evaluation for or treatment of gastric ulceration should be considered in horses that are persistently inappetent.
- Antimicrobial therapy
  - Controversial because it can prevent reestablishment of normal enteric flora and does not appear to improve prognosis in most adult horses with colitis.
  - Specific antimicrobial therapy for clostridial diarrhea and Potomac horse fever and occasionally for salmonellosis is indicated (see "Potomac Horse Fever," "Diarrhea, Clostridial," and "Salmonellosis" in this section).
  - Broad-spectrum antimicrobial therapy is indicated in patients with peritonitis or in profoundly neutropenic patients (which are at greater risk of developing secondary infections such as pneumonia or septic thrombophlebitis). This therapy may include:
    - Potassium penicillin: 22,000 IU/kg IV q6h and gentamicin (6.6 mg/kg IV q24h) or enrofloxacin (5 mg/kg IV q24h)
    - Metronidazole: 15 to 25 mg/kg PO or PR may be used to provide additional anaerobic coverage and may be beneficial in patients with suspected clostridial or antimicrobial-induced colitis.
- Other
  - Isolate the patient if at all possible. Minimize exposure of other horses to feces from the patient, clean the patient's stall last, and disinfect tools and equipment used on the affected horse.
  - Loosely wrapping or bagging the tail and daily cleaning of the hind limbs is necessary to prevent scald with severe diarrhea.
  - Probiotic therapy is controversial and not proven to be effective in equine diarrhea, although there is some evidence to support the use of products containing *Saccharomyces boulardii* in horses with colitis (see "Diarrhea, Clostridial" in this section).
  - Some evidence suggests that some horses with severe colitis may be hypercoagulable because of subclinical disseminated intravascular coagulation and thus are at greater risk of thrombotic complications. Heparin (20–40 IU/kg IV or SC q8h) may be beneficial in these cases.

FIGURE 1 Acute colitis. Postmortem appearance of large colon showing severe inflammation and edema of the mucosa.

POSSIBLE COMPLICATIONS

- Laminitis
- Thrombophlebitis
- Peritonitis
- Colonic infarction
- Colonic fibrosis and chronic diarrhea

RECOMMENDED MONITORING

Monitor the packed cell volume, total protein concentration, serum creatinine, and serum electrolyte concentrations closely during initial therapy and tailor fluid therapy accordingly.

PROGNOSIS AND OUTCOME

- Fair to good with adequate supportive care in patients that maintain a good appetite
- Guarded with concurrent laminitis or peritonitis
- Guarded to poor with severe abdominal distension, persistent colic, or serosanguineous peritoneal fluid

PEARLS & CONSIDERATIONS

- It is important to note that colitis may occur in the absence of diarrhea (because of the massive absorptive capacity of the equine colon) and should be considered as a differential diagnosis in any horse with colic or fever of unknown origin.
- Even though colitis is successfully managed medically in the majority of cases, exploratory celiotomy should be considered in horses with suspected colitis that have persistent and severe colic signs to rule out an obstructive lesion and evaluate the integrity of the colon.

ElibVet.com

Colitis X

BASIC INFORMATION

DEFINITION

Peracute colitis, endotoxic shock, and anaphylaxis of unknown etiology

EPIDEMIOLOGY

CONTAGION AND ZOONOSIS Although an infectious or toxic cause is suspected, disease typically occurs in an individual horse on a farm rather than as an outbreak.

HISTORY, CHIEF COMPLAINT

- Severe colic, fever, and acute collapse with or without diarrhea are most often observed.
- Some horses are simply found dead without observation of prior illness.

PHYSICAL EXAM FINDINGS

- Severe depression to obtundation or severe, intractable colic.
- Pyrexia is common, but hypothermia may be present in terminal cardiovascular collapse.
- Tachycardia
- Tachypnea
- Red to purple mucous membranes and dramatically prolonged capillary refill time.
- Mild to severe abdominal distension.
- Decreased to absent gastrointestinal borborygmi.
- Severe (± hemorrhagic) diarrhea, soft feces, or scant manure may be noted.
- Rectal examination usually reveals edema in the rectum and colon wall. Occasionally, large colonic gas distension may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of colitis X is unknown, although an infectious or toxic cause is suspected.
- The severe colonic edema and mucosal damage observed in horses with colitis X is believed to be a specific organ manifestation of anaphylaxis in response to an unknown antigen.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Peracute salmonellosis
- Clostridial diarrhea
- Cantharidin toxicity
- See "Salmonellosis," "Diarrhea, Clostridial," and "Blister Beetles" in this section

INITIAL DATABASE

- Other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)
- Leukopenia and typical electrolyte derangements are usually seen, but the presentation occasionally may be so acute that clinicopathologic abnormalities are not observed.
- Transabdominal ultrasonography typically reveals moderate to severe focal or diffuse edema in the colon wall (>5–10 mm thick).

ADVANCED OR CONFIRMATORY TESTING

- Testing for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section) should be performed.
- A diagnosis of colitis X is made based on the peracute presentation and typical clinical signs in conjunction with characteristic pathologic findings and the absence of detection of a specific pathogen.
- Gross and histopathologic findings at necropsy include severe, segmental, or diffuse colonic edema with or without focal regions of mural hemorrhage. Evidence of endotoxic shock and cardiovascular collapse is also noted.

TREATMENT

THERAPEUTIC GOAL(S)

Supportive care

ACUTE GENERAL TREATMENT

- Fluid and colloidal support, antiinflammatory and antiendotoxic therapy, and other supportive care should be initiated as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).
- However, affected horses usually do not respond or respond only transiently to treatment and die despite aggressive therapy.

PROGNOSIS AND OUTCOME

Grave

PEARLS & CONSIDERATIONS

Horses with peracute salmonellosis or clostridial colitis may present very similarly. Thus isolation of affected horses and comprehensive testing for these pathogens should be performed because of the potential risk of disease in herdmates and other exposed horses.

Compartment Syndrome

BASIC INFORMATION

DEFINITION

An increase in pressure in a confined anatomic space that leads to ischemic damage to the tissue

EPIDEMIOLOGY

RISK FACTORS

- Anesthesia
- Fracture
- Puncture wound
- Infection (ie, *Clostridium* spp.)
- Soft tissue trauma
- Circumferential burns
- External bandage, cast, or splint
- Reperfusion injury
- Arterial or venous obstruction
- Intense exercise
- Envenomation

ASSOCIATED CONDITIONS AND DISORDERS

- Most commonly occurs in soft tissue structures that are bounded by fascia and bony structures

ElibeVet.com

- May occur with any condition in which perfusion pressure decreases below tissue pressure in a closed anatomic space

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT History of anesthesia, trauma, infection, burns, perfusion abnormalities, intense exercise, or snakebite

PHYSICAL EXAM FINDINGS

- The most common clinical sign is tense muscle swelling with a decreased range of motion of the affected area.
- Paraesthesia with pain that is more than expected with the diagnosed injury may be noted.
- Pulselessness is recognized in humans and may be present in horses as well.

ETIOLOGY AND PATHOPHYSIOLOGY

- Soft tissue injury results in swelling in the confined space.
- Tissue pressures increase because of edema and hemorrhage.
- When the tissue pressure increases above the diastolic blood pressure, circulation is impaired, leading to decreased tissue oxygenation and alterations in cell metabolism.
- Cells may be irreversibly damaged with severe oxygen depletion because of release of inflammatory mediators and histamine.
- Muscle and nervous tissue are the most sensitive to the negative effects of compartment syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Avascular necrosis
- Venous thrombosis

INITIAL DATABASE

- Intracompartmental pressure measurements are useful for diagnosis in humans.
  - No methods have been developed to measure compartmental pressures consistently in horses.
  - Diagnosis is made from clinical signs and history.

TREATMENT

THERAPEUTIC GOAL(S)

Restore perfusion to the soft tissues.

ACUTE GENERAL TREATMENT

- Remove any constricting bandages or casts.
- Place the limb at the level of the heart if the patient is recumbent.
- Change the recumbency of the patient (ie, from left lateral to right lateral) every 3 to 4 hours.
- Corticosteroids and anticoagulants may be beneficial. Vascular structures must be patent for medications to have effect.
- Surgical decompression via a fasciotomy is the gold standard (Figure 1). Perform a large longitudinal incision with scissors or a scalpel blade.
  - Avoid vessels or nerves.
  - Ensure release of all constricting fascia.
  - Remove necrotic tissue.
- Direct muscle visualization is recommended in humans. Cover the fasciotomy with a moist, sterile dressing.
- Three to 5 days after fasciotomy, the incision can be closed if the patient is doing well.

FIGURE 1 Compartment syndrome occurring after a constricting tail wrap. Approximately 75% of the tail was affected. Fasciotomy was performed twice with daily debridement, and the wounds covered with silver sulfadiazine to allow for moist healing. The tail fully healed without amputation. Sensation and hair follicles were preserved.

POSSIBLE COMPLICATIONS

- Complications associated with fasciotomy include scarring, infection, hematoma, deep vein thrombosis, and neurovascular injury.
- An incomplete fasciotomy may cause chronic stiffness and muscle contracture.

PROGNOSIS AND OUTCOME

Long-term prognosis for the horse is good for life as long as the inciting cause for the compartment syndrome has been addressed and corrected.

PEARLS & CONSIDERATIONS

COMMENTS

If left untreated, postischemic scarring and contracture may occur.

ElibeVet.com

Congenital Heart Disease

BASIC INFORMATION

DEFINITION

Congenital heart disease (CHD) is caused by malformations of the heart or great vessels related to abnormal formation of the embryonic heart that are present at birth. Anatomic defects range from simple to complex and from trivial to life threatening. CHD is potentially heritable.

SYNONYM(S)

- Congenital heart defects
- Cardiac malformations

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most commonly recognized in foals and yearlings but may also be identified in older horses.
- Severe, complex, or multiple malformations often cause clinical signs in foals.

GENETICS AND BREED PREDISPOSITION The prevalence of CHD is unknown, but cardiac defects were identified in 3.5% of foals examined at necropsy. It is possible that some defects carry a genetic liability. Arabian horses may be predisposed to ventricular septal defect (VSD) and tetralogy of Fallot.

RISK FACTORS There are no proven associations for CHD in horses. Potential but unproven causes include drugs, viral infection, environmental toxins, and nutritional disorders.

ASSOCIATED CONDITIONS AND DISORDERS CHD generally occurs in isolation but may be associated with persistent fetal circulation or respiratory infection.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Various classification schemes can be used to categorize CHD, including systems assessing segmental concordance of veins, atria, ventricles, and great vessels along with morphologic lesions of the valves and cardiac septae. A clinical classification includes:
  - Shunts: Communications between systemic and pulmonary circulations at the level of the atria (atrial septal defect [ASD]), ventricle (VSD), or ductus arteriosus (patent ductus arteriosus [PDA]).
    - VSDs are considered the most common heart malformation and can be single, multiple, small, or large. The aorta may be malaligned and override the septum.
    - In most cases, a VSD is paramembranous (perimembranous), meaning the hole is dorsal and involves the fibrous component of the septum. Echocardiographically, these defects are below the right and noncoronary cusps of the aortic valve, adjacent to the tricuspid valve, and ventral to the supraventricular crest ("subcristal").
    - Other locations include muscular ("apical," "trabecular"); right ventricular inlet septum (ventral to the septal tricuspid leaflet); and subarterial, below each semilunar valve ("supracristal").
    - Cardiac auscultation and echocardiographic examination findings are influenced by the location of the defect.
    - Aortic regurgitation may develop from aortic root prolapse.
  - Valvular malformations are rare.
    - Stenosis or atresia of the pulmonic and tricuspid valves leads to right-to-left intracardiac shunting across an ASD or VSD, causing cyanosis.
    - Aortic valve, mitral valve, and associated left ventricular malformations may lead to shock or congestive heart failure (CHF).
  - Complex CHD in horses includes endocardial cushion defects, common atria, single ventricle, tetralogy of Fallot, and malformation or malposition of the great vessels. The latter include double-outlet right ventricle, persistent truncus arteriosus, and transposition of the great vessels generally associated with one or more defects in the cardiac septae.

HISTORY, CHIEF COMPLAINT

- Many affected animals demonstrate no overt clinical signs other than a heart murmur.
- Complex CHD or severe defects may cause exercise intolerance or signs of CHF, including tachypnea and ventral edema.
- Failure to grow or unthriftiness may be evident.
- Atrial fibrillation (AF) may develop from cardiac enlargement.

PHYSICAL EXAM FINDINGS

- CHD should be considered in any horse with a prominent heart murmur and should be suspected in foals and yearlings with loud murmurs or a palpable precordial thrill.
- Cardiac murmurs are characterized by timing, point of maximal intensity, loudness or grade, radiation, and character (see "Cardiac Auscultation" in Section II).
- The typical holosystolic murmur of a paramembranous VSD is loudest over the right, ventral-cranial thorax. An ejection murmur may be heard over the craniodorsal heart base on the left.
- Subarterial VSD is often loudest over the pulmonic valve area and left craniodorsal heart base.
- Diastolic murmurs typically indicate the presence of aortic regurgitation.
- Continuous murmurs may be caused by persistent PDA.
  - Tachypnea, exercise intolerance, or cyanosis in foals is most often caused by respiratory disease or infection; however, CHD should also be considered.
  - Tricuspid or pulmonary atresia often produces profound cyanosis.
  - Potential signs of CHF include tiring, tachypnea, and respiratory distress.
  - Jugular venous distension, ventral edema, pleural effusion, and resting tachycardia are typical signs of right-sided or biventricular CHF.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathophysiology of VSD is caused by left-to-right shunting with volume overload of the left ventricle. Right-sided enlargement depends on the size of the defect and the presence of obstruction to right ventricular outflow.
  - A large VSD creates a functional "common ventricle," and shunting occurs along the path of lowest resistance.
  - When pulmonary vascular resistance is normal, signs relate to high pulmonary blood flow with risk of left-sided or biventricular CHF.
  - When complicated by pulmonic stenosis, pulmonary atresia, or high pulmonary vascular resistance, a right-to-left shunt may occur, and clinical signs stem from limited cardiac output and arterial hypoxemia.
- Complex abnormalities of segmental discordance also follow these general rules, and signs relate largely to the amount of pulmonary over- or undercirculation.
- Clinical signs in primary valvular malformation are similar to those observed in other species.
- Superimposition of AF in moderate to severe CHD may impair exercise capacity or precipitate CHF.

ElibEVet.com

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Functional ejection murmurs are ubiquitous and may pose a diagnostic dilemma. An ejection murmur loudest over the great vessels is found with some cardiac defects, but in most cases, a left basilar ejection murmur simply represents a functional (flow) disturbance unrelated to heart disease (see "Cardiac Auscultation" in Section II).
- The differential diagnosis of a loud heart murmur (with or without CHF) includes CHD, infective endocarditis, degenerative valvular disease, valvulitis, ruptured chordae tendineae, myocarditis, cardiomyopathy, tachyarrhythmia-induced cardiomyopathy, and aorto-cardiac fistula (ruptured aortic sinus into the heart). Pericarditis may create a friction rub.

INITIAL DATABASE

- Complete physical examination
- Auscultation of the heart and lungs
- Examination of the precordium for thrills, cardiac displacement, or increased area of cardiac dullness
- Inspection of mucous membranes
- Palpation of the arterial pulse
- Visual assessment of jugular venous pulse and pressure
- Two-dimensional imaging of the heart for enlargement and overt lesions

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography complemented by Doppler studies is the gold standard for diagnosis of CHD.
  - Quantitation of defect or heart size is useful for identifying moderate to severe defects. VSD measuring less than 2.5 cm across the greatest diameter (in mature horses) is often well tolerated. Right ventricular wall hypertrophy suggests pulmonary stenosis, vascular disease, or a functionally common ventricle. Moderate to severe left atrial dilatation suggests a hemodynamically important shunt, mitral valve disease, or left ventricular failure.
  - Contrast echocardiography with agitated saline may identify a right-to-left shunt.
  - Color Doppler studies can identify abnormal flow patterns from shunting or valvular disease.
  - Spectral continuous wave Doppler can quantify pressure differences. A VSD flow of greater than 4.5 m/s indicates a small (restrictive) defect. High-velocity tricuspid regurgitation (>4 m/s) indicates right ventricular outflow obstruction or pulmonary hypertension.
- An electrocardiogram should be recorded if an arrhythmia is evident.
- Arterial blood gas and packed cell volume are indicated in cases of cyanosis.
- Thoracic radiography, thoracic ultrasonography, airway endoscopy, or cytologic evaluation of tracheal wash fluid should be considered when there are signs of primary lung or pleural disease.

TREATMENT

THERAPEUTIC GOAL(S)

- Definitive therapy for VSD involves cardiopulmonary bypass surgery; however, new "hybrid" procedures involving catheter devices delivered by a transventricular approach and guided by epicardial echocardiography are possible, although perhaps not practical.
- Medical management of CHF or of arrhythmias associated with CHD may be considered.
- Breeding of affected animals should be discouraged, especially in Arabian horses.

ACUTE GENERAL TREATMENT

If CHF develops, initial treatment includes IV digoxin and furosemide.

CHRONIC TREATMENT

- Exercise capacity should be assessed and exercise limited if indicated. In many cases, the lesion does not create an obvious problem.
- Chronic therapy of CHF if deemed appropriate (see "Cardiac Failure" in this section)
- Horses with AF can be treated with quinidine or electrocardioversion if indicated. Significant cardiomegaly reduces success and predisposes to reversion to AF.
- Horses with severe malformations should not be used or bred. When clinical signs are severe, persistent, or associated with poor quality of life, euthanasia may be suggested.

DRUG INTERACTIONS

- Drugs increasing pulmonary vascular resistance worsen right-to-left shunting.
- Drugs increasing systemic vascular resistance increase left-to-right shunting.

POSSIBLE COMPLICATIONS

Sudden death, progressive cardiomegaly, CHF, arrhythmias, and arterial hypoxemia

RECOMMENDED MONITORING

- Horses with mild to moderate CHD should be reevaluated at least yearly by history, auscultation, and echocardiography. Cases of moderate to severe CHD should be examined more often.
- Exercise intolerance, tachypnea, tachycardia, or ventral edema should prompt immediate reassessment.

PROGNOSIS AND OUTCOME

- Prognosis is highly variable, depending on the lesion and severity.
- Potential outcomes for VSD include tolerance, partial or complete closure by adherence of the tricuspid valve or fibrous tissue, or from aortic valve prolapse; progressive aortic regurgitation; AF; CHF; pulmonary hypertension; or reversal of the shunt with arterial hypoxemia and cyanosis.

PEARLS & CONSIDERATIONS

COMMENTS

- The rare occurrence of aortic and pulmonic stenosis reduces the indication for echocardiography in horses with soft to moderate ejection murmurs over the left craniodorsal heart base. In most of these cases, the murmur is functional.
- Many murmurs of VSD are loudest at the right ventral thorax.
- One cannot prognosticate from the loudness of a murmur.
- When a cardiac malformation is found in a foal, the mare should also be auscultated for possible CHD.
- Consultation with a specialist experienced in CHD is helpful.

PREVENTION

Do not breed horses with known CHD.

CLIENT EDUCATION

CHD can negatively impact the life, use, and value of a foal and cast doubt on the genetic reliability of the mare or stallion.

Contagious Equine Metritis

BASIC INFORMATION

DEFINITION

Contagious equine metritis (CEM) is a nonsystemic, highly contagious venereal infection of members of the family Equidae caused by *Taylorella equigenitalis*, a bacterium unrecognized before 1977.

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION To date, there is no evidence of variation among horse breeds with respect to susceptibility to *T. equigenitalis* infection. This also applies to different breeds of ponies that have been investigated. Based on experimental findings, donkey jennies can be successfully infected with *T. equigenitalis*, although the associated clinical signs tended to be less pronounced and of shorter duration than observed in pony mares.

RISK FACTORS

- Direct or indirect venereal contact with *T. equigenitalis*
- Occurrence of the carrier state in the stallion and the mare
- International or national movement of stallions and mares and shipment of semen
- Certain management practices (eg, "vanning in" or "walking-in" of mares to be bred naturally or by artificial insemination [AI])
- Failure to observe appropriate sanitary measures when breeding stallions naturally or when collecting semen for AI

CONTAGION AND ZOONOSIS

- Transmission of CEM occurs primarily by the venereal route through:
  - Direct genital contact between an infected mare and a stallion or vice versa
  - AI with semen from a carrier stallion. The risk of transmission by AI is significantly reduced by the use of extenders containing appropriate antibiotics. Spread of CEM through cryopreserved semen remains to be determined.
  - Indirect genital contact with fomites contaminated with *T. equigenitalis*, such as vaginal specula, forceps, obstetrical sleeves, and tail bandages used in examination of the reproductive tract of the mare. Failure to observe appropriate sanitary measures when handling the external genitalia of stallions has also been implicated in the indirect transmission of CEM. Among the items believed of major importance as potential sources of contagion in stallion collection centers is the external covering of the phantom, artificial vaginas, and wash buckets.
- Transplacental infection of the fetus
- Contact of the external genitalia of the foal with a *T. equigenitalis*–positive placenta or clitoral area of an infected mare at the time of foaling
- Exposure of the external genitalia of postpartum foal to bedding or pasture contaminated with *T. equigenitalis* infective placental fluids or vaginal discharge
- Transmission between stallions and colts through the use of common sponges or cloths contaminated with *T. equigenitalis* to wash the external genitalia
- CEM is not a zoonotic disease.

GEOGRAPHY AND SEASONALITY

- CEM has been reported to have occurred in some 29 countries worldwide since the disease was initially recognized in 1977. In countries where it is currently known or believed to occur, the infection is endemic largely in non-Thoroughbred breeds.
- Outbreaks of CEM and infection with *T. equigenitalis* invariably occur during the breeding season, whether in the Northern or Southern Hemispheres. On the other hand, carrier stallions or mares can be detected at any time either when undergoing pre- or post-entry testing required by an importing country or as part of a pre-breeding season screening program to identify carrier animals.

ASSOCIATED CONDITIONS AND DISORDERS Clinical signs of CEM in mares can closely mimic those caused by several serotypes of *Klebsiella pneumoniae* (1, 2, and 5 and possibly types 7 and 39), *Pseudomonas aeruginosa*, *Streptococcus equi* subsp. *zooepidemicus*, *Escherichia coli*, and (uncommonly) sporadic infections caused by other miscellaneous bacteria.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- CEM is an acute venereally transmissible disease that is restricted to the reproductive tract in mares. It is a non–life-threatening infection that is characterized by short-term infertility and very rarely, abortion around 7 months' gestation.
- The clinical outcome after primary exposure in a mare can vary considerably from overt disease to asymptomatic infection. *T. equigenitalis* exists as a commensal on the external genitalia of the stallion, causing neither a local nor systemic inflammatory reaction.

HISTORY, CHIEF COMPLAINT

- After an incubation period of 2 to 13 days, typically affected mares may present with an odorless, greyish-white, mucopurulent vulvar discharge of uterine origin. This can vary in amount and may persist for 2 weeks or longer. The discharge is accompanied by an endometritis, cervicitis, and vaginitis of varying severity.
- Irrespective of the presence or absence of clinical signs of infection, most mares fail to conceive after primary exposure to *T. equigenitalis* and return to estrus after a shortened diestrus period. The resultant infertility is short term with no long-term adverse effects on a mare's fertility. Persistence of *T. equigenitalis* in the reproductive tract of the mare need not compromise the maintenance of a normal pregnancy and birth of a healthy foal.

PHYSICAL EXAM FINDINGS

- Clinical signs of the disease are only found in mares, with stallions being asymptomatic carriers of the organism. In clinical cases of infection, affected mares develop a severe, diffuse acute endometritis along with inflammation of the cervix and vagina.
- Acutely or chronically infected mares are afebrile without displaying any clinical signs of systemic illness. Typical cases of CEM have a mucopurulent vulvar discharge, which may be so profuse as to run down the hindquarters, wetting the entire perineal area and inside the thighs and matting the tail hairs. In contrast, other mares may merely have a bead of discharge at the lower commissure of the vulva. Intrauterine fluid accumulation can often be detected on ultrasonographic examination of affected mares. On vaginoscopic examination, discharge can be observed seeping between the folds of the external os of the cervix and accumulating on the floor of the vagina. Affected mares have a concomitant cervicitis and vaginitis, which may be more severe than seen in other bacterial infections of the reproductive tract in the mare.

ETIOLOGY AND PATHOPHYSIOLOGY

- *T. equigenitalis* is a gram-negative, non–acid-fast coccobacillus.
- The bacterium has fastidious growth requirements, growing best on choco-

ElibeVet.com

latized blood agar under microaerophilic conditions of incubation.
- Two biotypes of *T. equigenitalis* exist, those that are sensitive and those that are resistant to streptomycin.
- *T. equigenitalis* is nonfermentative and nonproteolytic but is cytochrome oxidase, catalase, and alkaline phosphatase positive.
- In late 1997 and early 1998, a second species of *Taylorella* spp., *Taylorella asinigenitalis*, was identified in several donkeys, horse mares, and a stallion in the United States. This bacterium has yet to be confirmed as a cause of venereal disease in donkey jennies or mares.
- Mares acutely affected with CEM develop a severe diffuse endometritis and cervicitis, with accumulation of exudate between the endometrial folds that are edematous and congested.
- Mild multifocal salpingitis was a frequently observed feature in one experimental study on CEM.
- Cellular infiltration of the endometrium, which initially is primarily neutrophilic, becomes predominantly plasmacytic by 14 days.
- Subsequently, a mild diffuse or multifocal lymphocytic infiltration supervenes that can persist for up to 3 to 4 months after infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

A clinically similar infection of the reproductive tract can be caused by any of the following:
- *K. pneumoniae* (types 1, 2, 5 and possibly types 7 and 39)
- *P. aeruginosa*
- *S. equi*, subsp. *zooepidemicus*
- *E. coli*
- Miscellaneous other bacteria

INITIAL DATABASE

- Vaginoscopic and ultrasound examination of the reproductive tract of the mare
- Smears of endometrial and cervical swabs, and any vaginal discharge for cytologic examination using a rapid differential staining technique. The presence of numerous neutrophils, desquamated epithelial cells, and bacteria morphologically similar to *T. equigenitalis*, either free or phagocytosed within neutrophils, is strongly suggestive, although not confirmatory of CEM.
- Collection of individual endometrial or cervical swabs together with swabs from the clitoral fossa and clitoral sinuses and a specimen of vaginal discharge (if present) for bacteriologic culture and polymerase chain reaction (PCR) examination
- Screening stallions for *T. equigenitalis* is based on collecting individual swabs from the urethral fossa, urethral diverticulum, terminal urethra, and external surface of the penis and sheath for bacteriologic culture and PCR examination.
- Mares and stallions should be swabbed three times with at least 3 days between each sampling.
- It is very important that the culture sites in the mare and the stallion are appropriately sampled, the swabs immediately transferred to individual tubes of Amie's transport medium with charcoal, and the specimens kept refrigerated and plated out in the laboratory within 48 hours of collection.

ADVANCED OR CONFIRMATORY TESTING

- Bacteriologic culture is still the most widely accepted means of confirming the presence of *T. equigenitalis* in mares and stallions. It provides the opportunity to determine the cultural, antimicrobial sensitivity, and pathogenic and antigenic characteristics of isolates of the organism. It is a sensitive although somewhat lengthy means of diagnosing CEM.
- The PCR assay may provide a more rapid and sensitive method of demonstrating *T. equigenitalis* on swabs collected from mares or stallions. Preliminary data on the reliability of this assay in detecting the bacterium in extended or cryopreserved semen, although promising, requires additional verification.
- Test breeding is highly reliable for confirming the carrier state in stallions. It is based on demonstration of *T. equigenitalis* in the reproductive tract in one or both test mares or the development of CF antibodies to the organism within 15 to 40 days after breeding.
- Serology or the development of CF antibodies to *T. equigenitalis* is only of value in confirming recent infection in mares. Stallions do not mount a detectable humoral antibody response to the bacterium.

TREATMENT

THERAPEUTIC GOAL(S)

The goals of treatment of CEM are twofold:
- Promote more rapid resolution of clinical signs of the disease in the mare.
- Eliminate *T. equigenitalis* from the sites of persistence in the carrier stallion and the mare.

ACUTE GENERAL TREATMENT

- Although *T. equigenitalis* is sensitive to a wide range of antimicrobial drugs in vitro, currently, no one treatment necessarily guarantees both rapid resolution of clinical signs and clearance of the carrier state in mares.
- Mares with acute endometritis can be effectively treated by the intrauterine infusion of ampicillin (2 g in 60-mL saline or gentamicin [buffered] for each of 3 to 5 days); this may be combined with systemic treatment with sulfamethoxazole-trimethoprim (30 mg/kg PO for 5 days).

CHRONIC TREATMENT

- Treatment of clitoral carrier mares requires prior removal of any smegma-type material from the clitoral sinuses by flushing them with a cerumenolytic agent followed by irrigation with 4% chlorhexidine gluconate before packing them with 0.2% nitrofurazone or 1% silver sulphadiazine ointment.
- The clitoral fossa and sinuses are scrubbed for 4 more days with 4% chlorhexidine and packed with 0.2% nitrofurazone or 1% silver sulphadiazine ointment.
- Topical treatment of the distal reproductive tract of the mare may be combined with systemic treatment with sulfamethoxazole-trimethoprim (30 mg/kg PO for 5 days), and if dealing with a uterine carrier, with intrauterine infusion of ampicillin (2 g in 60-mL saline or gentamicin [buffered] for 3 to 5 days).
- In the case of carrier stallions, the external genitalia are scrubbed once a day for 5 days with 4% chlorhexidine scrub and the penis and sheath liberally covered with 0.2% nitrofurazone or 1% silver sulphadiazine ointment, with care being taken to pack the ointment into the urethral fossa and urethral sinus.
- Treatment of the external genitalia of the stallion may be combined with systemic administration of sulfamethoxazole-trimethoprim (30 mg/kg PO for 7 days).

POSSIBLE COMPLICATIONS

- Treatment of some carrier mares and stallions may have to be repeated one or more times before *T. equigenitalis* is finally eliminated from the reproductive tract.
- Carrier mares refractive to repeated treatments may have to undergo surgical ablation of the clitoral sinuses.

ElibVet.com

RECOMMENDED MONITORING

- After treatment, mares and stallions need to be retested by bacteriologic culture of the sampling sites prescribed for each, beginning no less than 21 days after the last day of topical treatment and no less than 7 days after completion of systemic treatment.
- In the case of mares, three sets of swabs must be collected at a sampling interval of not less than 3 days within a 7- to 12-day period to confirm the absence of infection.
- Treated stallions must be swabbed at least once before being test bred to two mares and confirmed culture negative for *T. equigenitalis*. Both test mares must remain culturally and serologically negative for infection up to 21 days after being test bred.
- Swabs from mares and stallions may also be subjected to PCR testing, with similar negative results for evidence of *T. equigenitalis*.

PROGNOSIS AND OUTCOME

- Clinical signs of CEM in the mare will resolve in time even without recourse to treatment.
- Although most mares acutely infected with *T. equigenitalis* clear the organism from their reproductive tract after resolution of signs of the disease, a percentage remain asymptomatically infected for months or years, the great majority as clitoral carriers and a much smaller number as uterine carriers.
- A clinically inapparent carrier state can be established in a significant percentage of stallions exposed to *T. equigenitalis*. Preferred sites of persistence of the organism are the urethral fossa and associated sinus. The carrier state can persist in the untreated stallion for years.
- Elimination of *T. equigenitalis* from the reproductive tract of the carrier mare and stallion can be successfully achieved after one or more courses of treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Although considered of questionable veterinary medical importance by sectors of the equine industry in some countries, CEM remains one of the most regulated OIE-listed Equine diseases in terms of international trade.
- *T. equigenitalis* has the potential to cause significant economic loss in previously unexposed breeding populations.
- The ease with which CEM can be spread internationally through the movement of carrier stallions and mares represents a continuing risk for countries with established freedom from the disease.
- Although evidence suggests that transmission of CEM can occur through the use of extended semen, the risks associated with the use of cryopreserved semen from a carrier stallion remain to be determined.
- Additional research may reveal that certain strains of the closely related bacterium *T. asinigenitalis* also have the potential to cause venereal disease in mares and donkey jennies.

PREVENTION

- CEM should be made a notifiable or if nonnotifiable, a reportable disease.
- Availability of laboratories with proven ability to provide a fully reliable diagnostic service for CEM
- More stringent standards of management and hygiene on breeding farms and at stallion collection centers
- Use of disposable or sterile equipment and materials in breeding sheds and at collection centers
- Comprehensive screening of stallions and mare populations to detect carrier animals
- Stallions and mares cultured positive for *T. equigenitalis* should not be used for breeding until proven free from the bacterium.
- Comprehensive postentry testing all stallions and mares imported from countries in which CEM is known or suspected to occur
- Currently, there is no vaccine against CEM.

CLIENT EDUCATION

- Availability of educational materials on CEM to increase awareness of the salient features of the disease among stallion and mare owners and breeders
- Seminars on how to improve breeding practices and management of stallions and mares to minimize the risk of spread of CEM and other venereal infections on farms and at stallion collection centers
- Through meetings and educational releases, emphasize:
  - The potential economic importance of CEM and not just in terms of international trade
  - The insidious nature of the disease in that many first-time infected mares will not develop overt clinical signs other than a period of temporary infertility lasting one or two estrous cycles.

Corneal Ulcers, Superficial Nonhealing

BASIC INFORMATION

DEFINITION

A superficial, nonhealing, noninfected corneal ulcer

SYNONYM(S)

Indolent ulcer

EPIDEMIOLOGY

RISK FACTORS

- Any type of ocular trauma
- Feeding hay from hay bags, nets, or balls

ElibeVet.com

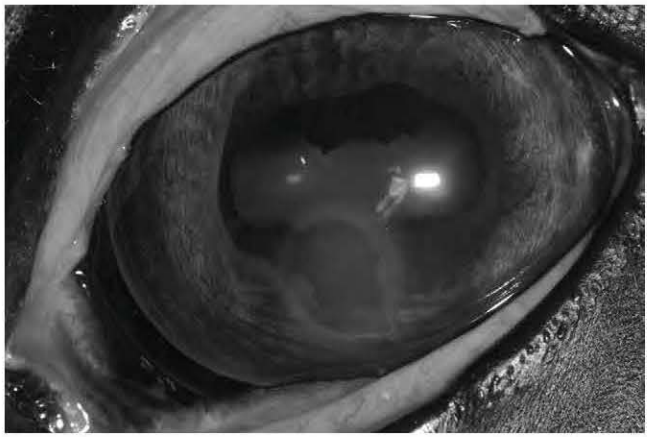

FIGURE 1 Superficial nonhealing corneal ulcer in a horse.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Superficial nonhealing corneal ulcer

HISTORY, CHIEF COMPLAINT Chronic, nonhealing corneal ulcer that is nonresponsive to topical medications

PHYSICAL EXAM FINDINGS Indolent corneal ulcers in horses are similar to small animal indolent ulcers. The characteristic appearance is a superficial ulcer with a redundant epithelial border. Other signs include minimal corneal neovascularization, focal edema, and moderate discomfort (Figure 1).

ETIOLOGY AND PATHOPHYSIOLOGY

- Superficial nonhealing cornea ulcers are chronic ulcers in which the corneal epithelium will not adhere to the underlying corneal stroma.
- A defect of the superficial corneal stroma is suspected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of corneal ulceration should be ruled out before a diagnosis is made.

- Foreign body (eg, burdock bristles)
- Ectopic cilia, distichiasis
- Infectious keratitis
- Viral keratitis
- Lagophthalmos (eg, facial nerve paralysis)
- Neurotrophic keratitis (lack of cranial nerve V innervation)
- Chronic trauma

INITIAL DATABASE

A bacterial and fungal culture should be submitted from all corneal ulcers in the horse. Cultures should be obtained from the margin of the ulcer itself before any therapeutic or diagnostic agents are distilled in the eye. After a culture has been obtained and the cornea has been fluorescein stained, topical anesthetic is applied, and a scraping is obtained from the ulcer for cytologic examination. The cells are placed on a glass slide and stained to examine for bacteria, fungal hyphae, and cell types. Gram, Giemsa, and Diff-Quik stains work well for examination. Only epithelial cells and a few neutrophils are typical of chronic superficial nonhealing corneal ulcers.

ADVANCED OR CONFIRMATORY TESTING

Corneal biopsy after superficial keratectomy

TREATMENT

THERAPEUTIC GOAL(S)

Treatment of indolent ulcers includes searching for the cause (foreign bodies, ectopic cilia, eyelid abnormality, repeated trauma) and promoting adherence of the epithelium to the corneal stroma.

ACUTE GENERAL TREATMENT

Treatment options reported in horses include

- Medical therapy
  - Topical broad-spectrum antimicrobials (eg, oxytetracycline)
  - Topical atropine if secondary uveitis
  - Systemic nonsteroidal antiinflammatory drugs to assist in pain control
- Surgical therapy (if nonresponsive to medical therapy)
  - Superficial keratectomy
  - Grid keratotomy has *not* been shown to be beneficial for healing in horses.

CHRONIC TREATMENT

Superficial keratectomy: Results in healing within 10 to 14 days

POSSIBLE COMPLICATIONS

The most common complication is bacterial or fungal keratitis caused by a chronic corneal ulcer.

RECOMMENDED MONITORING

Examine daily until the cornea has healed.

PROGNOSIS AND OUTCOME

Generally good with time

PEARLS & CONSIDERATIONS

COMMENTS

These ulcers are frustrating to treat and generally take up to 4 to 6 weeks to heal.

PREVENTION

- Minimizing ocular and corneal trauma may help prevent the development of infected corneal ulcers.
- Use of a quality fly mask is recommended.
- Feeding hay on the ground is recommended to minimize ocular trauma.

CLIENT EDUCATION

Client communication is essential so that expectations are not too high for quick healing of the corneal ulcer.

ElibVet.com

Corynebacterium Pseudotuberculosis Infection

BASIC INFORMATION

DEFINITION

Corynebacterium pseudotuberculosis causes suppurative processes and abscesses in several species. The biotype *equi* affects horses and occasionally cattle.

SYNONYM(S)

- For external abscesses: Pigeon fever, dryland distemper, false strangles
- For corynebacterial folliculitis: Contagious acne

EPIDEMIOLOGY

SPECIES, AGE, SEX

- May affect horses of any age (ranging from 3 months to 28 years), but young horses (ages 1 to 5 years) appear more susceptible.
- No sex predilection, although mares might be overrepresented

RISK FACTORS Other cases on the premises

CONTAGION AND ZOONOSIS

- Not contagious between horses; however, abscesses serve as source of environmental contamination
- Zoonotic potential exists; humans can develop lymphadenitis and pneumonia.

GEOGRAPHY AND SEASONALITY

- Endemic areas include the Southwestern United States, Australia, and Brazil.
- Soil-borne organism found worldwide; infection can occur any time of the year.
- Cases of external and internal abscesses occur mostly in endemic areas, and more frequently during fall and early winter, especially after heavy rainfall.
- Seasonal incidence appears to associate with presence of biting insects (eg, *Haematobia irritans*, *Musca domestica*, *Stomoxys calcitrans*, and *Culicoides* spp).

ASSOCIATED CONDITIONS AND DISORDERS

- *C. pseudotuberculosis* infection is characterized by a suppurative process and abscessation in several animal species but is recognized as the cause of specific disease syndromes only in horses and small ruminants.
- *C. pseudotuberculosis* infection in sheep and goats is known as caseous lymphadenitis.
- Organisms survive in soil for long periods (endemic farms), leading to insidious, often recurring disease that causes significant economic losses.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

There are four syndromes:

- External abscesses: Deep subcutaneous infection often located in pectoral, ventral abdomen, axillary, and inguinal or mammary areas
- Internal abscess
- Ulcerative lymphangitis: An excoriating, suppurating inflammation of the lymphatics usually confined to the distal limbs
- Corynebacterial folliculitis

HISTORY, CHIEF COMPLAINT

- Previous case on the premises
- Insidious onset

PHYSICAL EXAM FINDINGS

- External abscesses: Painful and warm swelling in the pectoral, ventral abdomen, axillary, and inguinal or mammary areas; systemic signs such as fever, lethargy, and decreased appetite are common.
- Internal abscesses: Prominent signs of systemic illness (persistent or recurring fever, lethargy, and poor appetite) are associated with weight loss, tachycardia, tachypnea, abdominal discomfort, and signs of organ dysfunction associated with the location of the internal abscess. It may occur in association with external abscesses.
- Ulcerative lymphangitis: Swelling of the distal limb associated with non–weight-bearing lameness generally affects one limb, most commonly a hindlimb. The affected limb is usually very edematous, with subcutaneous nodules that ulcerate, releasing green-tinged pus. The ulcers are slow to heal and are generally below the fetlock.
- Corynebacterial folliculitis: Pustules form in areas of the skin in contact with tack and harness; thought to originate from contamination of traumatized skin with the organism.

ETIOLOGY AND PATHOPHYSIOLOGY

- The portal of entry of the organism is thought to be abrasions of the skin. Many insects have been incriminated as vectors for the transmission of *C. pseudotuberculosis*, including *H. irritans*, *M. domestica*, *S. calcitrans*, and *Culicoides* species.
- The incidence of the disease varies from year to year presumably because of environmental factors and vectors.
- *C. pseudotuberculosis* is a gram-positive, pleomorphic rod-shaped, facultative intracellular, facultative anaerobic bacterium.
- The organism contains corynomycolic acid in the cell wall (confers the ability to resist lysosomal digestion and survive within macrophages) and produces several exotoxins, including phospholipase D and sphingomyelinase (degrade endothelial cell wall leading to increased vascular permeability), that facilitate carriage of the bacteria by lymphatic drainage from the site of infection to regional lymph nodes. The abscess formation in regional lymph nodes is an important feature of the infection.
- Incubation period is 3 to 4 weeks.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- For lymphangitis or cellulitis
  - Sporadic bacterial lymphangitis or cellulitis caused by:
    - *Streptococcus* spp.
    - *Staphylococcus* spp.
    - *Pseudomonas aeruginosa*
    - *Rhodococcus equi*
  - Sporotrichosis by *Sporothrix schenckii*
  - Phycomycosis by *Pythium insidiosum*, *Basidiobolus* spp.
  - Insect or arthropod bite
  - Other causes
  - Cutaneous glanders by *Burkholderia* (*Pseudomonas*) *mallei* (exotic in the United States and reportable)
  - Epizootic lymphangitis by *Histoplasma farciminosum* (outside the United States)
- For external abscesses
  - Strangles (*Streptococcus equi* subsp. *equi*)
  - Abscess by other bacteria (eg, *Streptococcus* spp., *R. equi*)
  - Hematoma
  - Seroma
  - Foreign body
  - Neoplasia
- For internal abscesses
  - Bastard strangles (*S. equi* subsp. *equi*)
  - Internal abscess by other bacteria (eg, *Streptococcus* spp., *R. equi*)
  - Neoplasia
- For corynebacterial folliculitis
  - Staphylococcal folliculitis
  - Dermatophilosis
  - Dermatophytosis

INITIAL DATABASE

- Complete blood cell count (CBC), serum biochemistry profile, and fluid analysis of abdominal fluid
- CBC often reveals normocytic normochromic anemia (chronic disease), leu-

ElibVet.com

kocytosis, and neutrophilia, particularly in cases of internal abscesses.
- Hyperproteinemia, hyperglobulinemia, and hyperfibrinogenemia are common, especially in cases of internal abscesses.
- Biochemistry profile: Abnormalities indicating dysfunction corresponding to the organ involved (eg, liver dysfunction associated with hepatic abscessation).
- Peritoneal fluid analysis: Increased protein and nucleated cell count often associated with suppurative inflammation; present in cases of abdominal abscesses.

ADVANCED OR CONFIRMATORY TESTING

- Abscesses deep in the musculature or internal organs or body cavities might require ultrasonography for detection or localization.
- Evaluation of the specimen from the abscess, peritoneal fluid, or transtracheal wash by:
  - Gram stain: Gram-positive, rod-shaped pleomorphic bacteria
  - Aerobic bacterial culture (biochemistry and Gram stain)
- Serologic titer by synergistic hemolysis inhibition (SHI) test: Measures IgG to the exotoxin phospholipase D and indicates chronicity and severity of the infection and antibody response
  - SHI titer up to 1:128 indicates exposure; SHI titer of 1:512 or higher strongly suggests infection.
  - Low SHI titer does not rule out the disease.
  - Many horses with external abscess have low SHI titers before drainage of the abscess.
  - Almost all horses with internal abscesses have SHI titers of 1:512 or higher.

TREATMENT

THERAPEUTIC GOAL(S)

- Main goals are to eliminate suppurative exudates and provide pain management as needed. The infective exudates should be disposed of properly to minimize environmental contamination.
- Treatment depends on the form and the location of lesions.

ACUTE GENERAL TREATMENT

Variable according to the form and location of lesions
- Eliminate suppurative exudates.
  - Establish drainage of external and internal abscesses.
  - For best drainage, the abscess must be allowed to mature.
  - External abscesses
    - Hot compresses, warm soaks, and poultices expedite abscess maturation.
    - When the abscess is mature, lance at the most ventral portion.
  - Internal abscesses: Marsupialization if possible
  - Clean lesions in ulcerative lymphangitis and folliculitis.
  - If possible, lavage with antiseptic solution should be performed.
- Provide analgesia and antiinflammatory treatment as needed, especially if lameness is present in cases of ulcerative lymphangitis.
- Antibiotic therapy
  - Recommended in cases of internal abscesses and ulcerative lymphangitis
  - Controversial in cases of external abscesses
  - Warranted if signs of severe systemic illness
  - Organism has broad antibiotic susceptibility in vitro (penicillins, cephalosporins, trimethoprim-sulfonamide, tetracyclines):
    - Potassium penicillin G: 22,000 IU/kg IV q6h
    - Procaine penicillin: 22,000 IU/kg IM q12h
    - Ceftiofur: 2.2 to 4.4 mg/kg IV or IM q12h
    - Trimethoprim-sulfamethoxazole: 30 mg/kg PO q12h
  - Drug penetration can limit the effectiveness of antimicrobial therapy.
  - Rifampin in addition to one of the above drugs or chloramphenicol are good alternatives to improve penetration.
    - Rifampin: 5 mg/kg PO q12h
    - Chloramphenicol: 50 mg/kg PO q12h
    - Length of treatment is variable.

CHRONIC TREATMENT

- Prolonged antimicrobial treatment is required for:
  - Ulcerative lymphangitis: 30 days
  - Internal abscesses: At least 6 weeks; up to 14 weeks
- Antimicrobial choice must take into consideration the lengthy course of treatment.

POSSIBLE COMPLICATIONS

- Antibiotic therapy might be problematic because:
  - Abscesses have thick capsule.
  - Drugs must be able to penetrate well and able to kill intracellular bacteria.
  - The organism might show antibiotic susceptibility in vitro but not in vivo.
- In cases of external abscesses, systemic antimicrobial therapy is thought to prolong the course of disease (ie, delay resolution).

RECOMMENDED MONITORING

Internal abscesses require repeated evaluation (eg, imaging of abscess, CBC and fibrinogen, abdominocentesis and fluid analysis, bacterial culture).

PROGNOSIS AND OUTCOME

- Prognosis depends on the form and the location of lesions.
  - For external abscesses: Good
  - For internal abscesses: Guarded (mortality rate of 30%–40% despite treatment; 100% if untreated)
  - For ulcerative lymphangitis: Guarded (because of disfigurement and debilitation)
  - If diagnosed and appropriately treated early in the course of the disease, the prognosis improves.
- Resolution of external abscesses
  - If drainage and no systemic antimicrobials: Average of 3 weeks after drainage, up to 60 to 90 days
  - If systemic antimicrobial and drainage: Average of 30 days
- Resolution of internal abscesses: Variable, averaging 2 months; can take as long as 4 to 6 months

PEARLS & CONSIDERATIONS

COMMENTS

When infection is established in the premises, the disease is likely to occur again.

PREVENTION

- Isolation of infected animal, particularly after drainage has been established
- Good sanitation and disposal of contaminated materials
- Insect control
- Vaccination with autogenous bacterin toxoid is limited to endemic areas.

CLIENT EDUCATION

Ulcerative lymphangitis is thought to be associated with poor hygiene and an abundance of biting insect vectors.

BASIC INFORMATION

DEFINITION

A state in which a stallion has one or both testes in a location other than the scrotum

SYNONYM(S)

Retained testicles, rigs, ridgelings, or originals

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses are one of domestic animal species with the highest prevalence rate of cryptorchidism. The overall prevalence is about 3% to 4%, with a much higher percentage in certain breeds.

GENETICS AND BREED PREDISPOSITION

- Percherons, American Saddlebreds, and American Quarter Horses have a higher risk than Thoroughbreds, Standardbred, Morgans, Tennessee Walking Horses, and Arabians.
- Unilateral testis retention occurs more often than bilateral. The right testis is more often retained in the inguinal canal and the left testis is more commonly retained in the abdomen cavity.

RISK FACTORS

- Familial: Cryptorchidism recurs in families and displays variability in the degree of manifestation (inguinal, abdominal, ectopic testes) and in the pattern of occurrence (breed differences).
- Drugs: The vulnerability of testicular descent to estrogenic and antiandrogenic influence in certain species (eg, pigs) should raise questions when potential hormones or drugs with hormone-like effects (eg, estradiol, diethylstilbestrol, progestagens, cimetidine, flutamide, finasteride) are considered during pregnancy.

ASSOCIATED CONDITIONS AND DISORDERS Increased risk of testicular neoplasia is associated with the retained testicle. Teratomas are the most common testicular tumor associated with a retained testicle in young horses.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Depending on the precise location of the retained testicle, different nomenclature may be used.

- Inguinal cryptorchid (high flanker) is defined as a stallion with one testis that did not pass the superficial inguinal ring.
- Complete abdominal cryptorchid has both the testis and the epididymis in the abdominal cavity.
- In partial abdominal cryptorchid, a portion of the epididymis lies in the inguinal canal.
- Ectopic retained testicles are located subcutaneously and cannot move toward the scrotum.

HISTORY, CHIEF COMPLAINT

- A good case history is very important to reduce the risk of errors.
- On visual examination of a stallion, one or two testicles are missing from the scrotum.
- Castrated stallion with a nebulous history and suspicious male-like behavior.

PHYSICAL EXAM FINDINGS The conformation of the scrotum is meticulously assessed for the presence of testicles and for signs of castration scars. If no evidence of a testicle is noticed, the animal should be sedated (xylazine) to ensure good relaxation of the cremaster muscle revealing the testicle. In addition to the visual examination, palpation of the scrotum and the inguinal area is essential.

ETIOLOGY AND PATHOPHYSIOLOGY

- Sex differential events are generally influenced by multigenetic and multienvironmental factors.
- Failure of the testis to regress in size, overstretching of the gubernaculum, or insufficient abdominal pressure could mechanically prevent the engagement of the testis in the vaginal ring and further stop the testis' advance through the inguinal canal.
- Defective hypothalamic-pituitary axis and deficiency of gonadotrophin hormone have been proposed.
- Factors such as Müllerian inhibiting substance (MIS), genitofemoral nerve and calcitonin gene-related peptides, and insulin-like factor-3 could play a role in cryptorchidism.
- Definitive experimental evidence has yet to be obtained.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Unilateral cryptorchid (ectopic, inguinal, and abdominal)
- Bilateral cryptorchid (ectopic, inguinal, and abdominal)
- Behavioral problem
- Gonadal agenesis (extremely rare)
- Intersex: XY sex reversal (rare)

INITIAL DATABASE

- History
- Palpation (scrotum and inguinal area)
- Transrectal palpation
- Deep palpation of the inguinal canal often allows the location of the testis in an inguinal cryptorchid. Differentiation between subcutaneous fat and testicular tissue is important.
- Palpation of the inguinal region is completed by transrectal palpation. The vaginal ring or internal inguinal ring is relatively easy to find, and one or two fingers may be inserted. Transrectal palpation of the ductus deferens in the inguinal ring suggests a testis located in the inguinal canal or in the scrotum. Contrarily, the absence of the ductus deferens suggests an abdominal location of the retained testis.
- In the absence of one or both testicles in the scrotum, the persistence of stallion-like behavior (erection, mounting, and sexually aggressive behavior) of an otherwise assumed castrated male could be the main complaint.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonographic examination (inguinal, transabdominal, and transrectal)
- Hormone essay
- Systematic transabdominal ultrasonography (3.5-MHz transducer) in both caudal abdominal and inguinal regions can locate the retained testis. Transabdominal ultrasonography is a diagnostic technique with high sensitivity (93.2%) and specificity (100%). A systematic and meticulous transabdominal craniocaudal scanning method of the area of the caudal aspect of the abdomen from midline to the flank and of the inguinal area is performed. The hyperechoic albuginea and the

ElibeVet.com

central vein of the testis or the epididymis are readily identified. When the testis is not found, transrectal ultrasonography is a method to precisely locate the testis.

- Endocrinologic profiling is a useful diagnostic tool when ultrasonography (transabdominal, inguinal or transrectal) is not available or did not enable a confident diagnosis of cryptorchidism. The endocrinologic profile includes baseline testosterone or estrone sulphate concentrations and human chorionic gonadotropin (hCG) stimulation test for testosterone. The baseline testosterone level in geldings (<40 pg/mL) is significantly lower than in stallions (>100 pg/mL). With uncertain results, testosterone levels after hCG stimulation could be used to confirm the diagnosis of cryptorchidism. A blood sample is obtained at 0, 60, and 120 minutes after hCG administration (10000 IU), and the testosterone concentration is compared with the baseline level at time 0 (94.6% accurate test). Some cryptorchids show a late response (48 to 72 hours after hCG stimulation). Practically, blood should be sampled at 0, 1, 2, 48, and 72 hours after hCG injection and the samples taken at 0, 1, and 2 hours sent to the laboratory. When suspicious cryptorchidism is not confirmed, the 48- and 72-hour samples could be sent later. Test result interpretation is based on specific reference range from individual laboratories.
- In geldings, the estrogen sulfate baseline concentrations is expected to be low (<50 pg/mL), but cryptorchids show high concentrations (>400 pg/mL). Excluding horses younger than 3 years old and donkeys, 96% accuracy has been reported.

TREATMENT

THERAPEUTIC GOAL(S)

- Removal of the retained and descended testes

ACUTE GENERAL TREATMENT

- The appropriate surgical approach can be selected depending on different factors:
  - Location of the retained testis
  - Temperament of the horse
  - Health of the horse
  - Function of the horse
  - Experience or preference of the surgeon
  - Cost of the surgical approach
- The different surgical approaches are:
  - Inguinal approach for inguinal and abdominal retained testicles
  - Parainguinal approach when the vaginal process cannot be located or when the testis is too big to be removed by the inguinal canal
  - Paramedian approach for bilateral cryptorchids or animals with stallion-like behavior that are unreliable and dangerous to work with or with an unknown castration history. Flank and laparoscopic approaches for abdominal retained testicles.

CHRONIC TREATMENT

Medical treatment as described for humans is not recommended because of the heritable nature of the condition.

POSSIBLE COMPLICATIONS

- Hemorrhage
- Evisceration
- Edema
- Septic funiculitis
- Clostridial infection
- Septic and nonseptic peritonitis
- Hydrocele
- Continued masculine behavior (false rigs)

RECOMMENDED MONITORING

Activity should be restricted to hand-walking for the first 3 weeks.

PROGNOSIS AND OUTCOME

Return to normal behavior within 3 to 4 weeks after surgery and prognosis for life are excellent.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

Keep good records.

PREVENTION

Remove affected animals from the breeding program.

Cryptosporidiosis

BASIC INFORMATION

DEFINITION

Infection of the gastrointestinal (GI) tract by the protozoan parasite *Cryptosporidium parvum*, causing diarrhea

SPECIES, AGE, SEX

Horses of any age may potentially be affected, but clinical disease is most common in foals.

RISK FACTORS

- Immunodeficiency: Clinical disease is most often identified in association with the stress of hospitalization and concurrent infection or in foals with severe combined immunodeficiency.
- Risk factors for fecal shedding include:
  - Age younger than 6 months
  - History of diarrhea in the past 30 days
  - Residence on specific breeding farms

CONTAGION AND ZOONOSIS

- Transmission is by the fecal-oral route.
- Strains are transmissible between species.
- Zoonotic; may cause severe diarrhea in humans.

ElibVet.com

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Many infections are subclinical.
- May result in severe disease.

HISTORY, CHIEF COMPLAINT Diarrhea

PHYSICAL EXAM FINDINGS
- Diarrhea of variable severity
- Dehydration
- Fever

ETIOLOGY AND PATHOPHYSIOLOGY
- Oocysts are sporulated and infectious at the time they are excreted in the feces and may persist in the environment.
- Infection occurs by ingestion of oocysts.
- Cryptosporidia develop in the GI epithelial cells and cause damage to microvilli, which may result in malabsorption, maldigestion, and diarrhea.
- Short prepatent period (72–96 hours)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Enteric clostridiosis
- Salmonellosis
- Rotavirus, coronavirus
- Foal heat diarrhea
- Parasitic diarrhea
- Septicemia

INITIAL DATABASE
- Laboratory findings are nonspecific; evidence is often found of dehydration along with acid-base and electrolyte abnormalities consistent with diarrhea.
- Evaluate neonatal foals for passive transfer of antibody and septicemia.

ADVANCED OR CONFIRMATORY TESTING
- Identification of *C. parvum* in feces (oocysts are smaller than those of most coccidia—4–5 µm)
  - Microscopic examination with special staining (acid-fast, acridine orange, modified Ziehl-Neelsen)
  - Immunofluorescence assay
  - Flow cytometry
- Histopathology: Villous atrophy; organisms may be visualized

TREATMENT

THERAPEUTIC GOAL(S)
Resolution of diarrhea

ACUTE GENERAL TREATMENT
- Supportive care for diarrhea should be provided.
- No data are available regarding specific therapy for *C. parvum* infection in horses.
- Pharmacologic control has been difficult in other species.
- Drugs that may be effective include nitazoxanide, paromomycin, and azithromycin.

PROGNOSIS AND OUTCOME
- Generally self-limiting in immunocompetent hosts.
- Severe cases may result in marked dehydration, weakness, and death.

PEARLS & CONSIDERATIONS

COMMENTS
- This is an uncommon cause of diarrhea in horses but should be considered, especially in hospitalized, stressed, and immunocompromised foals.
- Highly transmissible to humans.

PREVENTION
- Oocysts resistant to most common disinfectants. Exposure to 5% ammonia solution or 10% formalin for 18 hours will kill oocysts; freezing, thorough drying, and moist heat may also be effective.
- Removal of manure may limit oocysts in the environment.

CLIENT EDUCATION
Good hygiene is essential when handling foals with diarrhea.

Cushing's Disease (Pituitary Pars Intermedia Dysfunction)

BASIC INFORMATION

DEFINITION
A clinical condition of old horses associated with hirsutism, laminitis, depression, polyuria (PU) and polydipsia (PD), muscle wasting, weight loss, docility, polyphagia, and recurrent infections

SYNONYM(S)
- Pituitary pars intermedia dysfunction (PPID) is the appropriate term.
- Pituitary adenoma
- Pars intermedia adenoma
- Pituitary-dependent hyperadrenocorticism

EPIDEMIOLOGY

SPECIES, AGE, SEX
- Horses older than 7 years of age (range, 7–40 years)
- More prevalent in ponies

GEOGRAPHY AND SEASONALITY
More evident in the spring and summer when horses with PPID fail to shed their hair coat

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Hirsutism (60%–80%) is the most frequent clinical sign in affected horses.

PHYSICAL EXAM FINDINGS
- Chronic laminitis is a consistent finding in these horses.
- PU and PD have been reported in up to 75% of horses.
- Failure to shed hair coat in spring or summer is a consistent finding.
- Weight loss, lethargy, increased docility
- Secondary infections (dermatitis, sinusitis, pneumonia), dental disease
- Excessive sweating (hyperhidrosis) and lack of sweating (anhidrosis)
- Redistribution of fat deposits
- Pendulous abdomen, sway back, and loss of muscle mass
- Other clinical signs include abnormal estrus cycles and neurologic signs (seizures, narcolepsy).

ETIOLOGY AND PATHOPHYSIOLOGY
- The hypothalamus, via dopamine, inhibits cells (melanotropes) of the pars intermedia of the pituitary gland.
- Hypothalamic neuronal oxidative damage results in loss of dopaminer-

ElibVet.com

gic inhibition of melanotropes, which leads to hyperplasia, adenoma formation, and excessive production of adrenocorticotropic hormone (ACTH), α-melanocyte-stimulation hormone (α-MSH), and β-endorphin
- Excessive ACTH leads to increased cortisol concentrations (hyperadrenocorticism) and clinical signs of the disease.
- Increased α-MSH concentrations may be responsible for abnormal hair shedding.
- Increased β-endorphin concentrations appear to be responsible for the calm behavior of these horses.
- High cortisol concentrations lead to hyperglycemia, insulin resistance, laminitis, immunosuppression, and secondary infections.
- Adenoma enlargement may result in additional hypothalamic damage.
- Neuronal degeneration may be responsible for seizures.
- PPID is a better term for this disease because unlike humans and dogs with Cushing's disease in which the adenoma is in the pars distalis (anterior lobe), the adenoma is in the pars intermedia in horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine metabolic syndrome
- Obesity and laminitis
- Hyperadrenocorticism
- Hypothyroidism

INITIAL DATABASE

- Dexamethasone suppression test (DST)*
- Thyrotropin-releasing hormone (TRH) stimulation test*
- Resting plasma ACTH concentrations*
- Resting cortisol concentrations
- Urinary corticoid:creatinine ratio
- Combined DST-TRH test*
- Hyperglycemia and increased insulin concentrations are a common finding in these horses.
- Domperidone response test
- Plasma α-MSH concentrations (human assays can be used; use a control horse)
- It is important to know seasonal variations when collecting samples for diagnosis.
- ACTH and α-MSH concentrations in healthy horses are increased at the end of summer and early fall (may lead to misdiagnosis).
- Cortisol concentrations after the DST in healthy horses are higher in late summer and early fall.

*The resting ACTH, DST, TRH stimulation test, and combined DST/TRH stimulation test are well accepted among practitioners.

TREATMENT

ACUTE GENERAL TREATMENT

- Pergolide (0.2–5.0 mg PO SID), a dopamine D2 receptor agonist, is the drug of choice. Most horses show improvement with doses of 0.75 to 1.5 mg/d of pergolide.
- In Europe, bromocriptine (0.03–0.09 mg/kg BID PO or SC) is an alternative dopamine agonist.
- Improvement is evident by 6 weeks of treatment and includes shedding of the hair coat, a decrease in plasma ACTH concentration, and a decrease in glucose concentration.
- Cyproheptadine (0.25 mg/kg PO SID), a serotonin antagonist, has been used with some success.
- Combinations of pergolide and cyproheptadine have been used.

CHRONIC TREATMENT

- These drugs do not cure PPID, and horses with clinical improvement should be treated for life.
- Clipping the hair coat may be necessary in hot weather.
- Avoid stressful conditions.
- Decrease intake of soluble carbohydrates (concentrates, sweet feed, corn).
- Provide specific treatment of chronic laminitis or solar abscesses.

PROGNOSIS AND OUTCOME

- Depends on clinical signs. Treatment is palliative.
- PPID is an incurable disease.
- Horses with mild laminitis and specific treatment can live for many years.
- Horses with severe laminitis or secondary infections have a guarded prognosis.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- The disease is incurable.
- Secondary infections are common.
- Avoid heat exposure.
- Treatment can be expensive.

Cyanide Toxicosis

BASIC INFORMATION

DEFINITION

Cyanide poisoning in animals usually results from ingestion of plants containing cyanogenic glycosides. Poisoning may also occur when cyanide is inhaled as gaseous hydrogen cyanide or is ingested in the chemical forms of sodium and potassium cyanide, but these causes are very uncommon in animals. Cyanide poisoning is rare in horses.

SYNONYM(S)

- Prussic acid poisoning
- Hydrogen cyanide (HCN) poisoning

EPIDEMIOLOGY

SPECIES, AGE, SEX All ages and species of mammals are susceptible to cyanide poisoning.

GEOGRAPHY AND SEASONALITY There are at least 2500 plant species in many plant families, including the Asteraceae, Chenopodiaceae, Euphorbiaceae, Fabaceae, Juncaginaceae, Linaceae, Poaceae, and Rosaceae, that are known to contain cyanogenic glycosides. A few of the more common plants with cyanogenic potential include service berry, elderberry, Johnson grass, Sudan grass, arrow grass, corn, cherry laurel, wild cherry, and chokecherry.

ElibeVet.com

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute cyanide poisoning
- Chronic cyanide poisoning is discussed in "Sorghum and Sudan Grass Toxicosis" in this section

HISTORY, CHIEF COMPLAINT Sudden death is usually the presenting feature of cyanide poisoning.

PHYSICAL EXAM FINDINGS

- Severe dyspnea, open-mouthed breathing, staggering gait, prostration
- Mucous membranes initially are congested and bright red, becoming cyanotic near death.
- A lethal dose of cyanide results in death within a few minutes to 1 hour.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cyanide reversibly inhibits mitochondrial cytochrome oxidase and blocks electron transport, resulting in decreased oxidative metabolism and oxygen utilization.
- Plant-associated cyanide toxicity depends on enzymatic hydrolysis of cyanogenic glycosides that liberates the toxic cyanide ion responsible for toxicity. Plants do not contain free HCN because the cyanogenic glycosides and the hydrolyzing enzymes are compartmentalized in the plant.
- Damage to the plant cell compartments is necessary to start the hydrolytic process. Optimally, this occurs at a pH greater than 4 or when the plants are damaged as a result of drought, wilting, freezing, or crushing.
- Plant-induced acute cyanide poisoning in horses is poorly documented in the literature, but cyanide poisoning in ruminants is well documented. This species difference is related to the ability of rumenal digestive microflora to rapidly hydrolyze cyanogenic glycosides and the low pH of the horse's stomach in contrast to the more alkaline pH of the rumen.
- Plant cyanide-producing potential is highest in new growth and declines significantly as leaves mature.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of sudden death
- Ionophore toxicity
- Carbon monoxide poisoning
- Yew (*Taxus* spp.) poisoning
- Milkweed (*Asclepias* spp.) poisoning
- Oleander (*Nerium oleander*) poisoning
- Perilla mint (*Perilla frutescens*) poisoning
- Electrocution
- Malicious poisoning with chemicals such as fluoroacetate or zinc phosphide

INITIAL DATABASE

Venous blood and mucous membranes may be bright red

ADVANCED OR CONFIRMATORY TESTING

- Lactic acidosis occurs as a consequence of anaerobic metabolism.
- No gross abnormalities are evident on postmortem examination.
- Stomach contents should be collected immediately after death, frozen in an air-tight container, and submitted for cyanide detection. Tissues such as spleen, liver, and muscle can also be analyzed for cyanide. Autolyzed tissues can give false-positive cyanide results.
- Refrigerated blood from live animals can be tested for cyanide. Blood cyanide levels above 1 ppm are highly suggestive of acute toxicity.
- Suspect plant material that the animal has been consuming should be collected for cyanide analysis. Plant cyanide levels above 200 ppm are potentially toxic.
- Rapid testing for cyanide in plant or stomach contents can be done with Cyantesmo paper (Macherey-Nagel, Dueren, Germany).

TREATMENT

THERAPEUTIC GOAL(S)

- Avoid stressing the animal as much as possible.
- Provide antidotal treatment and supportive care
- Remove the source of cyanide.

ACUTE GENERAL TREATMENT

- Sodium thiosulfate administered IV is an antidotal therapy for cyanide poisoning.
- A combination of sodium thiosulfate and sodium nitrite can also be used but may not be as safe. Sodium nitrite causes the formation of methemoglobin that binds with cyanide to form cyanmethemoglobin, and the formation of methemoglobin further compromises oxygen carrying capacity of the red blood cells.
- Hydroxocobalamin (Cyanokit) is the preferred treatment for cyanide poisoning in humans and has been used in dogs, but its use is not yet documented in horses.

PROGNOSIS AND OUTCOME

Animals surviving more than 1 hour after the onset of signs often recover.

PEARLS & CONSIDERATIONS

COMMENTS

Cyanide poisoning was initially thought to be involved in the Mare reproductive loss syndrome (MRLS) reported from central Kentucky in 2001. Eastern tent caterpillars feeding on cherry tree leaves and subsequently eaten by horses grazing the pastures where the caterpillars were prevalent in massive numbers were thought to have poisoned the mares. Extensive experiments in which caterpillars were fed to horses showed that cyanide was apparently not the cause of MRLS. However, the eastern tent caterpillar appears to be involved in MRLS, possibly through an as yet unidentified toxin or by causing damage to the intestinal mucosa, allowing bacteria to enter the blood and affect the fetus (see "Actinobacillosis" in this section).

PREVENTION

- Reduce exposure to known cyanogenic glycoside-containing plants.
- Feed a balanced ration to ensure that horses do not exclusively eat potentially toxic plants.
- Do not plant cherry trees in or around horse pastures.

Cyathostominosis

BASIC INFORMATION

DEFINITION

Parasitic infection in the large colon or cecum with cyathostomes (small strongyles)

SYNONYM(S)

- Larval cyathostomiasis
- Cyathostomiasis

EPIDEMIOLOGY

SPECIES, AGE, SEX Most common in horses between ages 1 and 6 years, which have less resistance to parasitic infection

GEOGRAPHY AND SEASONALITY Commonly occurs in winter and spring

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Subclinical infestation
- Clinical disease (see below)

HISTORY, CHIEF COMPLAINT

- Weight loss
- Inappetence
- Diarrhea
- Colic (of variable severity)
- Fever may or may not be present
- Ventral edema

PHYSICAL EXAM FINDINGS

- Poor body condition and rough hair coat
- Variable pyrexia
- Ventral edema frequently present
- Other findings as for other causes of colitis (See "Colitis/Diarrhea, Acute" in this section)
- Rectal examination
  - Usually as for other causes of colitis, with rectal mucosal edema and fluid colonic contents.
  - Occasionally, live larvae (small red or white worms) may be seen grossly in the feces or on the rectal sleeve.
  - Rarely, mesenteric lymphadenopathy or irregularities in the colonic surface are palpable per rectum in severe cases.
  - Intestinal intussusceptions are occasionally associated with cyathostominosis and may be palpable per rectum as a firm mass, usually in the right caudal abdomen. Alternatively, distension of the large or small intestine may be noted with such intestinal obstruction.

ETIOLOGY AND PATHOPHYSIOLOGY

- The life cycle of cyathostomes is directly regulated by environmental temperature.
  - Eggs are passed in the feces and develop into L1, L2, and then infective L3 larvae in the environment in temperate weather (45° to 85° F). Development is impaired by hot, dry weather or freezing temperatures.
  - L3 larvae are ingested by horses on pasture and enter a period of dormancy (weeks to years) by encysting in the cecal and colonic wall.
  - When environmental conditions are favorable for further development, these hypobiotic larvae emerge from their cysts and develop in the colonic lumen into mature (L4 and L5) larvae, which lay eggs that are then passed in the feces.
- In most climates, emergence of encysted larvae and clinical cyathostominosis occurs in the late winter and early spring, but in hotter climates, clinical disease may be seen in the late fall.
- Associated clinical signs (weight loss, diarrhea, colic, fever, and hypoproteinemia) are attributable to disruption of the colonic mucosal barrier caused by penetration or reemergence of large numbers of encysted larvae.
- Intestinal intussusception (most often cecocolic, cecocecal, or colocolic) associated with cyathostominosis may result from abnormal peristaltic contractions because of severe mural inflammation associated with encysted larvae.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

INITIAL DATABASE

- In general, as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).
- Leucocytosis and neutrophilia are common findings.
- Hypoproteinemia and hypoalbuminemia are fairly consistent findings.
- Transabdominal ultrasonography may reveal multifocal or diffuse increased mural thickness (>5 mm) in the cecum or colon in patients with large numbers of encysted larvae. An intussusception may be visualized ultrasonographically, appearing as a "bull's eye," with an intestinal wall or walls visible within the lumen of another segment of intestine.
- The presence of serosanguineous peritoneal fluid or persistent signs of abdominal pain in a horse with suspected or confirmed cyathostominosis should prompt consideration of an intussusception and may warrant exploratory celiotomy.

ADVANCED OR CONFIRMATORY TESTING

- Fecal flotation
  - Large numbers of strongyle larvae or eggs are consistent with cyathostominosis.
  - However, strongyle eggs may not be seen even in severe cases because clinical disease typically occurs during the prepatent period.
- Testing for other causes of colitis is also warranted, as detailed in "Colitis/Diarrhea, Acute" in this section.

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate encysted and intraluminal larvae.
- Provide supportive care.

ACUTE GENERAL TREATMENT

- Fluid and colloidal support, antiinflammatory and antiendotoxic therapy, and other supportive care as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)
- Anthelmintic therapy
  - Fenbendazole: 10 mg/kg PO q24h for 5 days (widespread resistance to benzimidazoles may limit the efficacy of this treatment).
  - Moxidectin: 0.4 to 0.5 mg/kg PO once (not for use in foals <4 to 6 months old).
  - Ivermectin and pyrantel pamoate are not effective against encysted cyathastomes but are effective against the intraluminal stages.

POSSIBLE COMPLICATIONS

Intestinal intussusception

PROGNOSIS AND OUTCOME

Fair to good with aggressive and appropriate therapy

PEARLS & CONSIDERATIONS

COMMENTS

- It is important to note that a negative fecal flotation result does not rule

ElibEVet.com

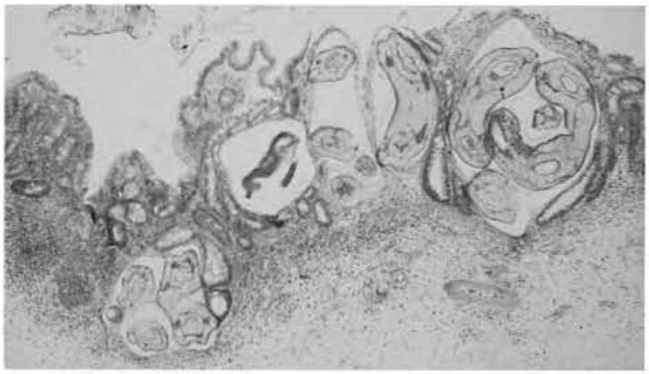

FIGURE 1 Histologic appearance of the colon showing multiple encysted cyathostomin larvae.

FIGURE 2 Cyathostomin larvae in fecal sample of horse affected by larval cyathostominosis.

out cyathostominosis as a cause of colitis.
- Empiric larvicidal deworming should be considered in equine colitis cases in which weight loss is an accompanying clinical sign or in which another specific cause is not determined.

PREVENTION

- Seasonal larvicidal deworming with fenbendazole or moxidectin during the early winter (or late summer in hot climates) may decrease the incidence of clinical cyathostominosis. However, fecal egg counts should be monitored and deworming strategies determined for individual farms to minimize the development of anthelmintic resistance.
- Appropriate manure and pasture management (with limited horse density) is also helpful in reducing transmission and parasite loads.

Cystitis, Bacterial

BASIC INFORMATION

DEFINITION

Bacterial infection of the urinary bladder

EPIDEMIOLOGY

RISK FACTORS

- Urolithiasis
- Neoplasia
- Incontinence
- Iatrogenic contamination (eg, passage of endoscopes, catheters)

ASSOCIATED CONDITIONS AND DISORDERS

- Sabulous urolithiasis
- Urolithiasis
- Urethral damage
- Incontinence

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Pollakiuria
- Hematuria
- Incontinence
- Mild chronic colic
- Frequently posturing to urinate

PHYSICAL EXAM FINDINGS

- Dysuria
- Urine scalding or crystals on the perineum or hind limbs
- Hematuria
- Incontinence

ETIOLOGY AND PATHOPHYSIOLOGY

- Usually secondary to urine retention
- Decreased urine flow allows for bacterial colonization.
- Hematuria occurs when the bladder or urethral mucosa is eroded or severely irritated.
- Common infectious agents of cystitis include:
  - *Escherichia coli*
  - *Proteus mirabilis*
  - *Pseudomonas aeruginosa*
  - *Corynebacterium renale*
  - *Klebsiella* spp.
  - *Enterobacter* spp.
  - *Streptococcus* spp.
  - *Staphylococcus* spp.
  - *Candida* spp. (fungal pathogen more common in neonates on antimicrobial therapy)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Estral behavior in mares
- Urolithiasis
- Pyelonephritis

INITIAL DATABASE

- Complete blood count (CBC) and serum chemistries
  - CBC is usually within normal limits.
  - Serum chemistries may reveal azotemia.
- Urinalysis: High number of white blood cells, epithelial cells, erythrocytes, and intracellular and extracellular bacteria
- Urine culture
- Palpation per rectum: Thickened bladder

ADVANCED OR CONFIRMATORY TESTING

- Quantitative urine culture (>10,000 CFU/mL is significant)
- Cystoscopy

ElibeVet.com

- Transrectal or transabdominal ultrasound examination

TREATMENT

THERAPEUTIC GOAL(S)

- Correct any predisposing problems.
- Resolve bacterial infection.

ACUTE GENERAL TREATMENT

- Antimicrobials based on culture and sensitivity results, especially those that are eliminated into the urine
  - Antibiotics should be administered for at least 1 week.
  - Trimethoprim-sulfonamides: 15 to 30 mg/kg PO q12h
  - Penicillin and an aminoglycoside (provided creatinine is normal)
- Procaine penicillin G: 22,000 to 44,000 IU/kg IM q12h
- Potassium penicillin: 22,000 IU/kg IV q6h
- Gentamicin: 6.6 mg/kg IV q24h
  - Ceftiofur: 2.2 to 4.4 mg/kg IM q24h or IV q12h
  - Enrofloxacin: 7.5 mg/kg PO or 5.5 mg/kg IV q24h
- Catheterization of the bladder if urinary retention is a predisposing factor

CHRONIC TREATMENT

- A 4- to 6-week course of antimicrobials may be necessary in some cases.
- Lavage the bladder with sterile saline ± antiseptics.
- Oral salt administration (50–75 g/d) to increase water intake
- Urinary acidification (efficacy is questionable)
  - Ammonium chloride: 20 mg/kg/d
  - Vitamin C: 10 to 20 g/d
  - $CaSO_4$ (gypsum): 100 g/d
  - Potassium magnesium aspartate: 2.5 g PO q12h

RECOMMENDED MONITORING

- Repeated urinalysis and urine culture
- Cystoscopy may be necessary to assess healing of the mucosa.

PROGNOSIS AND OUTCOME

- Experimental models of bacterial cystitis showed spontaneous recovery in 2 to 4 weeks, but complete resolution was seen in 3 to 6 days with treatment.
- Chronic infections may result in sabulous cystitis or pyelonephritis.

PEARLS & CONSIDERATIONS

COMMENTS

- Primary bacterial cystitis is uncommon.
- Predisposing conditions that lead to urinary retention or cystitis (urolithiasis) must be ruled out and treated as necessary.

PREVENTION

- Aseptic technique should be used whenever urinary catheters or other instruments are used within the urinary tract.
- Prophylactic antibiotic therapy may be effective whenever any surgery is performed or any instrument is introduced into the urinary tract.

Death Camas Toxicosis

BASIC INFORMATION

DEFINITION

Death camas (*Zigadenus* spp.) is native to North America and is poisonous to humans and other animals.

SYNONYM(S)

Star lily

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Horses and livestock eating the new growth or bulbs are at risk for poisoning.

RISK FACTORS Early spring grazing when the death camas shoots emerge before grasses

GEOGRAPHY AND SEASONALITY Perennial plants growing from an onion-like bulb with long, narrow, V-shaped basal leaves appearing in early spring. Flowers are radially symmetrical, bisexual, and six-tepalled (three petals and three sepals identical) and are generally white or yellowish-green. There are at least 14 recognized species in North America (Figure 1).

ASSOCIATED CONDITIONS AND DISORDERS A plant of the southeastern states, *Amianthium muscaetoxicum* (crow poison, fly poison, or stagger grass, as it is variously known) contains similar hypotensive and neurotoxic alkaloids to those found in *Zigadenus* spp. (Figure 2).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Excessive salivation, colic, and depression are the primary signs.

PHYSICAL EXAM FINDINGS Depending on the amount of death camas consumed, signs can be mild to severe with depression, colic, and excessive salivation being the most common findings in horses. Intestinal peristalsis may be increased in severe cases, resulting in diarrhea.

ETIOLOGY AND PATHOPHYSIOLOGY

- Both *Zigadenus* and *Amianthium* spp. contain varying quantities of cevanine alkaloids similar to those found in *Veratrum* spp. These alkaloids have hypotensive and neurotoxic effects and increase reflex activity.
- In sheep, death results from central respiratory depression.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Ionophore toxicity

INITIAL DATABASE

Hematology and serum biochemistry values are often normal.

ADVANCED OR CONFIRMATORY TESTING

Cevanine alkaloid detection in stomach contents

TREATMENT

ACUTE GENERAL TREATMENT

- If horses are seen grazing the plants or soon after signs are recognized,

ElibEVet.com

FIGURE 1 Meadow death camas (*Zigadenus venenosus*).

FIGURE 2 Crow or fly poison (*Amianthium muscaetoxicum*).

activated charcoal via nasogastric tube is beneficial.
- Supportive treatment should be provided as necessary.

PROGNOSIS AND OUTCOME

Horses rarely eat sufficient quantities of the plant to induce serious toxicity and generally recover within 2 to 3 days after ingesting death camas.

PEARLS & CONSIDERATIONS

COMMENTS

- Death camas and fly poison are native plants that may be concentrated in some pastures, making toxicity more likely.
- Death camas and fly poison are both toxic to humans, especially when the bulbs are mistakenly eaten for wild onion bulbs.

PREVENTION

Where the density of plants is high, selective herbicides may be useful in removing the plants.

CLIENT EDUCATION

Recognition of the plants aids in preventing toxicity.

SUGGESTED READING

AUTHOR: **ANTHONY P. KNIGHT**

EDITOR: **CYNTHIA GASKILL**

Dehydration

BASIC INFORMATION

DEFINITION

A state in which fluid losses (apparent losses as well as insensible losses combined) outpace fluid intake

SYNONYM(S)

- Hypovolemia
- Negative fluid balance

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals are particularly at risk because of their high body water content and surface-to-volume ratio.

CONTAGION AND ZOONOSIS Dehydration is not contagious itself; however, some of the diseases that cause it may be communicable to others (eg, colitis caused by *Salmonella* spp. or rabid encephalitis).

GEOGRAPHY AND SEASONALITY
- Cold weather may limit access to water because of freezing of water sources or reduced intake because of the decreased palatability of cold water.
- Hot weather may increase fluid and electrolyte losses through sweat.

ASSOCIATED CONDITIONS AND DISORDERS Diseases that increase fluid losses in excess of the horse's ability to take in fluids, toxins that increase vascular leakage, disruption of the protective

ElibeVet.com

dermis by burn injury, as well as disorders that inhibit the horse's ability to drink and swallow may cause dehydration.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hypertonic dehydration
- Isotonic dehydration
- Hypotonic dehydration

HISTORY, CHIEF COMPLAINT Variable because of the diverse etiology

PHYSICAL EXAM FINDINGS

- Depression; lethargy; tachycardia; reduced pulse quality; increased duration of skin tent test; dry mucous membranes; increased capillary refill time (CRT); cool extremities; mucus-covered fecal balls; or dry, scant feces (Figures 1 and 2)
- Weight loss is the gold standard for determining the percent of body weight lost to dehydration.
- The approximate percent dehydration can be estimated from physical examination findings as follows:
  - Heart rate 40 to 60 beats/min, CRT <2: approximately 6% dehydration
  - Heart rate 61 to 80 beats/min, CRT <3: approximately 8% dehydration
  - Heart rate 81 to 100 beats/min, CRT <4: approximately 10% dehydration
  - Heart rate 101+ beats/min, CRT >4, packed cell volume (PCV) >50%: approximately >10% dehydration; the horse is in hypovolemic shock

ETIOLOGY AND PATHOPHYSIOLOGY

- Pathophysiology: Dehydration results in a reduction of relative circulating volume. Decreased tissue perfusion reduces oxygen delivery to the tissues, increasing anaerobic metabolism and reducing tissue pH through acid accumulation and lactate production.
- Reduced intake
  - Environmental: Weather, lack of available water
  - Mechanical obstruction: Jaw fracture, pharyngeal injury, choking
  - Neurologic disorders causing dysphagia
  - Gastrointestinal disease: Gastric outflow obstruction, small intestinal obstruction, or ileus
- Increased losses
  - Enterocolitis
  - Primary renal disease
  - Significant nasogastric reflux caused by enteritis
  - Severe burns
  - Endotoxemia
- Relative dehydration: Salt toxicity

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dehydration is a secondary condition to a number of primary diseases and disorders.

INITIAL DATABASE

- Complete blood count
- PCV and total protein (TP)
- Blood lactate
- Serum chemistry
- Urinalysis

ADVANCED OR CONFIRMATORY TESTING

Based on physical examination findings and the initial database, system specific tests may be applicable:

- Oral or pharyngeal disorders: Oral examination, endoscopy, radiography
- Neurologic disease: Neurologic examination, cerebrospinal fluid analysis, serum titers, computed tomography, radiography, liver biopsy
- Gastrointestinal disease: Abdominocentesis, abdominal ultrasonography, rectal examination, nasogastric intubation, fecal culture (aerobic, anaerobic), fecal clostridial toxin screening
- Renal disease: Fractional electrolyte excretion tests, renal biopsy

FIGURE 1 Skin tent test for dehydration using the upper eyelid of the horse. This test may also be performed on the neck dorsal to the cervical vertebrae and cranial to the shoulder.

FIGURE 2 Prolonged skin tent test of >4 seconds. Based on the complete physical examination, this horse was more than 10% dehydrated.

ElibEVet.com

TREATMENT

THERAPEUTIC GOAL(S)

- Replacement of the circulating volume
- Normalization of electrolyte abnormalities
- Resolution of acid-base disorders
- Treatment of the underlying disease

ACUTE GENERAL TREATMENT

Fluid therapy:

- Generally administered IV or by nasogastric intubation in boluses or by constant-rate infusion. Oral fluids are not absorbed if the horse is more than 8% dehydrated.
- Dehydration is corrected in the first 24 hours, and then maintenance fluids are administered.
- Isotonic fluid requirements for dehydration are determined by the following calculation:

Volume (L) = Estimated dehydration
+ Estimated acute loss
+ Maintenance rate

in which:

  - Estimated dehydration = % Dehydration × Body weight (kg)
  - Dehydration is in decimal form (eg, 8% = 0.08)
  - Adult maintenance fluid rate = 60 mL/kg/day divided by 1000 mL for liters of fluid required
- Isotonic crystalloids (Normosol R, Plasmalyte, lactated Ringer's solution) are typically used.
  - Hypertonic saline or colloids may complement the crystalloid plan in hypovolemic shock in adults.
  - Hypertonic saline should never be administered to foals because of a risk of demyelination.
- Fluid therapy should be reassessed q12h to update losses and reassess response.
- Electrolyte supplementation may be required for electrolyte derangements or to provide maintenance electrolytes in fluids administered for longer than 48 hours.
  - Potassium
    - Maximum administration rate: 0.5 mEq/kg/h
    - Maintenance rate: 20 mEq/L in potassium-poor crystalloids
  - Magnesium: 50 to 100 mg/kg IV q24h
  - Sodium
    - Serum concentration should not change more than 0.5 mEq/h.
    - Serum sodium should not be corrected faster than 10 mmol/L over 24 hours.
  - Calcium
    - 10 to 25 mL 23% calcium gluconate/L
    - Maintenance rate: 10 mL calcium gluconate/L in calcium-poor crystalloids
  - Bicarbonate therapy is typically unnecessary. Acidosis usually corrects with fluid therapy alone.

CHRONIC TREATMENT

Depends on the underlying disease

DRUG INTERACTIONS

Bicarbonate may precipitate in calcium-containing fluids

POSSIBLE COMPLICATIONS

- Tissue edema: May result from overhydration, increased vascular permeability with endotoxemia, or cardiac dysfunction resulting in pulmonary hypertension. Colloids may be required to maintain colloid oncotic pressures and intravascular fluid.
- Hemodilution: May occur with overhydration; complicates monitoring.
- Cerebral edema and demyelination: May occur with extreme changes in sodium concentration.

RECOMMENDED MONITORING

- First 24 hours:
  - PCV and TP q6h
  - Urine output
  - Blood urea nitrogen and creatinine q24h
  - Electrolyte values q4–6h (if there is a severe derangement initially)
  - Physical examination q4h (heart rate, respiratory rate and character, mucous membranes, skin tent test, peripheral temperature)
  - Central venous pressure: May identify overhydration; low sensitivity in monitoring dehydration
- If therapy is sufficient and the patient is stable, monitoring may become less frequent.

PROGNOSIS AND OUTCOME

Good prognosis if primary disease can be resolved

PEARLS & CONSIDERATIONS

COMMENTS

- Horses should be monitored closely the first 24 hours of therapy to allow adjustments in administration rates and to ensure that the rehydration plan is adequate.
- The skin tent test may be a poor predictor of dehydration in old horses and neonates because of decreased organized dermal collagen.

PREVENTION

- Ensure adequate access to fresh, clean water in normal horses.
- Refer to specific disease processes for prevention.

CLIENT EDUCATION

- Fresh, clean water should be available at all times.
- Foals may dehydrate quickly and should be assessed by a veterinarian immediately if not nursing.

EDITORS: **R. REID HANSON** and **AMELIA MUNSTERMAN**

Dental Avulsions

BASIC INFORMATION

DEFINITION

Teeth that have been traumatically removed from their alveoli (section of the parent bone) may be salvageable for reimplantation.

SYNONYM(S)

Dental fracture

EPIDEMIOLOGY

SPECIES, AGE, SEX Young horses (median age, 6 years) in one published study

ElibeVet.com

ASSOCIATED CONDITIONS AND DISORDERS Mandibular fractures

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT
- Acute presentation with missing teeth or clear malocclusions
- Hemorrhage

PHYSICAL EXAM FINDINGS
- Incisor avulsion portion of the incisive plate.
- Feed may be packed around the avulsed tooth roots and alveolar bone.
- Some teeth may be retained solely by a portion of the gingiva.

ETIOLOGY AND PATHOPHYSIOLOGY These fractures are usually the result of the inquisitive nature of horses such as entrapment of the teeth under a wire or fence and ensuing panic. The horse pulls back, and the teeth are avulsed.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Dental fracture
- Mandibular fracture

INITIAL DATABASE
Oral and radiographic examination to include intraoral ventrodorsal projections

TREATMENT

THERAPEUTIC GOAL(S)
Incisor reattachment (incisive plate)

ACUTE GENERAL TREATMENT
- Sedation or general anesthesia, depending on the degree of soft tissue discomfort
- Removal of putrefying feed
- Wiring of teeth (bone) back to the mandible or maxilla; this may require an intraoral splint, depending on the fracture configuration

CHRONIC TREATMENT
Incisor removal if reattachment fails

POSSIBLE COMPLICATIONS
- Fixation failure
- Infection

RECOMMENDED MONITORING
Recheck in 6 weeks. Possible wire removal at this stage.

PROGNOSIS AND OUTCOME
Good

PEARLS & CONSIDERATIONS
If there is a possibility that the tooth may be saved, however tenuous, it is better to try to save it and possibly succeed rather than remove every tooth at the first examination.

SUGGESTED READING

Auer JA: Craniomaxillofacial disorders. In Auer JA, Stick JA, editors: *Equine surgery*, ed 3. New York, 2006, Saunders Elsevier, pp 1341–1362.

Dentigerous Cysts

BASIC INFORMATION

DEFINITION
A cystic structure, typically present at the base of the ear, containing either dental remnants or complete teeth

SYNONYM(S)
Temporal teratoma

EPIDEMIOLOGY
SPECIES, AGE, SEX Young horses, but the cyst may enlarge with age as dental elements mature

CLINICAL PRESENTATION
HISTORY, CHIEF COMPLAINT A nonhealing draining tract producing milky white or cream-colored fluid situated at the base of the ear

ETIOLOGY AND PATHOPHYSIOLOGY A congenital defect arising as an embryonic failure to close the first branchial cleft containing, by definition, dental elements

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Pathognomonic lesion and presentation

INITIAL DATABASE
Palpation and radiographic evaluation

TREATMENT

THERAPEUTIC GOAL(S)
No treatment is necessary unless the intermittent drainage is cosmetically undesirable. If so, complete extirpation of the cyst is necessary

ACUTE GENERAL TREATMENT
General anesthesia and surgical removal

POSSIBLE COMPLICATIONS
- Damage to the auriculopalpebral nerve and associated musculature
- Damage to the calvarium during removal

PROGNOSIS AND OUTCOME
Excellent

PEARLS & CONSIDERATIONS

COMMENTS
Attempt to avoid opening the cyst.

PREVENTION
Congenital lesion; prevention is impossible

SUGGESTED READING

 ElibeVet.com

Depigmentation Disorders (Vitiligo)

BASIC INFORMATION

DEFINITION

- Leukoderma: Depigmentation of the skin
- Leukotrichia: Depigmentation of the hair
- Reticulated leukotrichia: Cross-hatched or netlike pattern of leukotrichia
- Spotted leukotrichia: Individual small areas of leukotrichia

SYNONYM(S)

- Vitiligo: Idiopathic depigmentation; this is an overall term that includes both leukoderma and leukotrichia
- "Snowflakes"

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common in horses but may be seen in other Equidae as well.
- Mostly in young horses but may be seen in any age
- Genetics and breed predisposition
  - Most commonly seen in (gray) Arabian horses and Shires, but any breed can be affected
  - The condition may be hereditary.

ASSOCIATED CONDITIONS AND DISORDERS A subform of equine vitiligo: Arabian fading syndrome or "pinky syndrome"

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Idiopathic vitiligo
- Leukoderma
- Leukotrichia
- Asymptomatic reticulated leukotrichia
- Hyperesthetic leukotrichia: A painful subform of reticulated leukotrichia. This may be an unusual form of erythema multiforme (associated with herpes virus infection or vaccinations).

HISTORY, CHIEF COMPLAINT Various degrees of depigmentation affecting the hair, skin, or both

PHYSICAL EXAM FINDING

- Gradually expanding depigmented macules
- Distribution of lesions may be symmetrical or segmental.
- Lesions typically affect the lips, muzzle, and eyelids; less commonly, the anus, vulva, sheath, and hooves may be affected or lesions may be generalized.
- Leukotrichia without leukoderma is common.
- No preexisting lesions in affected areas
- Pruritus is absent.
- Depigmentation may wax and wane but is usually permanent.
- Occasionally, lesions become repigmented.
- Usually nonpainful except in the early stages of hyperesthetic leukotrichia during which crusts may be present that get replaced by white hair
- Arabian fading syndrome: A form of equine vitiligo that develops in young (1–2 years of age) Arabians, more commonly in grey animals. It is characterized by round, depigmented macules at mucocutaneous junctions and is commonly permanent. If a mare develops the condition during pregnancy or shortly after parturition, the foal may be at higher risk for future development of vitiligo.

ETIOLOGY AND PATHOPHYSIOLOGY

- Vitiligo is assumed to be genetically programmed depigmentation, but to the author's knowledge, the pathophysiology of vitiligo, leukoderma, and leukotrichia in horses remains unknown.
- Three hypotheses for pigment loss in human vitiligo have been advanced:
  - Autotoxicity hypothesis: Reactive melanin precursor molecules are thought to predispose melanocytes to destruction, possibly because of inhibition of thioredoxin reductase, a free radical scavenger associated with the melanocyte cell membrane.
  - Neural hypothesis: Melanocytes originate from the neural crest and have characteristics of nerve cells; thus, neural injury has been advanced to explain dermatomally distributed vitiligo.
  - Autoimmune hypothesis: Melanocytes can be destroyed by humoral or cellular immune mechanisms; in humans and horses with vitiligo, autoantibodies against melanocytes have been found, but it is unclear whether these antibodies are the cause or a result of the disease.
- Multiple mechanisms may contribute to development of vitiligo in individual horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acquired depigmentation through external factors, often at sites of previous inflammation leading to the destruction or nonfunctioning of the melanocytes
- Examples include pressure wounds, freeze branding, chemical burns, local anesthetic with epinephrine for nerve blocks, radiation, discoid or systemic lupus erythematosus, infectious bites (eg, onchocerciasis, dourine [*Trypanosoma equiperdum*], *Culicoides* spp.), aural plaques, coital exanthema (equine herpesvirus-3), and excessive amounts of exogenous thyroid hormone supplementation leading to presumed vitamin A deficiency.

INITIAL DATABASE

- Detailed history to rule out external causes (especially previous injuries)
- Physical examination: Normal appearance of hair and skin (except the lack of pigment)

ADVANCED OR CONFIRMATORY TESTING

Biopsies for histopathologic examination show normal skin (with absence of melanin).

TREATMENT

THERAPEUTIC GOAL(S)

- Repigmentation of hair and skin (can rarely be achieved)
- Prevention of sunburn of depigmented skin

ACUTE GENERAL TREATMENT

- Observation only (benign neglect) is the preferred treatment.
- Daily application of sunscreen (zinc oxide) before turning the horse out, stabling during daylight hours, or covering of affected areas (fly mask)

CHRONIC TREATMENT

- Reports of treatment for equine vitiligo are anecdotal.
  - Vitamin A (large quantities of carrots) in cases of excessive thyroid hormone supplementation
  - Copper supplementation (copper is important for the rate-limiting enzyme in melanogenesis)
  - Other treatments adapted from humans (unproven to be either safe or effective in horses)
  - Topical corticosteroids: High-potency fluorinated corticosteroids (eg, fluocinolone with dimethyl sulfoxide, Synotic) applied to lesions for 1 to 2 months and then

changed to a less potent corticosteroid; if there is no response after 3 months, treatment is discontinued; repigmentation 4 months or longer in humans; may recur after treatment is discontinued; side effects may include skin atrophy (treatment is reported to be 64% effective in childhood vitiligo).

- Topical tacrolimus (Protopic, 0.03% ointment): Use has not been described in horses; safe and effective for treatment of vitiligo in children (86% showed some repigmentation after 12 weeks of treatment).

PROGNOSIS AND OUTCOME

Usually a cosmetic disease only. Some horses repigment within 1 year; others may wax and wane, but most often the depigmentation is permanent.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

For affected show horses, it is possible to dye the depigmented hair.

PREVENTION

Because of potential heritability of equine vitiligo, breeding of affected horses is not recommended

SUGGESTED READING

Pigmentary abnormalities. In Scott DW, Miller WH, editors: *Equine dermatology*. St Louis, 2003, Saunders Elsevier Science, pp 587–599.

AUTHOR: **ANNETTE PETERSEN**

EDITOR: **DAVID A. WILSON**

Dermatitis, Atopic

BASIC INFORMATION

DEFINITION

A hypersensitivity disorder in which the patient becomes sensitized to inhaled or percutaneously absorbed allergens such as dust, pollens, and molds, causing pruritus or urticaria.

SYNONYM(S)

Allergic inhalant dermatitis, allergies, atopy

EPIDEMIOLOGY

SPECIES, AGE, SEX Age of onset is 1 to 6 years, although it can occur in older horses that have moved to different botanical zones.

GENETICS AND BREED PREDISPOSITION Familial, Thoroughbreds, and Arabians may be predisposed.

RISK FACTORS Genetic predisposition and sensitization to allergens at a young age

GEOGRAPHY AND SEASONALITY May be seasonal or nonseasonal and may be more common or severe in warmer areas with longer pollen seasons

ASSOCIATED CONDITIONS AND DISORDERS Insect hypersensitivity, eosinophilic granulomas, allergic airway disease, chronic obstructive pulmonary disease, or head shaking

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Pruritus, urticaria, or pruritic urticaria

HISTORY, CHIEF COMPLAINT Seasonal or nonseasonal pruritus or urticaria

PHYSICAL EXAM FINDINGS Alopecia and excoriations of the face, ears, neck, legs, or ventrum secondary bacterial folliculitis

ETIOLOGY AND PATHOPHYSIOLOGY A type 1 hypersensitivity reaction in which an allergen is inhaled, ingested, or percutaneously absorbed, resulting in the production of allergen-specific IgE. When the IgE fixed on the surface of mast cells reacts with the offending allergen, mast cell degranulation occurs, causing release and production of various pruritogenic compounds such as histamine, leukotrienes, and prostaglandins.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Insect hypersensitivity, food hypersensitivity, contact dermatitis, mange mites, storage mites, pediculosis, trombiculosis, oxyuriasis

INITIAL DATABASE

Diagnosis is made by history, clinical findings, response to therapies, and ruling out other differentials.

ADVANCED OR CONFIRMATORY TESTING

- Histopathology is supportive but not confirmative: Superficial and deep perivascular dermatitis with eosinophils.
- Intradermal allergy testing: Preferred
- Serological allergy testing: Unreliable

TREATMENT

THERAPEUTIC GOAL(S)

Ameliorate the clinical signs. Atopy cannot be cured, only managed.

ACUTE GENERAL TREATMENT

- Corticosteroids
  - Prednisone or prednisolone: 1 to 2 mg/kg/d PO; then tapered to the lowest possible alternate day dose
  - Dexamethasone: 0.1 to 0.2 mg/kg/d PO; then tapered to the lowest possible q72h dose.
- Antihistamines
  - Hydroxyzine: 1 to 2 mg/kg PO BID to TID
  - Doxepin: 1 mg/kg PO BID
  - Amitriptyline: 1 mg/kg PO BID
  - Chlorpheniramine: 0.25 to 0.5 mg/kg PO BID
  - Diphenhydramine: 1 to 2 mg/kg PO BID to TID
- Shampoos and rinses (eg, oatmeal soaks, pramoxine, glucocorticoids)
- Fatty acid supplements

CHRONIC TREATMENT

- Allergen-specific immunotherapy (preferably based on intradermal testing) is the most specific treatment.
- Symptomatic therapy with antihistamines, low alternate-day dose prednisolone, or topical antipruritics

POSSIBLE COMPLICATIONS

Secondary bacterial infection must be identified and eliminated with antibacterial shampoos and systemic antibiotics.

RECOMMENDED MONITORING

- Monitor and control infections.
- Decrease exposure to insects if the patient has concurrent insect hypersensitivity.

ElibeVet.com

PROGNOSIS AND OUTCOME

Prognosis is good for control of the disease, although cure is not possible.

PEARLS & CONSIDERATIONS

COMMENTS

If symptoms exist longer than 2 months out of the year, then immunotherapy is the safest, most specific, and often the least expensive treatment option. There are no drug residues to be concerned about for show animals.

PREVENTION

- Affected animals should not be considered for breeding
- Avoidance of the offending allergens is beneficial but often impractical.

SUGGESTED READING

Rees CA: Response to immunotherapy in six related horses with urticaria secondary to atopy. *J Am Vet Med Assoc* 218:753, 2001.

AUTHOR: **DAVID SENTER**

EDITOR: **DAVID A. WILSON**

Dermatitis, Contact

BASIC INFORMATION

DEFINITION

Rare form of hypersensitivity associated to contact with potential allergens. Substances that have been identified as potential sources are soaps, shampoos, plants, bedding material, topical medications, insect and fly repellents, leather, disinfectants, dyes, blankets, and pads.

SYNONYM(S)

Contact hypersensitivity

EPIDEMIOLOGY

GEOGRAPHY AND SEASONALITY Contact dermatitis may be either seasonal or nonseasonal, depending on the inciting agent.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Frequently, the complaint is the presence of vesicles or papules over the specific contact area. After the vesicles rupture, an erythematous area with serous discharge is found. Pruritus and pain are rare and minimal if present.

PHYSICAL EXAM FINDINGS

- Localized inflammatory reactions occur where the foreign material has been in contact. Generally, the lesions are very well localized, but multiple areas are occasionally affected.
- Areas of self-mutilation or secondary bacterial contamination may be present in the lesions.

ETIOLOGY AND PATHOPHYSIOLOGY

- In general, the particles that create the hypersensitivity are nonallergenic on their own, but when in contact with the skin, they penetrate through the epidermis and bind to carrier proteins, resulting in allergic contact dermatitis.
- The resulting type of sensitivity is a type IV hypersensitivity reaction.
- Some horses have more sensitivity reactions to fly sprays, and it can be exacerbated by applying these products before saddling and tacking because the pressure of the saddle and tack compress the offending chemical between equipment and hot sweaty skin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Parasitic hypersensitivity
- Culicoides hypersensitivity
- Pastern dermatitis
- Food hypersensitivity
- Drug eruptions
- Sarcoptic or psoroptic mange
- Ectoparasites

INITIAL DATABASE

The history, clinical signs, and physical examination can lead to a preliminary diagnosis.

ADVANCED OR CONFIRMATORY TESTING

Patch testing is confirmatory of contact dermatitis. It involves applying the suspected affecting substance on a cloth that is then applied to the skin with adhesive tape for 48 hours. If a marked reaction is present, it is suggestive of contact dermatitis. It is important to consider the possibility of reaction to the tape or the cloth material. A blank negative should be used to identify a positive reaction.

TREATMENT

THERAPEUTIC GOAL(S)

Eliminate the source of reaction and decrease skin reaction as quickly as possible.

ACUTE GENERAL TREATMENT

- Remove the horse from the environment or source of the allergen.
- Administering oral or topical corticosteroids will decrease the clinical signs but will not cure the problem.

PROGNOSIS AND OUTCOME

- Excellent prognosis after the allergen is identified and removed from the environment of the horse
- Minimal scarring is expected after small localized lesions, but if larger areas are affected, some scarring is to be expected.

PEARLS & CONSIDERATIONS

- Avoidance of the offending allergens is the best way of preventing contact dermatitis.
- Animals that have sensitive skin may react to different types of substances, so it is important to consider the different active ingredients in products when selecting shampoos, insect repellents, and soaps.

BASIC INFORMATION

DEFINITION

Common acute and chronic exudative dermatitis caused by an actinomycete. Commonly seen during rainy and humid periods.

SYNONYM(S)

Rain rot, rain scald, mud rash, mud fever

EPIDEMIOLOGY

Horses, cattle, sheep, goats and occasionally humans can be affected.

RISK FACTORS

- Horses that live outdoors and have minimal to no shelter are at a higher risk of developing the disease. Very wet and humid summers can also predispose horses to be affected because of the moisture that is maintained in the hair coat, which provides the appropriate conditions for the organism to proliferate.
- Debilitated, immunocompromised, or malnourished horses are more susceptible to developing the disease, but in general, any horse can develop the disease.

CONTAGION AND ZOONOSIS Mechanical transmission by both biting and nonbiting flies and ticks is possible, and fomites (blankets, brushes) can also cause the disease. Humans, especially those who are immunocompromised, can occasionally be affected by the disease.

GEOGRAPHY AND SEASONALITY The disease is seen worldwide and generally during very rainy seasons, mostly in the fall and winter or very rainy summers.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Presence of lesions over the dorsum of the horse that look like large drops have scalded the horse. These lesions typically exude, causing hair mats that can form a plaque. These lesions can be very painful but are rarely pruritic.

PHYSICAL EXAM FINDINGS Multiple lesions, usually less than 2 cm in diameter, over the rump, loin, and saddle area of the horse, occasionally on the face and in some cases on the legs. In severe cases, horses may show signs of systemic disease and require parenteral antibiotic treatment.

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiologic agent is *Dermatophilus congolensis*, a gram-positive actinomycete bacterium. It is a non–acid-fast, branching, filamentous aerobic bacterium that is seen as parallel rows of coccoid zoospores.
- A carrier animal, moisture, and skin abrasions are necessary conditions for development of the disease.
- The primary source of infection is chronically affected animals. When the lesions in these animals are moistened, the infective stage zoospores are released. The moisture causes epidermal maceration and the organism to be infective.
- The organism can be isolated from the environment of the affected horse.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Dermatophytosis
- Folliculitis caused by *Staphylococcus aureus* or *Corynebacterium pseudotuberculosis* infection
- Pemphigus foliaceus
- Viral infections
- Severe urticaria
- Generalized granulomatous disease

INITIAL DATABASE

- Complete history, physical examination, and distribution of lesions
- Removal of "paintbrush" lesions made of a scab with the undersurface covered with exudates is typically diagnostic.
- Bacterial or fungal culture of the exudates under the scab
- Gram stain identification of the filamentous organism with its classic alignment in parallel rows of 2 × 8 coccoid zoospores, giving it the appearance of railroad tracks
- Culture can be helpful if fresh lesions are submitted but not for old ones.
- Biopsies help differentiate it from other diseases. Findings include neutrophilic folliculitis and intraepidermal pustules.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove horse from wet environment; keep the horse dry and protected from biting insects.
- Control worsening of the disease by transmission to other horses.
- Remove infective crusts and appropriately dispose of them because the organism can persist for up to 4 years.
- Prevent systemic disease.
- Provide appropriate skin hygiene.

ACUTE GENERAL TREATMENT

- Removal of crusts: This can be extremely painful, and depending on the severity of lesions, the horse may require sedation to successfully remove them.
- In severe and chronic cases in which systemic involvement is suspected, use of procaine penicillin at 22,000 IU/kg IM BID or trimethoprim sulfa at 30 mg/kg PO BID for a minimum of 7 days may be required.
- Use of shampoos containing chlorhexidine or iodine may be beneficial to soften the scabs and allow for easier removal and to prevent secondary bacterial infection.

CHRONIC TREATMENT

- Use of antibacterial shampoos is beneficial in decreasing the bacterial load.
- In hot and humid climates where rainfall amounts are large, use of insect repellent on a daily basis is recommended.

DRUG INTERACTIONS

Use of long-term antibiotics may cause digestive disturbances, so daily monitoring of fecal consistency is recommended.

PROGNOSIS AND OUTCOME

- The prognosis is good, but animals can be chronically infected and either develop the disease or be sources of infection for other animals.

ElibEVet.com

- No permanent scarring will be left from removal of the scabs, but the horse can be painful shortly after removal of all the scabs and during the recovery period until normal, healthy skin is present.
- No immunity will be developed by affected horses, so relapses are possible if the appropriate conditions are present.

PEARLS & CONSIDERATIONS

COMMENTS

- Removal and appropriate disposal of the scabs is important in prevention of the disease. The scabs should not be removed and disposed of on the ground because the organism has been shown to live for up to 4 years if adequate conditions are present.
- Use of gloves when removing scabs and when treating affected horses is important to decrease the possibility of human contagion.

PREVENTION

Provide adequate shelter so that the animal is protected from severe weather. If the animal still gets extremely wet, try to dry the horse as best as possible to minimize the risk of developing the disease because of appropriate moisture and humidity in the skin.

AUTHOR: **ALFREDO SANCHEZ LONDOÑO**

EDITOR: **DAVID A. WILSON**

Dermatophytosis

BASIC INFORMATION

DEFINITION

Highly contagious superficial fungal infection of skin, hair, or hooves of horses and cattle and occasionally sheep and goats

SYNONYM(S)

Ringworm

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Commonly seen in horses and cattle, less frequently in goats, and rarely in sheep
- Young animals are more susceptible to the infection. This increased susceptibility is because of their lack of immunity and potentially poor nutrition.

RISK FACTORS Overcrowding of animals, poor nutrition, and warmth and humidity are important risk factors in development of the disease.

CONTAGION AND ZOONOSIS Horses can get infected through direct contact with infected hair, animals, or fomites. Zoonoses are possible if direct contact with affected animals occurs.

GEOGRAPHY AND SEASONALITY The disease is seen worldwide and is commonly seen during the winter months because of overcrowding, which provides adequate conditions for the organism to grow.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Presence of multiple circular alopecic lesions, mostly on the face, legs, girth, shoulder, and chest

PHYSICAL EXAM FINDINGS

- The classic appearance in horses is a ring lesion with the central area often showing signs of healing. Scaling and crusting of these lesions can be variable, and pruritus is minimal or absent and may become exudative. The lesions may expand and start coalescing, creating large patches of alopecia. Some of these lesions may show a silver tinge to them, hyperpigmentation, and lichenification.
- Multiple lesions are typically present, but solitary lesions may rarely be present.
- Immunocompromised foals or horses may be severely affected and may develop generalized dermatophytosis.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Trichophyton equinum, Microsporum equinum, Trichophyton mentagrophytes*, and *Trichophyton verrucosum* infection
- Direct or indirect transmission may occur. Contaminated grooming equipment, blankets, and tack may be a source of transmission, as can insects.
- Stress or concurrent disease may predispose horses to development of dermatophytosis.
- The incubation period is between 2 and 3 weeks. During this period, other horses very likely are already infected and starting to show signs of disease.
- Dermatophytes only invade fully keratinized and nonliving tissues, which leads to weak hair shafts and alopecia.
- Superficial infections are the most common and develop thick crusts and a classic moth-eaten appearance and a ring pattern.
- Erythema is not usually seen and can be difficult to identify in pigmented skin.
- Most infections are self-limiting over a 5- to 10-week period, but treatment is recommended to limit the spread of infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Staphylococcus folliculitis*
- Dermatophilosis
- *Pemphigus foliaceus*
- *Culicoides* or insect hypersensitivity
- Mange
- Generalized granulomatous disease
- Alopecia areata
- Anhidrosis
- Occult or flat sarcoid
- Chronic skin rubs
- Abrasions
- Mercury poisoning
- Wound or exudative scalding

INITIAL DATABASE

- Direct microscopic examination of infected hairs with follicles attached from the periphery of lesions
- Skin scrapings from alopecic areas
- The most reliable diagnostic tool is fungal culture, but this can take up to 4 weeks. Use of Sabouraud's medium with phenol red dye can help in the diagnosis because the agar will change to a bright red color within a few days

ElibeVet.com

if the dermatophyte is present in the sample.
- Biopsy is rarely used but can be done to rule out other diseases and identify fungal spores.

TREATMENT

THERAPEUTIC GOAL(S)
- Limit the spread of the disease to other horses by isolating affected horses from the herd.
- Eliminate infective spores in the environment.
- Use fungicidal treatment on the horse and sporicidal treatment of the environment.
- Treat all at-risk or in-contact horses.
- Prevent zoonotic transmission.
- Clean and disinfect all tack, blankets, and grooming equipment.

ACUTE GENERAL TREATMENT
- Clip affected areas but be sure to disinfect clippers after use to prevent infection of other areas.
- Chlorhexidine- or miconazole-based shampoos are very effective and should be used as needed depending on the severity of the disease. Povidone-iodine–based shampoos can also be effective in eliminating infective spores.
- Lime sulphur (1 cup to 1 gallon of water) and bleach 1:10 with water are very effective but need to be measured appropriately; otherwise, they can be either extremely irritating to the skin or completely ineffective against the fungus.
- The environment should be cleaned with a 6% bleach solution or alternatively sporicidal disinfectants such as halogenated peroxygen agents (Virkon) or quaternary ammonium compounds (Trigene).

CHRONIC TREATMENT
- Refractory cases may require use of systemic griseofulvin (5–10 mg/kg/d for 30–60 days). Griseofulvin therapy can be extremely expensive.
- Use of 20% sodium iodide given IV (250 mL/500 kg once or twice every 7 days) has been attempted.

DRUG INTERACTIONS
- Griseofulvin should not be used in pregnant mares because of its teratogenic effects.
- Sodium iodide treatment is contraindicated in pregnant mares because it can cause abortion.

PROGNOSIS AND OUTCOME
- Spontaneous regression is commonly seen and is related to the development of immunity. The duration of immunity is unknown and may be incomplete.
- Horses have a good prognosis if appropriate treatment is instituted early in the course of the disease and appropriate environmental management is instituted.

PEARLS & CONSIDERATIONS

COMMENTS
- Younger horses take a longer time to recover from the disease than older ones because of their lack of resistance.
- Outbreaks may occur on premises that have previously been infected.

CLIENT EDUCATION
- Always use gloves when applying treatment to the affected areas to decrease the risk of human transmission.
- Do not share equipment with any other horses until the equipment has been disinfected. All tack, blankets, and grooming equipment should be disinfected before use on other horses.
- Infections in humans are typically self-limiting and respond effectively to antifungal treatments.

EDITOR: **DAVID A. WILSON**

Diarrhea, Chronic

BASIC INFORMATION

DEFINITION
Persistent or intermittent diarrhea of at least 1-month duration

CLINICAL PRESENTATION
HISTORY, CHIEF COMPLAINT
- Persistent or intermittent diarrhea for longer than 1 month
- Variable appetite
- Variable signs of abdominal pain; diarrhea often occurs in the absence of colic or inappetence
- ± Weight loss

PHYSICAL EXAM FINDINGS
- Poor body condition is often noted.
- Other findings are quite variable. No abnormalities other than diarrhea may be present, or clinical signs of dehydration and toxemia, as for acute colitis (see "Colitis/Diarrhea, Acute" in this section), may be noted.
- Rectal examination:
  - Often within normal limits.
  - Thickened rectal or colonic mucosa may be noted.
  - Rarely, mural or intraluminal intestinal masses are palpated.

ETIOLOGY AND PATHOPHYSIOLOGY A variety of distinct etiologies can manifest with chronic diarrhea via a variety of mechanisms, including:
- Partial large colonic obstruction, such as an enterolith or mural intestinal neoplasia. This may irritate the colonic mucosa or intermittently partially obstruct the colonic lumen, only allowing passage of softer fecal material around the obstruction.
- Sand enteropathy: sand irritates and inflames the colonic mucosa.
- Infectious causes, such as parasitism or salmonellosis, or rotavirus in foals. These also result in damage to and chronic inflammation of the colonic mucosa.
- Primary infiltrative or inflammatory intestinal disease impairs the normal absorptive capacity of the colonic mucosa.
- Colonic fibrosis secondary to previous severe acute colitis. This also impairs the normal absorptive capacity of the colonic mucosa.
- Gastroduodenal ulcer disease in foals is presumed to alter the absorptive function of the small intestine, which may overwhelm the colonic absorptive capacity in the less mature colon of a foal.
- Maldigestion or abnormal fermentative function of colonic flora may be

ElibeVet.com

caused by slight alterations in the nonpathogenic colonic flora population, resulting in altered volatile fatty acid synthesis or absorption, which may impair colonic water and electrolyte absorption.
- Other systemic disease, such as hepatic disease and congestive heart failure may cause portal hypertension, altering fluid dynamics in the colonic vasculature and impairing water absorption.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Partial large colonic obstruction (enterolith or mural intestinal neoplasia)
- Sand enteropathy
- Infectious causes: parasitism, salmonellosis
- Colonic fibrosis secondary to previous severe acute colitis
- Primary infiltrative or inflammatory intestinal disease
- Abnormal fermentative function of colonic flora (altered volatile fatty acid synthesis or absorption)
- Gastroduodenal ulcer disease in foals
- Rotavirus in foals
- Hepatic disease
- Congestive heart failure

INITIAL DATABASE

- Complete blood count: may be within normal limits or may show evidence of chronic inflammation with leukocytosis, mild anemia, and hyperfibrinogenemia
- Serum biochemistry profile:
  - Metabolic acidosis caused by bicarbonate loss and variable electrolyte derangements may be present (hypokalemia, hyponatremia, hypochloremia, and hypocalcemia, as for acute colitis) but are not consistent findings.
  - Serum total protein concentration may be increased because of hyperglobulinemia with chronic inflammation or may be decreased because of enteric protein loss (hypoalbuminemia).
  - Liver function should be evaluated by assessment of serum sorbitol dehydrogenase and gamma glutamyltransferase activity and serum bile acid concentration. Inflammatory intestinal disease may result in mild hepatic inflammation and mild increase in hepatocellular enzymes, but marked increases and increased serum bile acids are suggestive of primary hepatic dysfunction.
- Transabdominal ultrasound examination:
  - Fluid contents in the colon or cecum are often appreciated.
  - Colonic mural thickness may be increased (>5 mm) focally or diffusely.
  - Concurrent small intestinal mural thickening (>5 mm) is suggestive of diffuse inflammatory or infiltrative intestinal disease.
- Peritoneal fluid analysis: may be grossly and cytologically normal or may reveal a mildly increased nucleated cell count and protein concentration consistent with intestinal inflammation.

ADVANCED OR CONFIRMATORY TESTING

Determining a definitive diagnosis in cases of chronic diarrhea is difficult. Diagnostic testing for specific etiologies may include the following:
- Fecal flotation for parasites.
- Serial fecal polymerase chain reaction or cultures for salmonellosis (five to 15 samples may be needed).
- Abdominal radiography for sand enteropathy.
- Gastroduodenoscopy in foals.
- D-Glucose or D-xylose absorption test, if weight loss, hypoalbuminemia, or small intestinal mural thickening is present. Although this test assesses small intestinal rather than colonic absorptive function, it can provide information as to whether malabsorptive disease is diffuse or confined to the large colon.
- Rectal mucosal biopsy: In some cases of inflammatory or infiltrative intestinal disease, a diagnosis can be obtained via rectal mucosal biopsy. However, a normal rectal biopsy result does not rule out inflammatory intestinal disease confined to the more proximal intestinal tract. In addition, many causes of intestinal inflammation may result in nonspecific inflammation on rectal mucosal biopsy.
- Exploratory celiotomy and intestinal biopsy:
  - Intestinal biopsies may be obtained via laparotomy or laparoscopically from some locations. Several sites should be biopsied, and samples should be evaluated histopathologically and cultured for *Salmonella* spp.
  - May be indicated if above test results are negative or inconclusive.
  - Laparotomy allows possible resolution of some causes, such as sand enteropathy, enterolith, or resection of focal intestinal neoplasia.
  - However, if diarrhea is caused by altered colonic fermentative function, no gross or histopathologic abnormalities will be noted on exploratory or intestinal biopsy.

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate the primary cause.
- Alter the colonic flora to support resolution of diarrhea.

ACUTE GENERAL TREATMENT

- If a specific etiology is determined, treatment may include:
  - Larvicidal deworming for parasites with fenbendazole (10 mg/kg PO q24h for 5 days) or moxidectin (0.4–0.5 mg/kg PO once). Concurrent administration of flunixin meglumine (0.5 to 1.1 mg/kg PO or IV q12–24h) may decrease concurrent colonic inflammation associated with deworming in heavily parasitized horses.
  - Administration of laxative therapy or laparotomy and pelvic flexure enterotomy for sand enteropathy (see "Sand Enteropathy" in this section).
  - Enrofloxacin (5 mg/kg IV or 7.5 mg/kg PO q24h) for chronic salmonellosis.
  - Immunosuppressive therapy with corticosteroids for inflammatory bowel disease (see "Inflammatory Bowel Disease" in this section).
  - Surgical removal of an enterolith or resection of focal intestinal neoplasia.
  - Gastroprotectants for gastroduodenal ulcer disease in foals (see "Gastric Ulceration in Foals" in this section).
- If a specific cause is not determined, therapy may include:
  - Presumptive larvicidal deworming (because encysted cyathastomes may not produce a patent infection)
  - Administration of bismuth subsalicylate (4–5 mL/kg PO or via nasogastric tube q6–12h) for 5 to 7 days may be helpful in some horses.
  - Empiric diet change to alter the colonic flora and volatile fatty acid production. Often, changing to a complete pelleted ration results in slow but successful resolution of the diarrhea, although improvement may take 6 to 8 weeks.
  - Administration of iodochlorhydroxyquin (10–20 mg/kg PO q24h) is reportedly successful in some horses, although the beneficial effects may be transient. The mechanism is unknown, but it is presumed to alter the colonic flora. If effective, the horse should be

ElibeVet.com

maintained on it because diarrhea tends to recur when the drug is discontinued.

PROGNOSIS AND OUTCOME

Variable, depending on the primary cause

PEARLS & CONSIDERATIONS

COMMENTS

Chronic diarrhea can be a very frustrating problem for horse owners and veterinarians because of the difficulty in determining a definitive diagnosis. If a diagnosis is not determined with noninvasive diagnostic testing, empiric diet change as above may be warranted before exploratory celiotomy or intestinal biopsy.

EDITOR: **TIM MAIR**

Diarrhea, Clostridial

BASIC INFORMATION

DEFINITION

Colitis or diarrhea caused by *Clostridium perfringens* or *Clostridium difficile*

RISK FACTORS

Treatment with antimicrobial agents (*C. difficile*)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- *C. perfringens:*
  - Common fecal isolate from normal horses and foals
  - Clinical disease more common in foals
- *C. difficile:*
  - Rarely isolated from adult horses but appears to cause subclinical infection in many healthy foals (<1 month old)
  - May play a role in antimicrobial-associated colitis in adult horses and may be associated with some cases of proximal enteritis (see "Enteritis, Proximal" in this section)

HISTORY, CHIEF COMPLAINT

- Inappetence, colic, fever, and diarrhea are most common, as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).

PHYSICAL EXAM FINDINGS

- As for other causes of colitis (see "Colitis/Diarrhea, Acute").
- Hemorrhagic diarrhea is seen frequently (but not always) in horses with colitis caused by *C. perfringens.*
- In some cases, the initial findings are more consistent with proximal enteritis than colitis (see "Enteritis, Proximal" in this section), with moderate- to large-volume gastric reflux and small intestinal distension on rectal examination.

ETIOLOGY AND PATHOPHYSIOLOGY

- Clostridial organisms are anaerobic, spore-forming, gram-positive rods.
- Many clostridial species, including some strains of *C. difficile* and *C. perfringens*, may be normal enteric flora in horses.
- Clinical disease occurs as a result of overgrowth of, or infection with, toxin-producing strains.
  - *C. difficile* can produce at least five toxins, of which type A (enterotoxin) and type B (cytotoxin) are best understood.
  - *C. perfringens* can also produce several toxins. The two most common isolates identified in clinical disease in horses include type A, which produces the α toxin, and type C, which produces the α and β toxins. Some strains may also produce enterotoxin, which has also been associated with clinical disease.
- Overgrowth of toxin-producing strains of *C. difficile* has been associated with antimicrobial-associated colitis in adult horses.
- Infection may also occur with ingestion of clostridial organisms or spores from the environment or from the feces of clinically or subclinically infected animals.
- Clostridial toxins directly damage enterocytes by a variety of mechanisms, resulting in inflammation and necrosis of colonic epithelial cells, damaging the mucosal barrier, resulting in systemic exposure to bacterial toxins and loss of fluid, electrolytes, and plasma proteins into the intestinal lumen, as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

INITIAL DATABASE

- As for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section).
- With *C. perfringens* infection in foals, intramural gas (hyperechoic regions casting acoustic shadows) in the wall of the colon or small intestine may be seen on transabdominal ultrasonography.

ADVANCED OR CONFIRMATORY TESTING

- Confirmation of clostridial colitis requires detection of the toxin(s) in the feces.
  - Enzyme-linked immunosorbent assays (ELISAs) for *C. difficile* A and B toxin and *C. perfringens* enterotoxin are commercially available.
  - Toxin production can also be determined by polymerase chain reaction or bioassay, although these tests are not available in all laboratories.
  - The duration and frequency of toxin production are unknown in equine clostridial diarrhea, so testing of serial samples may be warranted if clostridial infection is strongly suspected.
- Fecal Gram stain findings can be supportive of a diagnosis of clostridial diarrhea if large numbers of gram-positive rods are seen.
- Similarly, fecal culture yielding a pure culture of *C. difficile* or *C. perfringens* may be supportive, although toxin production should still be documented as above.
- Testing to rule out other causes of colitis is also warranted as detailed in "Colitis/Diarrhea, Acute" in this section.

ElibeVet.com

TREATMENT

THERAPEUTIC GOAL(S)

- Supportive care
- Antimicrobial therapy

ACUTE GENERAL TREATMENT

- Fluid and colloidal support, antiinflammatory and antiendotoxic therapy, and other supportive care as for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)
- Antimicrobial therapy: metronidazole (15–25 mg/kg PO or PR q8h)
- This is effective in most cases, although sporadic metronidazole resistance has been reported. Vancomycin has been effective in treating metronidazole-resistant clostridial strains, although use of this agent in veterinary medicine is controversial.
- Other therapy:
  - *Saccharomyces boulardii*, a nonpathogenic yeast organism, is effective in the treatment of clostridial diarrhea in humans and may decrease the severity of diarrhea in horses with colitis from many causes. Products containing *S. boulardii* are available commercially for use in horses.
  - Di-tri-octahedral smectite (Bio-Sponge) has been documented to bind clostridial toxins in vitro and may also be helpful in clostridial diarrhea in horses.

POSSIBLE COMPLICATIONS

As for other causes of colitis (see "Colitis/Diarrhea, Acute" in this section)

PROGNOSIS AND OUTCOME

- Fair with early therapy and supportive care
- Guarded with *C. difficile* infection secondary to antimicrobial administration in adult horses

PEARLS & CONSIDERATIONS

Because of the lack of availability of assays for all clostridial toxins and thus the difficulty in reaching a rapid and definitive diagnosis, presumptive treatment with 3 to 7 days of metronidazole therapy may be appropriate in many cases of equine diarrhea in which another specific cause is not determined. However, the potential for development of metronidazole resistance should also be considered with such empiric therapy.

Diarrhea of the Neonatal Foal

BASIC INFORMATION

DEFINITION

Loose or watery fecal consistency

EPIDEMIOLOGY

RISK FACTORS

- Sepsis
- Failure of passive transfer
- Peripartum asphyxia syndrome
- Pica

CONTAGION AND ZOONOSIS Salmonellosis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Noninfectious
  - Foal heat diarrhea
  - Asphyxia-associated gastroenteropathies: peripartum asphyxia syndrome
  - Necrotizing enterocolitis
  - Mechanical enterocolitis
  - Dietary intolerances
- Infectious
  - Clostridial enteritis
  - Salmonellosis
  - Enterotoxigenic *Escherichia coli*
  - Rotavirus
  - *Cryptosporidium parvum*

HISTORY, CHIEF COMPLAINT

- Loose manure
- Decreased appetite, lethargy
- Normal attitude and appetite in foal heat diarrhea
- Ingestion of foreign material may be observed or suspected

PHYSICAL EXAM FINDINGS

- Temperature: Hyperthermic or hypothermic
- Heart rate: Often tachycardic
- Mentation: Depressed, lethargic, decreased affinity for the dam
- Mucous membranes: Injected, tacky, bright, muddy; prolonged capillary refill time
  - Perineum: Wet with diarrhea unless very projectile; inspect walls of the horse's stall for evidence of diarrhea.
  - Hydration: Severely dehydrated foals have sunken eyes, sluggish jugular refill, and cool extremities.
  - Foal heat diarrhea: Foals are hydrated; afebrile; and have normal mentation, attitude, and appetite.

ETIOLOGY AND PATHOPHYSIOLOGY

- Noninfectious
  - Foal heat diarrhea: Unknown; believed to be related to maturational changes of the gastrointestinal (GI) tract; occurs between approximately 5 and 15 days of age.
  - Asphyxia-associated gastroenteropathies: Hypoxic insult to the GI tract and hypoperfusion; possibly reperfusion injury sustained during hypoxic event (umbilical cord compression, dystocia, red bag delivery).
  - Necrotizing enterocolitis: Unknown; necrotizing insult to the GI tract; suspected to be associated with prematurity or hypoxia.
  - Mechanical enterocolitis: Ingestion of sand, dirt, bedding, or the dam's tail hair may result in mechanical irritation of the GI mucosa.
  - Dietary intolerances: Feeding a milk replacer often results in diarrhea; lactase deficiency occurs with the loss of the mucosal brush border of the small intestine. (*Clostridium difficile* and rotavirus infections are especially associated with lactase deficiency.)
- Infectious
  - Clostridial enteritis: *C. difficile* and *Clostridium perfringens* are most commonly involved; both can be primary pathogens to foals without preceding risk factors.
  - Salmonellosis: bacteremia and sepsis are common with GI tract salmonellosis.
  - *E. coli*: enterotoxigenic strains may result in bacteremia and diarrhea.
  - Rotavirus: affects the small intestine by causing blunting of the microvilli and secondary maldigestion and malabsorption; decreased absorption and increased secretion result in diarrhea. Loss of lactase production adds an osmotic component to

ElibeVet.com

diarrhea by allowing lactose to enter the colon.
  - *C. parvum*: occurs more frequently in immunocompromised (severe combined immunodeficiency) foals but occurs rarely in immunocompetent foals.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Infectious versus noninfectious diarrhea

INITIAL DATABASE

- Complete blood count (CBC)
  - Leukopenia or leukocytosis is common in horses with infectious diarrhea.
  - CBC is normal in foal heat diarrhea.
  - Normal CBC results alone do not rule out an infectious cause of diarrhea.
- Lactate
  - A handheld measurement device has been validated for use in horses.
  - Lactate level above 2.0 mmol/L in horses with hypovolemia, dehydration, and sepsis.
- Serum biochemical profile
  - Normal in foal heat diarrhea
  - Electrolyte derangements, metabolic acidosis: GI losses
  - Azotemia: prerenal in dehydration
  - Hypoglycemia: caused by decreased milk ingestion and increased glucose consumption in horses with sepsis

ADVANCED OR CONFIRMATORY TESTING

- Fecal culture (aerobic and anaerobic)
- Fecal smear with Gram stain
- Radiography of the abdomen to rule in or out sand ingestion
- Lactose tolerance test or response to lactase supplementation
- Polymerase chain reaction for toxins of *C. perfringens*
- Immunoassay for toxins of *C. difficile*
- Immunoassay or electron microscopy for rotavirus
- Acid-fast staining oocytes on fecal smear, immunofluorescence assay, or electron microscopy for *C. parvum*

TREATMENT

THERAPEUTIC GOAL(S)

- Maintain hydration.
- Maintain adequate organ system perfusion.
- Normalize acid-base balance.
- Normalize electrolytes.
- Provide nutrition as dictated by GI tract disease.
- Prevent sepsis from translocated bacteria across compromised bowel wall.
- Direct treatment of the causative agent when appropriate.

ACUTE GENERAL TREATMENT

- IV crystalloids and colloids for volume resuscitation
  - Boluses of 10 to 20 mL/kg crystalloids given over 20 to 30 minutes until hypovolemia is resolved and urine is produced.
  - Maintenance rate of crystalloids depends on rate of ongoing losses (2–6 mL/kg/h).
  - Colloids (hetastarch, plasma) should be used if protein is decreased. Doses of 3 to 5 mL/kg can be used effectively in foals to maintain adequate colloidal oncotic pressure.
- Metabolic acidosis may be caused by hypoperfusion (hyperlactatemia) or relative hyperchloremia.
  - Restore adequate circulating volume with crystalloids, colloids, and pressors if needed.
  - Treat relative hyperchloremia with sodium bicarbonate; calculate the amount needed as 0.3 × Body weight (kg) × Base deficit; administer 50% of the calculated deficit over 2 to 4 hours and the remainder over the next 12 to 18 hours.
- Direct treatment
  - Metronidazole for clostridial enteritis
  - Removal of foreign material in the environment if ingestion is suspected

CHRONIC TREATMENT

- Systemic antimicrobial agents
  - Aminoglycoside (gentamicin, 8.8 mg/kg IV q24h, or amikacin, 22 mg/kg IV q24h) plus a β-lactam such as potassium penicillin (22,000 IU/kg IV q6h) or procaine penicillin (20,000 IU/kg IM q12h) or a cephalosporin, such as ceftiofur (2.2–1.00 mg/kg IV or IM q6–12h)
- GI protectants
  - Kaolin or pectin compounds and bismuth subsalicylate: 0.5–4.0 mL/kg PO q6–24h
  - Stagger these medications from other oral medications
- Gastric ulcer prophylaxis
  - Controversial but recommended by the author
  - Omeprazole (4 mg/kg PO q24h), ranitidine (6.6 mg/kg PO q8h or 1.5 mg/kg IV q8–12h), or famotidine (2.8 mg/kg PO q12h or 0.3 mg/kg IV q12h)
- Nutrition
  - Foals with abdominal distension, ileus, reflux, colic, profuse, or watery diarrhea and foals with likely lactose deficiency or osmotic diarrhea should be withheld from milk temporarily.
  - Dextrose in IV crystalloids (4–8 mg/kg/min or 240 mL/h of a 5% dextrose solution for a 50-kg foal) with frequent measurement of blood glucose) may be used for 12 to 24 hours.
  - Prolonged intolerance of milk may necessitate parenteral nutrition.

POSSIBLE COMPLICATIONS

- Septicemia from translocation of bacteria across compromised bowel
- Localization of bacteria in sepsis cases to bone, joint, eye, lung, and so on

RECOMMENDED MONITORING

- Packed cell volume and total solids
- Blood glucose, lactate, electrolytes, and gases
- Urine specific gravity
- Therapeutic drug monitoring in foals on aminoglycosides

PROGNOSIS AND OUTCOME

Prognosis is directly affected by the severity of disease. It is the author's opinion that most foals survive with few to no complications when treated rapidly and aggressively.

PEARLS & CONSIDERATIONS

COMMENTS

- Quarantine and adherence to isolation protocols in suspected infectious diarrhea cases is imperative to limit transmission of disease.
- Disinfection of the foal's environment after disease is resolved is also imperative. (Phenol disinfectants are useful against rotavirus and many bacteria.)

PREVENTION

- Disinfection of foaling stalls between mares
- Quarantine of affected foals
- Disinfection of environment

Diastema Formation

BASIC INFORMATION

DEFINITION

Diastema (Greek: an interval; *pl.* diastemata): a space between two adjacent teeth in the same dental arch. As pertaining to the equine cheek teeth, this is, by definition, pathologic.

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS Periodontal disease

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital or acquired
- Two subtypes: Open and closed (valved)

HISTORY, CHIEF COMPLAINT

- Acute or chronic weight loss
- Quidding
- Reluctance to drink cold water
- Halitosis
- Nasal discharge

PHYSICAL EXAM FINDINGS

- Feed packed between the cheek teeth despite oral lavage
- Gingivitis: Reddened gums, pain on palpation, and possible gingival recession
- Increased gingival sulcus depth adjacent to the teeth

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology:
  - Congenital: Abnormal spacing or absence of adjacent dental buds; polyodontia or oligodontia; rotation or incorrect angulation of emerging teeth may also be a factor
  - Acquired: Dental displacements, fractured crowns, and tooth loss; iatrogenic by premature removal of deciduous teeth
  - Irrespective of the cause, there are two forms of disease:
    - Open diastemata: Bounding teeth are vertical such that the resulting space resembles a rectangle with the long sides formed by the rostral and caudal teeth and the short sides formed by the gingival margin and the buccal cavity.
    - Closed (valved) diastemata: Bounding teeth are sloped such that the space resembles an inverted triangle. The apex of the triangle is at the buccal cavity, and the base is the gingival margin. A narrow ingress into this space acts as a valve, allowing partially masticated feed into the space; however, no egress occurs. Putrefaction occurs with subsequent associated gingivitis and periodontal disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dental fracture

INITIAL DATABASE

- Complete oral examination: sedation, full-mouth speculum, light source and mirror
- Radiographic examination: lateral, bilateral oblique, and dorsoventral projections

ADVANCED OR CONFIRMATORY TESTING

Oral endoscopy

TREATMENT

THERAPEUTIC GOAL(S)

- Diastema widening to allow feed ingress and egress
- Treatment of associated periodontal disease

ACUTE GENERAL TREATMENT

- Sedation (or general anesthesia, depending on the degree of soft tissue discomfort)
- Removal of putrefying feed
- Mechanical widening of diastema using a conical burr
- Lowering of the excessive transverse ridge that commonly develops on the opposing tooth (because of a failure of occlusion)

POSSIBLE COMPLICATIONS

- Inadequate widening of the diastema
- Failure to remove the excessive transverse ridge on the opposing tooth
- Inadvertent entry into the caudal pulp chambers of the rostral tooth and the rostral pulp chambers of the caudal tooth
- Oromaxillary fistulation in chronic cases

RECOMMENDED MONITORING

Recheck in 3 to 6 months. Ensure resolution of associated periodontal disease, feed egress, and repeat lowering of the developing excessive transverse ridge on the opposing tooth.

PEARLS & CONSIDERATIONS

PREVENTION

Complete, competent oral examination every 6 to 12 months

CLIENT EDUCATION

Complete, competent oral examination every 6 to 12 months

SUGGESTED READING

Disseminated Intravascular Coagulation

BASIC INFORMATION

DEFINITION

Disseminated intravascular coagulation (DIC) is a thrombohemorrhagic syndrome resulting from the inappropriate systemic activation of the coagulation system caused by systemic inflammation. Disproportionate endothelial cell activation causes intravascular fibrin formation and microangiopathic thrombosis, resulting in organ ischemia, necrosis, reperfusion injury, and multiorgan dysfunction. Concurrent widespread hemorrhage may occur because of consumption of coagulation factors, fibrinogen, and platelets.

ElibeVet.com

SYNONYMS

- DIC
- Consumptive coagulopathy
- Dysfibrinogen syndrome

EPIDEMIOLOGY

RISK FACTORS Any primary disorder that causes systemic inflammation, including endotoxemia, sepsis, shock, trauma, hemorrhage, neonatal hypoxic-ischemic encephalopathy syndrome, local infections (endometritis), envenomation, neoplasia, immune-mediated disease (purpura hemorrhagica), gastrointestinal disease (large colon volvulus, colitis), and heatstroke

ASSOCIATED CONDITIONS AND DISORDERS

- A component of the massive and inappropriate inflammatory response resulting from traumatic or septic conditions
- Has been linked to endotoxemia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- DIC progresses through three continuous, overlapping stages:
  - Hypercoagulation: Not noted clinically
  - Compensated or subclinical stage: May see alterations in coagulation profiles or end-organ dysfunction
  - Fulminant or uncompensated stage: Fulminant coagulopathy and signs of hemorrhage

HISTORY, CHIEF COMPLAINT

- Typically indistinct
- Varies based on the primary disease process
- Hemorrhage noted in end-stage DIC

PHYSICAL EXAM FINDINGS

- Depend on primary disease process, the location and severity of fibrin deposition, and the extent of clotting factor depletion
- May not see overt clinical signs in patients with subclinical DIC
  - Pale mucous membranes
  - Tachycardia
  - Tachypnea
  - Petechia, progressing to diffuse bruising (ecchymosis)
  - Hematuria
  - Melena
  - Epistaxis
  - Icterus
  - Venous thrombosis
  - Colic

ETIOLOGY AND PATHOPHYSIOLOGY

- DIC may be initiated by one of three methods.
  - Procoagulants (tissue factor or a specific neoplastic procoagulant) expressed by adenocarcinoma or lymphoma directly stimulate coagulation pathways.
  - Bacterial endotoxins (gram-negative bacteria) or exotoxins (gram-positive bacteria) present in severe sepsis, stimulating the release of inflammatory cytokines that initiate an imbalance of coagulation.
  - Trauma, releasing inflammatory mediators and tissue factor, and causing direct damage to endothelial cells that initiates a systemic inflammatory response.
- In systemic inflammation, the disrupted endothelium and activated mononuclear cells produce proinflammatory cytokines that initiate an imbalance of coagulation.
  - Tissue factor is expressed by mononuclear cells and endothelium, initiating the extrinsic coagulation pathway.
  - Intravascular fibrin formation is promoted because of disruption of anticoagulant mechanisms.
- Anticoagulation pathways are inhibited by downregulation of antithrombin III (ATIII), thrombomodulin, and protein C.
- Abnormal coagulation is promoted by consumption of anticlotting factors, including thrombomodulin and antithrombin III.
  - Fibrinolysis is inhibited by plasminogen activator inhibitor type 1 released by the endothelium.
  - Thrombocytopenia and consumption of coagulation factors may occur as DIC progresses, initiating the hemorrhagic phase.
- Thrombosis causes local ischemia, acidosis, necrosis, and reperfusion injury, which perpetuates DIC and may lead to multiorgan failure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Anticoagulant or rodenticide exposure
- Severe thrombocytopenia
- Inherited or acquired platelet dysfunction
- Hydroxyethyl starch administration (prolonged clotting times)
- Liver failure

INITIAL DATABASE

- Initial testing is focused on identification of the disease process or a risk factor linked to DIC. A complete blood count, platelet count, and blood smear evaluation should be performed.
  - Platelet counts are usually decreased in patients with acute coagulopathy because of consumption or immune-mediated destruction.
  - Platelet function tests may indicate subclinical DIC caused by reduced function by fibrinogen degradation products (FDPs) or fibrin binding to platelets.
- Serum chemistry profile
- Urinalysis
- Chest and abdominal ultrasonography
- Abdominocentesis

ADVANCED OR CONFIRMATORY TESTING

- The presence of DIC is supported by an identified risk factor through the initial database plus abnormal coagulation test results, positive fibrinolysis results, clot inhibitor consumption results, or end-organ failure.
- No single test is confirmatory for DIC; however, three abnormal coagulation test results and clinical signs of hemorrhage or thrombosis are indicative of this condition.
  - Procoagulant and coagulation tests: require age-matched control subjects because activated partial thromboplastin time (APTT) and prothrombin time (PT) are commonly increased in normal neonates.
- PT
  - Tests the extrinsic and common coagulation pathways
  - Increase of 20% compared with age-matched control subjects is significant
  - Highly indicative of survival in horses with colic
- APTT
  - Tests the intrinsic and common pathways
  - Sensitive for identification of subclinical DIC but not specific
  - Both PT and APTT may be increased in normal neonates
- Fibrinogen
  - Large production capacity by the liver in horses
  - Not commonly decreased in horses with fulminant DIC; reductions are suspicious
- Thromboelastography
  - Viscoelastic method of assessing clot formation in vitro using a vibrating sensor
  - Significantly increased in foals with coagulation abnormalities; associated with increased mortality
- Fibrinolysis activation tests
  - D-Dimer or fibrin/FDP concentrations
  - Produced by plasmin degradation of fibrinogen or cross-linked fibrin
  - Typically increased in DIC indicative of fibrinolysis
  - Poor prognostic indicator in horses
- Clot inhibitor consumption tests
  - ATIII activity
    - May increase in the peritoneal cavity with strangulating lesions
    - Typically decreased in DIC
    - Associated with a negative outcome

ElibeVet.com

- End-organ damage or failure tests
  - Lactate: May be increased with hypercoagulation, indicating decreased tissue perfusion
  - Creatinine: Azotemia may occur because of decreased renal perfusion and end-organ failure
- Necropsy may provide a definitive diagnosis
  - Microthrombi noted in one or more organs is indicative of DIC
  - Tissues must be fixed rapidly after death to identify microthombi or the clots dissolve

TREATMENT

THERAPEUTIC GOAL(S)

Diagnose and correct the primary condition, reverse coagulopathies, restore normal hemostasis, and prevent end-organ failure caused by thrombosis.

ACUTE GENERAL TREATMENT

- Treat the primary condition
  - Ensure adequate tissue perfusion with IV fluid therapy.
  - If the patient is anemic, administer whole blood transfusion or polymerized hemoglobin solution.
  - Supplemental nasal oxygen may be indicated.
- Address endotoxemia
  - Low-dose flunixin meglumine to reduce prostaglandin release: 0.25 mg/kg q8h IV
  - Polymixin B to bind to endotoxin and prevent cell activation: 6000 IU/kg q8–12h IV
  - Risk of nephrotoxicity in dehydrated horses
- Address consumptive coagulation disorders
  - Fresh-frozen plasma for supplemental ATIII and coagulation factors; repeated doses may be required
  - Platelet-rich plasma
- Address thrombosis
  - Heparin
  - Unfractionated sodium heparin
    - Increases activity of ATIII, inactivates Xa, inhibits conversion of prothrombin to thrombin.
    - Higher doses inactivate thrombin and act as a cofactor to ATIII-mediated inhibition of factors IX, X, XI, and XII.
    - 5 to 80 U/kg bolus; then 5 to 25 U/kg/h continuous-rate infusion or 40 to 80 IU/kg q8h SC or IV.
    - May cause thrombocytopenia and erythrocyte agglutination.
    - Administer plasma concurrently if ATIII activity is less than 60% of normal.
  - Low-molecular-weight heparin
    - More reliable effects and a longer half-life without the side effects of unfractionated heparin
    - Dalteparin (Fragmin): 5 to 100 U/kg q24h SC
    - Enoxaparin (Lovenox): 40 to 80 U/kg q24h SC
    - Cost may limit use
  - Aspirin
    - Inhibits cyclooxygenase enzymes, reducing thromboxane A2 production and platelet aggregation
    - 15 to 100 mg/kg q8h PO or 30 mg/kg q24–48h PO

DRUG INTERACTIONS

- Avoid aspirin, heparin, and hydroxyethyl starches in patients in fulminant hemorrhagic DIC or with prolonged clotting times or thrombocytopenia.
- Ensure adequate hydration and renal function before administering nonsteroidal medications or polymixin B.

RECOMMENDED MONITORING

- Serial platelet counts and in vitro clotting times.
- Repeated serum chemistries to monitor organ function.
- Serial lactate monitoring for signs of decreased tissue perfusion.
- With unfractionated heparin therapy, monitor for hemorrhage, decreasing platelet count or packed cell volume, and excessive prolongation of in vitro clotting times.
- Low-dose sodium heparin is antithrombotic without affecting APTT and is recommended over calcium heparin, which prolongs the APTT and reduces hematocrit.

PROGNOSIS AND OUTCOME

Guarded to poor

PEARLS & CONSIDERATIONS

COMMENTS

- Recognition of the risk factors that may lead to the development of DIC is required to provide early and adequate monitoring for patients with DIC.
- Therapy for patients with DIC in the fulminant stage is difficult and will not be successful without resolution of the primary disease.

PREVENTION

Timely therapy and resolution of the disease processes that can lead to DIC is the key to prevention.

CLIENT EDUCATION

The development of DIC represents a severe, and often fatal, complication of systemic disease.

Dorsal Displacement of the Soft Palate

BASIC INFORMATION

DEFINITION

Intermittent dorsal displacement of the soft palate (DDSP) is a purely dynamic upper airway obstruction occurring during exercise. In this clinical presentation, the caudal edge of the soft palate is located dorsal to the epiglottic cartilage, resulting in an obstruction during exhalation as air is being diverted through the oropharynx. Permanent dorsal displacement of the soft palate is seen at rest and may be accompanied by dysphagia. This clinical presentation thus

ElibeVet.com

leads to early interference with ventilation during exercise and may be accompanied by lower airway infection in its more severe form.

SYNONYM(S)

Palate displacement

EPIDEMIOLOGY

SPECIES, AGE, SEX Higher prevalence in younger horses (ages 2 to 3 years)

GENETICS AND BREED PREDISPOSITION It is unknown if there is a genetic predisposition to this disease, although racehorses (Standardbred and Thoroughbreds) are more commonly affected; it cannot be determined if the high prevalence in those breeds is really breed related or related to their being subjected to the most strenuous exercise conditions.

RISK FACTORS Racing conditions and upper airway inflammation

ASSOCIATED CONDITIONS AND DISORDERS Aside from the aforementioned upper airway inflammation, associated conditions include various epiglottic abnormalities such as shortened or deformed epiglottic cartilage, appearance of epiglottic flaccidity, and subepiglottic masses (cysts or granulomas). Similarly, palatal abnormalities such as cysts or granulomas are occasionally seen with dorsal displacement of the soft palate.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Intermittent displacement of the soft palate
- Permanent displacement of the soft palate

HISTORY, CHIEF COMPLAINT

- Typically, racehorses with intermittent DDSP experience a sudden decrease in performance in the last half of the race. The trainer, driver, or jockey generally reports a "gurgling" sound during exercise or as the horse slows down. Sport horse riders report a respiratory noise more marked with collection, which may or may not be accompanied by a decrease in performance.
- Horses with permanent DDSP have the same abnormal upper respiratory noise starting with initiation of exercise. In addition, signs of dysphagia can be seen with this presentation.

PHYSICAL EXAM FINDINGS

- The most common sign of this condition is auditory (ie, hearing an abnormal fluttering noise). However, some horses with dorsal displacement of the soft palate do not make an abnormal upper respiratory sound; the percentage of "silent" displacers has been estimated to be as high as 38%.
- Few other signs of DDSP are seen on external physical examination except for evidence of upper airway inflammation (enlarged submandibular lymph node, bilateral nasal discharge) or billowing of the cheeks during exercise as airflow is diverted through the mouth.

ETIOLOGY AND PATHOPHYSIOLOGY

- Decreased neuromuscular control of the intrinsic nasopharyngeal muscles, specifically the palatinus and palatopharyngeus
- Caudal position of the larynx
- Results in resistive breathing during exhalation with no measurable airway obstruction during inhalation

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Epiglottic entrapment
- Nasopharyngeal collapse
- Alar fold paralysis
- Recurrent laryngeal neuropathy

INITIAL DATABASE

- Videoendoscopic examination at rest allows identification of predisposing factors such as changes in epiglottic shape, nasopharyngeal masses, or inflammation. The value of resting examination in predicting intermittent DDSP at exercise is low because approximately 80% of horses with confirmed DDSP at exercise do not show abnormalities at rest. In addition, almost all horses can be made to displace their soft palates at rest, so this observation solely at rest is not sufficient for the diagnosis of intermittent DDSP at exercise.
- Permanent DDSP can be diagnosed at rest and may be associated with evidence of tracheal aspiration of feed material.
- Laryngeal ultrasonography indicates that the position of the basihyoid of a horse with DDSP is more ventral. However, the actual mean difference in the depth of the basihyoid varies approximately 3 mm (probably too sensitive to measurement error). At the time of this writing, this diagnostic modality is promising but still premature.
- Sound analysis during exercise reveals a concentration of spectral energy in the range of 20 to 90 Hz.

ADVANCED OR CONFIRMATORY TESTING

Videoendoscopy at exercise (either during treadmill exam or with wireless videoendoscopy) allowing the observation of the soft palate dorsal to the epiglottis for more than 8 continuous seconds is the gold standard of diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce upper airway inflammation so that intrinsic neuromuscular tone is restored.
- Remove structural abnormalities interfering with subepiglottic position of the soft palate.
- Prevent caudal and ventral movement of the larynx during exercise. This can be achieved with a change in tack or by surgical intervention.

ACUTE GENERAL TREATMENT

No treatment is needed at the termination of exercise; postexercise hypernea will restore arterial blood gases hemostasis.

CHRONIC TREATMENT

- Reduce abnormal upper airway inflammation with a course of systemic steroids (dexamethasone or prednisolone).
- Rest if upper airway inflammation is present.
- Use of tongue-tie or external device that displaces the laryngohyoid structures forward, dorsally, or both.
- Remove or reduce palatal or epiglottic masses.
- Surgical alteration of laryngohyoid position (sternothyroid muscle–tendon transection and laryngeal tie-forward).

POSSIBLE COMPLICATIONS

Dysphagia if staphylectomy is used as a modality of treatment

RECOMMENDED MONITORING

- Abnormal upper respiratory noise during exhalation
- Monitor abrupt decreases in performance during exercise with endoscopic examination

PROGNOSIS AND OUTCOME

The prognosis is fair, with 60% to 75% of horses responding to treatment.

PEARLS & CONSIDERATIONS

COMMENTS

Dorsal displacement of the soft palate is the most common cause of upper airway obstruction during exercise.

 ElibVet.com

PREVENTION

Decrease upper airway inflammation with proper vaccination and reduce exposure to infective agents.

CLIENT EDUCATION

This is a common cause of airway obstruction during exhalation and is akin to snoring in humans in terms of noise. The cause is decreased neuromuscular control of the pharynx and position of the laryngohyoid apparatus.

AUTHOR: **NORM G. DUCHARME**

EDITOR: **ERIC J. PARENTE**

Early Embryonic Loss

BASIC INFORMATION

DEFINITION

The failure to maintain pregnancy between fertilization and day 40 of gestation. This stage corresponds to the time of transition from the embryonic to the fetal stage of conceptus development.

SYNONYM(S)

Early embryonic death (EED), early pregnancy loss (EPL)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- EEL is usually seen in very young yearling mares or older mares in a range of 2.5% to 24%, with the highest incidence seen in mares older than 18 years of age.
- Younger mares usually experience EEL between days 15 and 35 of gestation.
- Older mares experience much higher embryonic losses during both oviductal (days 0–6) and the early uterine period (days 6–16).
- The effect of age on fertility usually originates in the oocyte, and embryos from the oviducts of especially older mares have shown to have significantly fewer cells and poor morphology.

GENETICS AND BREED PREDISPOSITION

- Chromosomal abnormalities such as chromosomal translocations and trisomy
- Thoroughbred mares in particular are proven to have low reproductive efficiency with EEL cited as the main reason for low production.

RISK FACTORS

- Endometrial disease
- Progesterone insufficiency
- Maternal age
- Maternal chromosomal abnormalities
- Anatomic defects such as poor perineal conformation, urine pooling, and so on predisposing to infectious endometritis.
- Venereal infections
- Foal heat breeding
- Poor nutrition

ASSOCIATED CONDITIONS AND DISORDERS

- Abortion
- Failure to conceive
- Endometritis
- Metritis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Failure to maintain pregnancy
- Return to estrus after a previous positive diagnosis for pregnancy

PHYSICAL EXAM FINDINGS

- Transrectal palpation results in failure to detect a chorionic vesicle at the base of either horn at or after 28 days of gestation. There may be a loss or decrease in uterine tone.
- Transrectal ultrasonography may reveal a sudden disappearance of the embryonic vesicle between examinations without evidence of premonitory signs. Other findings include signs of impending embryo loss such as an irregularly shaped embryonic vesicle, prolonged embryonic mobility (beyond day 16), signs of estrus such as excessive endometrial edema despite presence of the embryo, underdeveloped or small for their age embryos, absence of embryonic heartbeat, dislodgement of the vesicle with loss of fluid, increased echogenicity of fluid within the conceptus, or abnormal development of embryonic membranes.
- None, mucoid, or mucopurulent vulvar discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- Infectious causes
  - Contagious equine metritis caused by *Taylorella equigenitalis* may cause embryonic loss after initial infection (see "Contagious Equine Metritis" in this section).
  - Bacterial endometritis may be caused by several species of bacteria, the most important being *Streptococcus equi* subsp. *zooepidemicus*. Others include *Escherichia coli*, *Klebsiella pneumoniae* (capsule 1, 2, and 5), *Pseudomonas aeruginosa*, and *Bacteroides fragilis* (especially in postpartum and foal heat mares).
  - These organisms cause abnormal fluid retention and endometritis resulting in the release of complement, leukotriene B4, prostaglandin E, and prostaglandin $F_{2\alpha}$ (PG $F_{2\alpha}$) and premature lysis of the corpus luteum. This causes subsequent progesterone deficiency and embryonic mortality.
- Hormonal causes
  - Progesterone deficiency caused by the failure of the primary CL to develop adequately or because of luteolysis caused by PG $F_{2\alpha}$ release triggered because of endotoxemia of the gastrointestinal tract or other systemic illness
  - Anecdotal evidence of endocrine disorders such as hypothyroidism
- Genetic causes: Chromosomal abnormalities such as autosomal translocations and trisomy may produce unbalanced gametes, resulting in early embryonic loss.

ElibeVet.com

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Conception failure: Failure to detect a 14-day pregnancy by transrectal ultrasound examination.
- Differentiate from structures such as endometrial cysts and intrauterine fluid. Paraovarian structures can be confused with follicles but not with pregnancy because they are not in the uterus.

INITIAL DATABASE

- Complete blood count, serum biochemistry, and urinalysis are generally not indicated unless concurrent systemic illness is suspected.
- Maternal progesterone assays by enzyme-linked immunosorbent assay or radioimmunoassay. It is generally desirable to have levels above 4 ng/mL to maintain pregnancy. However, levels may vary depending on the reference laboratory.
- Serial ultrasound examination of mares with a history of EEL to monitor conceptus development as well as detect premonitory signs of impending embryo loss
- Maternal triiodothyronine (T3) and thyroxine (T4) levels in cases of suspected hypothyroidism

ADVANCED OR CONFIRMATORY TESTING

- Breeding soundness examination of old, barren mares or mares with a history of EEL
- Endometrial cytology or culture and endometrial biopsy in mares suspected of having endometritis
- Color Doppler ultrasonography to detect alterations in blood flow to the pregnant uterus and determine the uterine index. Low uterine index values are indicative of reduced blood supply to the pregnant horn and impending or ongoing embryonic mortality.
- Cytogenetic studies such as karyotyping may be indicated in mares suspected of having chromosomal abnormalities

TREATMENT

THERAPEUTIC GOAL(S)

- Minimize contamination during breeding to prevent infectious endometritis.
- Careful monitoring of embryonic development
- Treatment of concurrent illnesses
- Progestin supplementation in case of impending embryo loss

ACUTE GENERAL TREATMENT

- Prevention and treatment of postbreeding endometritis
  - Optimizing breeding management by breeding close to ovulation or inducing ovulation by administration of human chorionic gonadotropin or gonadotropin-releasing hormone analogues, thus reducing the need for more than one mating or insemination during estrus
  - Judicious use of uterine lavage, ecbolics such as oxytocin, and antibiotics after breeding to evacuate uterine fluid and stimulate uterine contractions
- Progesterone supplementation may be indicated in mares displaying signs of impending embryonic loss or in mares with a history of repeated EEL.
  - Altrenogest (Regumate; Hoechst-Roussel Agri-Vet) a synthetic progestin (0.044–0.088 mg/kg PO q24h starting 4–6 days after ovulation and continuing until day 120 of gestation). The dose may decline gradually over a 14-day period at the end of its administration.
  - Administration of 100 to 150 mg progesterone in oil q24h (available from compounding pharmacies) is also adequate to maintain pregnancy. The drawback is the need for daily injections.
- Surgical correction of anatomic defects to prevent urine pooling and fecal contamination of the genital tract

POSSIBLE COMPLICATIONS

- Abortion and high-risk pregnancy in later stages of gestation.
- Progesterone should not be used if infectious endometritis is suspected concurrently because this may prevent physical clearance of the infection from the uterus.

RECOMMENDED MONITORING

- Periodic monitoring of embryonic development by transrectal ultrasonography
- Monitoring maternal serum progesterone levels

PROGNOSIS AND OUTCOME

- Prognosis is fair to good in young mares with resolved cases of endometritis for conception and carrying the pregnancy to term.
- Older mares with history of repeated EEL and severe endometritis have a guarded to poor prognosis.
- Mares with chromosomal abnormalities do not respond to treatment and carry a poor prognosis to maintain pregnancy.

PEARLS & CONSIDERATIONS

COMMENTS

- EEL remains a cause of significant economic loss to the breeding industry. There is no cure for genetic causes of EEL such as chromosomal abnormalities; however, fertility and pregnancy rates can be considerably improved by using minimal-contamination breeding techniques and promptly and aggressively treating postbreeding endometritis.
- Although exogenous progesterone helps maintain high-risk pregnancies, serial monitoring is essential to confirm embryo viability because retention of the conceptus after death may result from continued treatment.

PREVENTION

- Optimal breeding management and treatment of endometritis
- Judicious use of hormonal medication in bred mares
- Karyotyping and early identification of mares suspected of having chromosomal abnormalities

CLIENT EDUCATION

- Educate clients regarding proper use of altrenogest, such as wearing gloves and washing the hands after use because this product can be absorbed through the skin.
- Help clients understand the genetic and age-related aspects and their refractoriness to treatment.

ElibeVet.com

Ehrlichiosis

BASIC INFORMATION

DEFINITION

Ehrlichiosis is caused by a variety of gram-negative bacteria of the *Anaplasmataceae* in which the primary infection is composed of intracellular infection of the hemolymphatic system. Hemolymphatic disease indicates disorders that affect the red and white blood cells, platelets, endothelial cells, or lymphoid cells and tissues.

SYNONYM(S)

Equine granulocytic ehrlichiosis (formerly *Ehrlichia equine*), human granulocytic ehrlichiosis

EPIDEMIOLOGY

SPECIES, AGE, SEX Younger animals (<4 years) are less severely affected

CONTAGION AND ZOONOSIS *Anaplasma equi* may be transmitted by ticks to a variety of animals and humans. Horses do not directly transmit this pathogen to humans, but there is a potential that horses may be infectious to ticks during their short ehrlichemic phase. Horses, similar to humans, are considered a dead-end host, and infection is considered acute without chronic carrier status after an acute episode.

GEOGRAPHY AND SEASONALITY

- Associated geographically with *Ixodes* spp., *Ixodes Pacificus*, and *Ixodes scapularis*
- Equine disease has been reported in Washington, Oregon, New Jersey, New York, Colorado, Illinois, Minnesota, Connecticut, Florida, and Wisconsin and outside the United States in Canada and Brazil.
- In northern Europe, *Ixodes ricinus* likely transmits the organism.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Subclinical
- Clinical
- Febrile vasculopathy
- Febrile acute ataxia

HISTORY, CHIEF COMPLAINT Development of febrile syndrome of depression, partial anorexia, limb edema, petechiation, icterus, ataxia, and reluctance to move

PHYSICAL EXAM FINDINGS

- The total clinical course of the disease ranges from 3 to 16 days. The horse has an initial high fever, fluctuating from 39.4° to 41.3° C (102.9°–106.3° F).
- The first clinical signs may be reluctance to move, distal limb and ventral edema, ataxia, depression, anorexia, icterus (Figure 1), and petechiation of the nasal septum mucosa. Severe weakness, staggering, or ataxia may occur with falling, recumbency, and injury; this may be severe to the point that horses sustain fractures after falling.
- More severe signs of disease develop by days 3 to 5, with fever and illness lasting 10 to 14 days if untreated. With the onset of more severe disease, there is an increase in the rectal temperature, an increase in the heart rate (50–60 beats/min), and often an increase in the respiratory rate. Rarely, cardiac arrhythmias consisting of ventricular tachycardia and premature ventricular contractions occur. The disease is normally self-limiting in untreated horses.
- Mortality is usually caused by sequelae consisting of secondary infection and injury. Abortion has not been observed in pregnant mares nor has laminitis been a reported feature of the clinical syndrome.
- Milder signs, including moderate fever, depression, moderate limb edema, and ataxia, develop in horses <4 years.
- Fever is usually the only clinical feature in horses <1 year.

ETIOLOGY AND PATHOPHYSIOLOGY

- *A. phagocytophilum* infection
- Poorly understood pathogenesis
- Tick infestation, bite, inoculation, and spread
- Infection of granulocytes, including platelets and neutrophils
- Inflammation of the spleen, liver, and lungs and damage caused by proinflammatory events
- Loss of granulocytic cell lines
- Development of clinical signs associated with widespread vasculitis, anemia, and thrombocytopenia
- Vascular inflammation leading to edema, cardiac impairment, and neurologic signs

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute viral infection, especially equine viral arteritis and equine infectious anemia virus
- Viral encephalitides
- Purpura hemorrhagica
- Disseminated intravascular coagulation
- Pancytopenia secondary to myelophthisic disease or drug toxicity

INITIAL DATABASE

- Complete blood count demonstrating anemia, thrombocytopenia, and leukopenia
- Cytologic evaluation of peripheral blood smear or buffy coat for detection of morulae in cytoplasm of neutrophils and eosinophils
- Electrolytes, blood urea nitrogen, and creatinine to assess cardiovascular status
- Bleeding profile is usually normal
- Liver function tests
- Blood ammonia

ADVANCED OR CONFIRMATORY TESTING

- The presence of three inclusion bodies in one blood smear or buffy coat preparation is definitive.

FIGURE 1 Horse infected with *Anaplasma phagocytophila*. (From Sellon DC, Long MT (eds): *Equine infectious diseases*. St Louis, 2007, Saunders Elsevier.)

ElibeVet.com

- Polymerase chain reaction (PCR) for detection of *A. phagocytophilum* DNA in smear
- Fourfold increase in endpoint serum titer measured by the indirect fluorescent antibody test

TREATMENT

THERAPEUTIC GOAL(S)

- Antimicrobial agent to treat organism
- Antiinflammatory agents to address vasculitis and fever
- Fluid therapy to address hypovolemia
- Prevention of self-trauma

ACUTE GENERAL TREATMENT

- Oxytetracycline: 7 mg/kg q24h for 5 to 7 days
- IV fluid and electrolyte therapy if indicated
- Flunixin meglumine: 0.5 to 1.1 mg/kg IV q12–24h
- Support wraps for distal limb edema
- Stall confinement
- Protective head gear

CHRONIC TREATMENT

Does not cause chronic disease

DRUG INTERACTIONS

The combination of tetracycline and nonsteroidal antiinflammatory drugs may result in injury to the renal system, with a higher risk in hypovolemic patients.

POSSIBLE COMPLICATIONS

- Fractures
- Exacerbation of preexisting conditions such as lymphedema and chronic cellulitis

RECOMMENDED MONITORING

- A dramatic response to therapy in terms of the animal's appetite and activity should occur within 12 hours.
- If no response is seen with two doses of tetracycline, then consideration of other causes of the clinical signs is highly warranted.

PROGNOSIS AND OUTCOME

- Excellent with treatment
- Many horses recover spontaneously, and no long-term sequelae are expected, even in untreated horses.

PEARLS & CONSIDERATIONS

COMMENTS

- Direct blood film visualization and analysis should be a cornerstone of veterinary practice.
- After tetracycline therapy has been instituted, PCR is of limited value.
- Always obtain extra purple top and red top tubes upon the horse's first visit and before treatment.
- Titers increase very quickly, and a fourfold increase in titer can be observed within the first 5 days of clinical signs.

PREVENTION

No vaccine is available, so tick control is the only prevention.

CLIENT EDUCATION

- Tick control on farms is important.
- Avoid heavily infested locations during the summer, fall, and winter months.

EDITORS: **DEBRA C. SELLON** and **MAUREEN T. LONG**

Ejaculatory Dysfunction

BASIC INFORMATION

DEFINITION

- Ejaculation is the process of sperm transport from the epididymis to the urethral meatus, resulting in expulsion of semen. Ejaculation is divided in two phases: seminal emission, which occurs at high arousal, and propulsatile ejaculation.

SYNONYMS

- Aspermia, anejaculation, retrograde ejaculation, urospermia, premature ejaculation

EPIDEMIOLOGY

SPECIES, AGE, SEX Males of any age

ASSOCIATED CONDITIONS AND DISORDERS

- Musculoskeletal disorders (sore back, lameness, degenerative joint, lameness after breeding, myositis, laminitis)
- Neurologic diseases (EPM)
- Vascular lesions (aortoiliac thrombosis)
- Cystic remnant of Müllerian ducts (uterus masculinus)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Ejaculation failure (aspermia, anejaculation): The most common cause of ejaculatory dysfunction. It is an intermittent or continuous failure of emission of semen and ejaculation in spite of normal sexual arousal and persistent mounting and thrusting.
- Sperm accumulation syndrome (spermiostasis/spermastasis): Abnormal accumulation of sperm within the ductal system.
- Urospermia: Emission of variable quantities of urine during ejaculation.
- Premature ejaculation: Very rare affliction in which ejaculation occurs before adequate insertion.
- Retrograde ejaculation: Process by which semen passes backward through the bladder neck into the bladder. It can be partial or total.

HISTORY, CHIEF COMPLAINT

- Poor breeding performance
- Difficulty in collecting semen
- Poor semen quality (intermittent or permanent)

PHYSICAL EXAM FINDINGS

- Possibly none; findings are variable depending on cause.
- Musculoskeletal or neurologic dysfunctions during mating or semen collection, such as failure to couple squarely and thrust; asymmetric hind limb weight bearing and thrusting; lateral instability; falling during thrusting or dismount; reluctance to mount or dismount; early dismount.
- Acute or chronic sources of pain affecting the urogenital tract (eg, epididymitis, scrotal inflammation).

ElibeVet.com

- Acute or chronic lesions of the penis.
- Ultrasonographic examination of:
  - The accessory sex glands could show dilated (fluid filled) and/or hyperechoic areas of the ampullae.
  - Arteries: For aortoiliac thrombosis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Ejaculation failure:
  - Acute or chronic pain of musculoskeletal origin (back pain, painful hind limb, lameness)
  - Urogenital tract problem (pain of the bladder, the penis, testis, or accessory sex gland)
  - Neurologic dysfunction (penile nerve damage, "tail nerving," incomplete spinal injury)
  - Vascular problems (aortoiliac thrombosis)
  - Psychogenic causes, such as poor handling (excessive punishment such as overuse of the chain shank or bit, overuse of the stallion, poor or inappropriate breeding environment (unstable phantom, slippery breeding shed floor), which induces pain, fear, or unpleasant experience.
- Sperm accumulation syndrome: Stallions with large testicles and high daily sperm production that are sexually rested for long periods. The sperm has a lower motility, reduced longevity, and poorer morphology.
- Urospermia: Unknown cause. Associated conditions include:
  - Neurologic dysfunction (cauda equina syndrome or equine herpesvirus-1 infection)
  - Poor or inadequate closure of the bladder neck
  - Neoplastic changes
  - Sorghum toxicosis
  - Sequelae of fractures and osteomyelitis
- Premature ejaculation: Unknown cause
- Retrograde ejaculation: Extremely rare
  - Impairment of the muscles or nerves of the bladder neck prohibit closure during ejaculation
  - Trauma or surgery of the bladder, prostate, or pelvic urethra
  - Congenital defect in the urethra or bladder
- Disease affecting the nervous system

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Must ensure that the stallion is having a complete ejaculation
- Aspermia from blockage or testicular dysfunction

INITIAL DATABASE

- Low number of sperm in the ejaculate
- Azoospermia
- Ultrasonographic examination of:
  - Accessory sex glands: Could show dilated (fluid filled) and/or hyperechoic areas of the ampullae
  - Arteries: For aortoiliac thrombosis

ADVANCED OR CONFIRMATORY TESTING

Measurement of seminal plasma alkaline phosphatase (SPAP) levels: SPAP >1000 IU/L (typically >3000 IU/L): fluid from the epididymis and testicles are present (complete ejaculate). SPAP <100 IU/L: the sample does not contain fluid from the epididymis and testicles (either failure to ejaculate or mechanical blockage preventing the semen from exiting the urethra, such as ampullary blockage). SPAP between 100 and 1000 IU/L, partial ejaculate, or partial blockage of the excurrent duct may suggest severe testicular or epididymal pathology.

TREATMENT

THERAPEUTIC GOAL

- Regaining fertility for natural breeding or managing condition through artificial reproductive techniques

ACUTE GENERAL TREATMENT

- Ejaculation failure:
  - Proper management: Expose the stallion to a mare in natural heat in a quiet environment and for a long period before collection.
  - To reduce pain:
    - Correctly adjust the phantom and ensure good footing in the shed
    - Nonsteroidal antiinflammatory drugs combined with acupuncture can also help if pain is the origin of the dysfunction (eg, phenylbutazone 2.2 mg/kg PO q12h for 3–5 days prior)
  - Maximize the conditions to the preferences of the stallion: Temperature and pressure of the artificial vagina, application of hot towels to the base of the penis.
  - In stallions that have difficulty mounting, collection can be made on the ground either by use of an artificial vagina or manual stimulation. Treatment with gonadotropin-releasing hormone to enhance arousal (50 µg Cystorelin SC 1 and 2 hours before breeding) or Diazepam to reduce anxiety (0.05 mg/kg slow IV, up to a maximum of 20 mg, regardless of weight) are used. Xylazine and imipramine are recommended to induce ejaculation without sexual excitement or stimulation (2.2 mg/kg imipramine PO followed 2 hours later by 0.66 mg/kg xylazine IV).
- Retrograde ejaculation:
  - Increase the tone of the bladder neck (sympathetic activity) or decrease parasympathetic activity
  - Imipramine 1.76 mg/kg PO q12h starting 4 days before collection
- Sperm accumulation syndrome:
  - Vigorous massage per rectum of the ampullae
  - Oxytocin (10-20 IU IV) just before collection
  - Prostaglandin $F_{2\alpha}$ is helpful to achieve ejaculation (0.01 to 0.15 mg/kg IM)
  - Collect often and frequently until sperm numbers are in line with predicted daily sperm production; then collect regularly to prevent reoccurrence.
- Urospermia:
  - Collect semen using an open artificial vagina immediately after urination, which can be obtained naturally in a fresh clean stall by a diuretic such as furosemide. Catheterization of the bladder may cause bacterial cystitis if used too often.
  - Imipramine, combined with draining of the bladder, can reduce the signs of urospermia in an affected stallion for a limited period.
- Premature ejaculation
  - Use cold water to wash the penis
  - Deflect the penis ventrally (or laterally) until insertion

POSSIBLE COMPLICATIONS

- May lose the stallion for breeding depending on cause and severity of problem

PROGNOSIS AND OUTCOME

- Depending on the condition, spermiostasis has a good prognosis; however, the prognosis could be guarded for psychogenic problems.

PEARLS & CONSIDERATIONS

- Spermiostasis must stress the importance of frequent breeding or collection

AUTHOR: **MOUHAMADOU K. DIAW**
EDITOR: **JUAN C. SAMPER**

Encephalopathy, Hypoxic-Ischemic

BASIC INFORMATION

DEFINITION

Syndrome of central nervous system (CNS) disease in foals with onset in the first 3 days of life, excluding infectious and traumatic causes and congenital and genetic defects

SYNONYMS

Perinatal asphyxia syndrome; neonatal maladjustment syndrome; "dummy," "wanderer," or "barker" foals

EPIDEMIOLOGY

SPECIES, AGE, SEX Onset is within the first 3 days of life.
RISK FACTORS Presumably, any cause of neonatal asphyxia (maternal illness, placental disease, dystocia, cesarean section, "red bag" delivery)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Delayed onset of CNS signs
- Abnormal at birth

HISTORY, CHIEF COMPLAINT
- Delayed onset of CNS signs: Foal born normally, stands and nurses normally, appears normal for first 12 to 48 hours before the onset of behavioral abnormalities
- Abnormal at birth: Foals born with risk factors for hypoxic-ischemic encephalopathy (HIE), do not stand and nurse normally, and do not show normal CNS function.

PHYSICAL EXAM FINDINGS
- Abnormal behavior: Decreased affinity for the dam, restlessness or somnolence, hyperresponsive to handling, abnormal posture, tongue protrusion, star gazing, head pressing, recumbency, abnormal breathing patterns, seizures
- Temperature, pulse, respiration, and mucous membranes are typically normal in most foals.

ETIOLOGY AND PATHOPHYSIOLOGY Unknown, but believed to be the result of hypoxic injury of the CNS neurons. The syndrome may occur without any risk factors. Damage to organ systems other than the CNS (renal, hepatic, gastrointestinal) suggests that global hypoxia-ischemia may play a role, but this has not been proven.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Sepsis
- CNS trauma
- Bacterial meningitis
- Hypoglycemia, severe electrolyte derangements
- Kernicterus
- Hepatoencephalopathy
- Congenital CNS defects

INITIAL DATABASE

- Complete blood count, serum chemistry panel, serum electrolytes, glucose
- Blood work results are normal unless HIE is complicated by a comorbid disease (eg, sepsis and HIE)

ADVANCED OR CONFIRMATORY TESTING

Cerebrospinal fluid assessment: May be normal or xanthochromic

TREATMENT

THERAPEUTIC GOAL(S)

- General support
- Control of seizures
- Prevention of infection

ACUTE GENERAL TREATMENT

- Treatment recommendations vary widely, even among seasoned clinicians with respect to direct treatment of the CNS disease. Empirical treatments include flunixin meglumine (1.1 mg/kg IV q12–24h), Magnesium sulphate ($MgSO_4$; 0.05 mg/kg/h loading dose, then 0.025 mg/kg/h), thiamine (5 mg/kg IV slowly or SC q24h), vitamin E (20 IU/kg SC or PO q24h), mannitol (0.5–2.0 mg/kg IV over 45 minutes q6h)
- General treatment is dictated by the severity of CNS disease.
  - Recumbent foals require padding and maintenance in sternal recumbency.
  - Foals with seizures require anticonvulsant therapy plus padded walls or head protection.
  - Some foals may require bladder catheterization
  - Many foals with HIE require feeding through a nasogastric tube.
- Seizure control: Diazepam for short-term control (0.1–0.2 mg/kg IV once or twice); if seizures persist, phenobarbital (10–20 mg/kg IV over 30 minutes loading dose followed by 5–7 mg/kg IV or PO q24h) or midazolam CRI (0.1–0.2 mg/kg/h)
- Prevention of infection: Broad-spectrum antimicrobial agents

PROGNOSIS AND OUTCOME

- Uncomplicated cases are generally those that experience a delayed onset of clinical signs. With appropriate treatment, these foals respond very well and do not have residual CNS deficits.
- Complicated cases, especially foals that show CNS signs at birth and HIE foals that have multiple organ system dysfunction generally have a poor prognosis.

PEARLS & CONSIDERATIONS

Diagnosis of HIE is one of exclusion. There is no definitive diagnostic test, so one must rely on history and physical findings coupled with exclusion of other differentials.

ElibeVet.com

Endocarditis, Infective

BASIC INFORMATION

DEFINITION

Endocarditis is usually the result of infections of the endocardial surface of the heart, either involving the valves (valvular endocarditis) or the walls (mural endocarditis) of the heart.

SYNONYM

Bacterial endocarditis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Endocarditis is rare in horses.
- It is seen in both young and adult horses; males are predisposed.

RISK FACTORS There are no reported risk factors, although right-sided endocarditis has been associated with jugular vein thrombophlebitis after transvenous catheterization.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Endocarditis can be categorized as acute, subacute, or chronic; bacterial or nonbacterial in origin; and valvular or mural (involving the endocardial walls), but most equine cases appear to be subacute or chronic and bacterial in origin and involve valvular structures (Figure 1).
- Rarely, parasitic infections may also result in endocarditis in horses.
- The left-sided valves (ie, mitral and aortic valve) are most frequently affected followed by the tricuspid and finally the pulmonic valve.

HISTORY, CHIEF COMPLAINT

- Most frequent presenting complaints: fever and associated clinical signs (eg, anorexia, depression), although fever may be intermittent or even absent in some patients
- Weight loss
- Signs of congestive heart failure, including tachypnea, coughing, edema, and complaints of severe exercise intolerance are possible
- Lameness (embolization into muscles or joint)

PHYSICAL EXAM FINDINGS

- Cardiac murmurs are heard in most patients, but endocarditis is not always accompanied by a detectable murmur, especially if nonvalvular structures are involved.
- Often, the endocardial lesions result in valvular regurgitation, but valvular stenosis may also occur.
- The classification of the murmur depends on the valves affected and whether a valvular regurgitation or stenosis is present. If the mitral or tricuspid valves are involved leading to regurgitation, a systolic murmur will be heard on either the left or right hemithorax. If the aortic valve is affected, often a diastolic murmur is heard because of valvular regurgitation. Valvular stenosis may also be a consequence of space-occupying lesions on the affected valves. In this case, a diastolic murmur may be auscultated over the tricuspid or mitral valves and a systolic murmur over the heart base if the aortic or pulmonic valve is stenotic.
- With heart failure, clinical signs such as tachycardia, tachypnea, coughing, harsh lung sounds caused by pulmonary edema, distension of the jugular veins, ventral pectoral or preputial edema, and weight loss may be encountered.

ETIOLOGY AND PATHOPHYSIOLOGY

- Occurs primarily in a subacute or chronic form and requires a complex interaction between endothelium, immune response, and circulating bacteria. After initial trauma to the endothelial cells and depositions of platelets and fibrin, a nonbacterial thrombotic lesion develops. During bacteremia, colonization with microorganisms occurs, creating a bacterial endocarditis visualized as a vegetative mass, leading to valvular regurgitations or stenosis and a cardiac murmur.
- Although a bacteremia is required, endocarditis may develop with no current or recent history of septic foci.
- The most frequently isolated bacteria are *Staphylococcus* spp., *Streptococcus* spp., *Actinobacillus* spp., *Pasteurella* spp., and *Escherichia coli*.
- Parasitic lesions caused by the nematode *Strongylus vulgaris* have also been reported (although rarely), primarily involving the aortic valves as well as the endothelium within the aorta and coronary arteries.

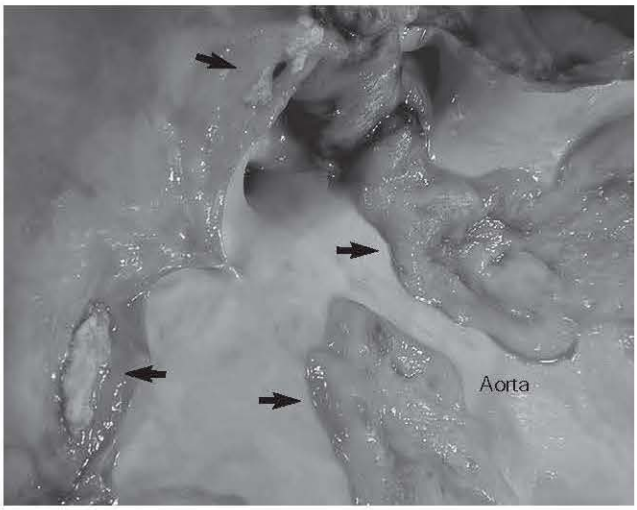

FIGURE 1 Heart with an opened left ventricle showing endocardial lesions of the aorta and aortic valves (*arrows*). (Courtesy Dr. H.E. Jensen, University of Copenhagen, Denmark.)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diagnosis is based on clinical findings of pyrexia, depression, weight loss, and possibly signs of heart failure and is supported by the presence of a cardiac murmur on auscultation. However, these signs are nonspecific and may reflect inflammation in any organ. An exact diagnosis is obtained by a positive blood culture result and echocardiographic examination showing vegetative lesions on the affected valves.
- Any disease resulting in systemic illness with fever, depression, and weight loss.
- Fibrotic and nodular thickening of the valves are incidentally visualized on echocardiography in horses. These structures generally have no inflammatory component but often result in a cardiac murmur. These findings can be difficult to differentiate echocardiographically from endocarditis lesions. However, these horses do not nor-

ElibEVet.com

mally have clinical or hematologic signs of infection unless they have an infection in another organ system. When in doubt, diagnostic testing and treatment for endocarditis should be initiated.

INITIAL DATABASE

- Hematology shows nonspecific signs of a chronic infection (eg, leukocytosis with neutrophilia, hyperfibrinogenemia, hyperproteinemia, and anemia).
- Blood cultures may be positive for bacteria. Ideally, three separate blood samples taken at least 1 hour apart should be submitted for culture before initiating antibiotic treatment. If the patient is severely ill, the samples can be taken in intervals of 5 to 10 minutes before initiating treatment. Often, patients have been treated initially with antibiotics because of fever and depression, so bacterial culture results may be negative. However, for optimal treatment, it is essential to attempt to isolate the bacterial organism.
- Two-dimensional echocardiography provides an accurate diagnosis by visualizing masses of different size, often with an irregular surface on the endocardium (Figure 2). Doppler echocardiography is used to quantify the severity of valvular regurgitation or stenosis.
- If infection with *S. vulgaris* is suspected, the lesions will be caused by aberrant migration of parasitic larvae. At this stage of infection, the parasites have not yet returned to the intestine, so fecal egg counts and larval cultures will have no diagnostic value.

ADVANCED OR CONFIRMATORY TESTING

Some horses develop severe cardiac arrhythmias along with endocarditis (eg, ventricular tachycardia, supraventricular or ventricular premature complexes, and atrial fibrillation). Therefore horses with endocarditis should have electrocardiograms (ECGs) recorded regularly. If indicated, these horses should be monitored with continuous telemetric ECG.

TREATMENT

THERAPEUTIC GOAL(S)

- Provide effective antimicrobial treatment to eliminate infection.
- Provide supportive therapy if heart failure is present.
- Provide antiarrhythmic drugs if clinically significant dysrhythmias are present.

ACUTE GENERAL TREATMENT

- Initially, parenteral broad-spectrum antimicrobial agents should be instituted, pending results of blood culture and antimicrobial sensitivity testing. A common first choice is potassium penicillin (50,000 IU/kg IV q8h or 22,000 IU/kg IV q6h) in combination with gentamicin (6.6 mg/kg IV q24h). If possible, antibiotics with good penetration into fibrinous tissue should be chosen.
- Supportive treatment should be provided for patients in heart failure, including diuretics to reduce congestion (eg, furosemide 1–2 mg/kg IV q12h) in combination with a vasodilator such as an angiotensin-converting enzyme (ACE) inhibitor (eg, enalapril 0.5 mg/kg IV q12–24h or quinapril 0.25 mg/kg PO q24h). These drugs have not been completely investigated in horses in heart failure, although the latter has shown efficacy in horses with mitral regurgitation. If severe tachycardia is present, digoxin can be given at a dosage of 0.0022 mg/kg IV q12h or 0.011 mg/kg PO q24h. (For more details on treatment of patients with heart failure, see "Cardic Failure" in this section.)
- Significant persistent dysrhythmias that contribute to clinical signs or are likely to progress to fatal dysrhythmias (eg, rapid ventricular tachycardia) should be addressed.
- If infection with *S. vulgaris* is suspected, anthelmintic treatment with ivermectin (200 µg/kg PO), moxidectin (400 µg/kg PO), or a 5-day course of fenbendazole (10 mg/kg PO) may be used to kill the migrating larvae.
- Nonsteroidal antiinflammatory drugs should be given to decrease fever and improve the patient's comfort level.
- Aspirin therapy has been recommended to decrease potential thrombus formation; however, neither that sequela nor the efficacy of aspirin in its prevention has been well documented in horses.
- Provide general supportive care to encourage the patient's appetite.

CHRONIC TREATMENT

- Continuation of antibiotic treatment is essential. The initial treatment may need to be altered according to the sensitivity pattern of the bacteria isolated.
- The horse should be treated with antibiotics for at least 5 to 6 weeks even if blood culture results are negative.
- Results of the complete blood count (CBC), serum chemistry panel, and echocardiography can be used to monitor the treatment duration.

POSSIBLE COMPLICATIONS

- Emboli originating from the vegetations may affect the lungs, brain, kidneys, joints, myocardium, and spleen, resulting in clinical signs associated with these organs.
- Cardiac arrhythmias may be seen secondary to extension of the inflammatory response in the area or because of embolic spreading to the myocardium.

RECOMMENDED MONITORING

- Clinical signs: fever, attitude, and appetite.
- Heart rate and rhythm.
- Character of murmur.
- CBC, fibrinogen, and globulin concentrations.

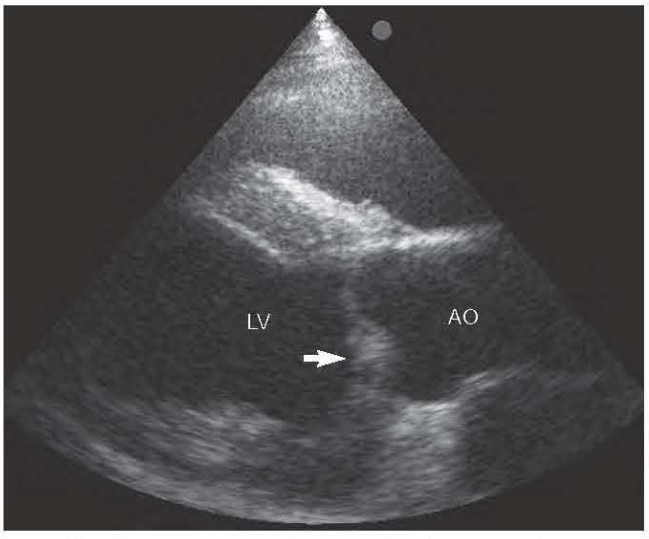

FIGURE 2 Long-axis echocardiogram of the aorta obtained from the right cardiac window showing a vegetative process on the left coronary cusp of the aortic valve (*arrow*). *AO,* Aorta; *LV,* left ventricle.

ElibeVet.com

- Periodic echocardiographic assessment of valvular lesions and severity of valvular regurgitation or stenosis to determine response to therapy.
- Monitoring should be continued after antimicrobial treatment has been discontinued to determine if relapses have occurred. If significant valvular abnormalities exist after therapy has been completed, the horse should be monitored for the possibility of development of congestive heart failure (clinical signs and echocardiography).

PROGNOSIS AND OUTCOME

- The prognosis is guarded because of the risk of embolic spreading and the risk of developing congestive heart failure. Although a bacteriologic cure may be achieved, the valves may remain incompetent or stenotic from scarring, leading to a worsening of valvular function over time and progression to heart failure.
- For horses with mitral and aortic valve endocarditis, the prognosis is generally regarded as worse than for tricuspid and pulmonic valve endocarditis because of the consequences of left-sided volume overload, heart failure, and pulmonary edema.
- The effect of treatment should be monitored by echocardiography. The lesions should diminish in size, and the surface of the vegetations should become smoother in response to treatment.

PEARLS & CONSIDERATIONS

COMMENTS

In horses with signs of infection and a cardiac murmur, it is essential to identify whether the murmur is recent in onset or has been longstanding and was present on earlier examinations of the horse before signs of infection occurred. A longstanding murmur is likely caused by noninfectious endocardial thickening and should therefore not be suspected as endocarditis.

CLIENT EDUCATION

Owners should be informed that the prognosis may be poor (especially for horses with aortic and mitral valve lesions), the treatment is prolonged and may be expensive, and the horse may not return to full athletic performance.

EDITOR: **MARY M. DURANDO**

Endometritis

BASIC INFORMATION

DEFINITION

Endometritis is inflammation of the endometrium and has many causes such as semen, bacteria, air, or foreign objects.

EPIDEMIOLOGY

SPECIES, AGE, SEX Physiologic postbreeding endometritis is seen in all mares. Pathologic endometritis is seen more commonly in older mares (especially postbreeding endometritis) but can occur in any age mare if uterine contamination with a sexually transmitted disease occurs or after insemination with frozen semen.

RISK FACTORS

- Older mares have an increased incidence of prolonged postbreeding endometritis from multiple factors.
- Mares with poor perineal conformation or a history of wind sucking are anatomically predisposed to uterine contamination with fecal and vaginal bacteria.
- Older (>12 years) maiden mares may be predisposed to excessive postbreeding endometritis because of a fibrotic, nonrelaxing cervix.
- In addition, urine pooling may lead to a sterile endometritis because of cranial urine flow into the uterus.
- Mares with compromised immune systems (caused by diseases such as Cushing disease) have a higher incidence of endometritis.

CONTAGIOUS AND ZOONOSIS Endometritis is not usually a contagious disease with the exception of certain sexually transmitted organisms, including *Taylorella equigenitalis*, some subtypes of *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPE

- Physiologic endometritis: The normal inflammatory response that occurs after breeding or parturition to allow for the expulsion of contaminants such as dead sperm or lochia.
- Mating-induced endometritis: The inflammatory response triggered by insemination. Normal inflammation allows for the phagocytosis and expulsion of unnecessary sperm, debris, and any bacteria that were introduced and should resolve within 24 hours of breeding.
- Persistent mating-induced: A continuation of mating-induced endometritis that persists for >72 hours after breeding. It is clinically relevant if the inflammation persists for >24 hours after breeding.
- Chronic endometritis: Endometritis that has persisted for more than one estrous cycle without resolution.
- Endometrosis: Chronic, degenerative changes to the endometrium that are irreversible and untreatable.

HISTORY, CHIEF COMPLAINT The chief complaint of mares with endometritis or endometrosis is often a failure to conceive ("repeat breeder"). Mares with endometritis may present 0 to 72 hours after breeding with vaginal discharge or tail rubbing or showing persistent estrus. Mares may also be found to have intrauterine fluid >24 hours after ovulation or at the pregnancy examination. In addition, endometritis may be an incidental finding on transrectal palpation or ultrasonography because of the lack of external signs.

PHYSICAL EXAM FINDINGS

- Mating-induced: Inflammation is seen after breeding. Vaginal discharge may be present but should be only a small amount. On ultrasonography, fluid may be present in the uterine lumen, and uterine edema may be increased compared with previous examinations. Physiologic inflammation should resolve within 24 hours of breeding.
- Persistent mating-induced: A continuation of mating-induced endometritis that persists >72 hours after breeding

ElibEVet.com

but is clinically relevant if it persists for >24 hours after breeding. Physical examination and ultrasound findings are similar to those of mating-induced endometritis but are often more severe.
- Chronic endometritis: Many mares with clinical endometritis are asymptomatic but fail to conceive after repeat breedings. Ultrasound findings may show intrauterine fluid or edema but may also be within normal limits. Further diagnostic testing (see below) may be necessary to identify mares with chronic endometritis.
- Endometrosis: Mares with endometrosis are asymptomatic or are repeat breeders.

ETIOLOGY AND PATHOPHYSIOLOGY

- Insults to the endometrium (sperm, bacteria, debris) lead to an inflammatory cell influx into the tissue and lumen.
- Physiologic inflammation to insemination should resolve within 24 hours.
- Resolution of endometritis involves physiologic inflammation, increased mucous secretion, and mechanical clearance.
- Mares susceptible to endometritis have delayed uterine clearance.
- The most common organism isolated from mares with endometritis is *Streptococcus equi* subsp. *zooepidemicus*. The most common gram-negative bacteria is *Escherichia coli*.
- Fungal endometritis is rare but is more common in mares that have been treated extensively for bacterial endometritis. *Candida* is the most common fungal agent.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Clinical signs: Tail rubbing caused by discharge or insect hypersensitivity
- Ultrasound findings: Early pregnancy (<22 days) or endometrial cysts

INITIAL DATABASE

- Ultrasound findings suggestive of endometritis include endometrial fluid, endometrial edema that is asynchronous with the stage of the estrous cycle, and poor uterine tone after ovulation or during diestrus.
- Endometritis is diagnosed by finding a significant number of neutrophils in the uterine lumen either via a double-guarded swab (positive result is >5% neutrophils), low-volume lavage (positive result is >15% neutrophils), or endometrial biopsy (positive result is >2 neutrophils per high power field). In addition, a uterine culture should be performed to identify the causative agent.
- The gold standard for diagnosis of endometritis is the culture of uterine biopsy tissue taken through a vaginal speculum to minimize secondary bacterial contamination. Culture results should be correlated with histopathology findings.
- The diagnosis of endometrosis is made by the evaluation of a uterine biopsy. Mares with endometrosis have chronic degenerative endometrial changes such as glandular nesting and fibrosis, lymphatic lacunae, and diffuse or perivascular fibrosis. Inflammation may or may not be present.

ADVANCED OR CONFIRMATORY TESTING

The culture of certain organisms such as *T. equigenitalis*, anaerobic bacteria, or fungi may require special media, storage, and transportation.

TREATMENT

THERAPEUTIC GOAL(S)

The goal of treatment is to resolve the inflammation by removing the inciting cause. In a breeding situation, resolution of endometritis is time sensitive. Treatment for endometritis must be aggressive because it needs to be resolved by day 3 after ovulation to minimize negative effects on the embryo.

ACUTE GENERAL TREATMENT

- Treatment generally varies depending on the severity of the inflammation, the mare's history, and the clinician's experience. Some mares may only require a single treatment; others may need to be managed intensively before and after breeding.
- Treatment options
  - Uterine lavage until efflux fluid is clear to help remove intrauterine debris, decrease the bacterial load, and gently dilate the uterus to allow removal of debris from endometrial glands and folds. Warmed (39°–45° C) sterile saline or lactated Ringer's solution is infused into the uterus 1 to 2 L at a time and then collected via gravity flow. The resulting fluid is evaluated for color and turbidity and can be spun down for cytology or culture. Uterine lavage should be performed within 4 to 6 hours but no later than 12 hours of insemination to avoid affecting subsequent pregnancy rates.
  - Ecbolics as needed to help with uterine evacuation. The most commonly used drug is oxytocin (20–40 IU IV or IM) given every 1 to 4 hours. If oxytocin is administered at very high doses (80–100 IU) or very frequently, it can lead to spastic uterine contractions that do not help evacuate fluid through the cervix. Carbetocin, a long-acting analogue of oxytocin, has been used in doses of 100 to 200 µg slowly IV for a longer duration of uterine contractility (1–2 hours).
  - Cloprostenol (250 µg/mL, 1 mL IM), a prostaglandin analogue, may be used before breeding to induce longer acting uterine contractions, but should not be given more than 12 hours after ovulation because it can have negative effects on the developing corpus luteum.
  - Mares with a fibrotic cervix require uterine lavage to help remove excess sperm and bacteria. In addition, prostaglandin E (100–200 µg in a small amount of sterile lubricant) can be applied topically to the cervix to aid in cervical dilatation.
  - Antibiotics or antifungals if necessary to help decrease the organism load within the uterus. Table 1 shows commonly used antibiotics and antifungals. The choice of antibiotic and route of administration depend on the organism cultured and its sensitivity, the mare's temperament, client cooperation, and cost. References for less commonly used antibiotics and antifungals are listed in the suggested reading.
  - Ancillary therapies in research include glucocorticoids (to suppress the immune inflammatory response) and mycobacterial cell wall extracts IU or IV (to modulate the inflammatory response). Recent studies describe different treatment and dosing regimens for glucocorticoid use, and further research is ongoing. Caslick's surgery should be performed on mares with poor perineal conformation or a history of fecal-

TABLE 1 Antibiotics and Antifungal Agents Commonly Used to Treat Endometritis*

Amikacin†
Potassium penicillin
Procaine penicillin
Trimethoprim sulfa
Gentamicin†
Ticarcillin with clavulanate
Enrofloxacin
Fluconazole (antifungal)†
Amphotericin B (antifungal)†

*Further dosing information can be found in "Endometritis, Bacterial and Fungal" in this section.
†Care should be taken when using antibiotics or antifungals known to be nephrotoxic or hepatotoxic. Owners should be advised of risks, and blood work should be monitored as necessary.

ElibVet.com

vaginal contamination. This can be done after therapy is complete or during the pregnancy examination.

POSSIBLE COMPLICATIONS

Caution should be used when introducing drugs and solutions into the uterus because high or low pH levels can damage the endometrium and lead to permanent fibrosis and adhesions.

RECOMMENDED MONITORING

Mares with a history of repeat breeding, pooling fluid after breeding, or other clinical signs of endometritis should be closely monitored on subsequent breeding cycles and treated if needed.

PROGNOSIS AND OUTCOME

- The treatment of mares with infectious endometritis caused by a sexually transmitted disease is generally rewarding and does not affect long-term fertility.
- Mares with chronic or repeated endometritis will have decreased fertility. The Kenney-Doig biopsy score can be used as a prognosticator for clients.
- Endometrosis is a chronic, degenerative disease. Therapy is aimed at minimizing the amount of inflammation, but the permanent fibrosis will decrease the mare's fertility.

PEARLS & CONSIDERATIONS

COMMENTS

- The treatment for endometritis is very variable by animal. Clinicians should use their personal knowledge, the client's financial investment in the case, and the history of the patient to plan a treatment regimen.
- Ideally, a stallion with high fertility should be chosen for "problem" mares to minimize extrinsic causes for the mare's subfertility.

CLIENT EDUCATION

Clients should be informed about the increased cost of breeding a mare with endometritis as well as the decrease in pregnancy rate compared with noninflamed mares.

Endometritis, Bacterial and Fungal

BASIC INFORMATION

DEFINITION

Inflammation of the uterine lining (endometrium) caused by the presence of bacterial or fungal organisms, creating an environment unsuitable for an embryo

SYNONYMS

Acute endometritis, chronic endometritis, uterine infection, uterine inflammation

EPIDEMIOLOGY

SPECIES, AGE, SEX Older (>15 years) mares are predisposed to bacterial infections

GENETICS AND BREED PREDISPOSITION Saddlebreds are predisposed to development of fungal infections.

RISK FACTORS

- Less than two thirds of the vulva below the brim of the pelvis
- Poor or decreased muscular tone to the vulva
- Poor conformation to the perineum
- Cervical abnormalities (trauma, adhesions, fibrosis)
- Abnormalities of the vulva (trauma)
- Decreased uterine contractility
- Exposure to pathogens during breeding
- Chronic intrauterine antibiotic administration
- Pendulous uterus
- Wind sucking: Aspiration of air into the reproductive tract
- Equine pituitary pars intermedia dysfunction
- Poor body condition (body condition score <4 of 9)

CONTAGION AND ZOONOSIS Exposure of a mare to venereal pathogens (*Taylorella equigenitalis, Pseudomonas aeruginosa, Klebsiella pneumonia*)

GEOGRAPHY AND SEASONALITY Uterine infections can occur at any time during the year and are not restricted geographically.

ASSOCIATED CONDITIONS AND DISORDERS

- Infertility
  - Low pregnancy rate
  - Increased pregnancy loss rate
- Systemic illness is rare

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute infectious endometritis
- Chronic infectious endometritis

HISTORY, CHIEF COMPLAINT

- Subfertility
- Shortened interovulatory period
- Vulvar discharge

PHYSICAL EXAM FINDINGS

- Mares appear systemically healthy.
- Intrauterine fluid present on transrectal ultrasound examination
- Vaginal discharge or fluid in the vaginal vault
- Speculum examination: Reddened cervix and cervical discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- Normally, the mare's uterus can rapidly clear infections if exposed to bacteria or fungi.
- Any breakdown in the defense mechanisms of the reproductive tract predisposes a mare to a uterine infection.
  - Conformation: Abnormalities of the perineum, vestibulovaginal seal, or cervix may allow increased numbers of pathogens to reach the uterus.
  - Uterine clearance: Decreased ability of the mare's uterus to contract, reducing clearance of fluid and contaminants from the uterus.
  - Innate immune system: Breakdown in the response toward pathogens in the uterus
- Exposure during breeding to a venereal pathogen

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

For intrauterine fluid:

- Urine pooling in the vaginal vault and uterus
- Mating- or postmating-induced endometritis
- Pyometra
- Pneumouterus (wind sucking) may allow bacteria to be carried into the

 ElibeVet.com

uterus. In addition, air is a local irritant to the endometrium.
- Mucus associated with estrus
- Heavy edema, inducing an exudate

INITIAL DATABASE

- Uterine culture via double-guarded uterine culture swab
  - Identifies microbiologic agent(s).
  - A negative culture result may not always indicate an absence of intrauterine bacteria.
- Uterine cytology
  - Sample of endometrial cells and intraluminal contents.
  - Commonly collected using a culture swab or brush and rolled onto a glass microscope slide and stained with Diff-Quik
  - Polymorphic neutrophils (PMNs) indicate active inflammation in the endometrium.
- Interpretation
  - Positive culture result with a positive cytology result is diagnostic of a uterine infections.
  - Negative culture with a positive cytology result suggests inflammation not caused by an infectious agent (postmating-induced endometritis, pneumovagina, urine pooling). However, intrauterine bacteria are not always cultured using standard techniques.
- In some cases, bacterial and fungal organisms may be seen on a cytology slide, and the uterine culture results are negative.
  - Positive culture result with a negative cytology result may be observed with some uterine bacterial infections (eg, *Escherichia coli*); may not always be associated with an inflammatory response.
  - Combination of bacterial culture of a single organism with the presence of more than 5 PMNs per 40× field confirms bacterial infection.

BOX 1 Etiologic Agents Detected in the Equine Uterus

Bacteria Known to Be Pathogenic
Streptococcus spp.
β-hemolytic
equi subsp. *zooepidemicus*
Escherichia coli
Pseudomonas spp.
aeruginosa
fluorescens
Klebsiella spp.
pneumoniae

Bacteria with Questionable Pathogenicity
Methicillin-resistant *Staphylococcus aureus*
Streptococcus spp.
α-hemolytic
nonhemolytic
faecalis
equisimilis
Bordetella bronchiseptica
Proteus spp.
mirabilis
vulgaris
Staphylococcus spp.
aureus
albus
intermedius
Serratia spp.
Corynebacterium spp.
Citrobacter spp.
Enterobacter spp.
Bacillus spp.
Acinetobacter spp.
Micrococcus spp.
Pasteurella spp.
Anaerobic
Bacteroides fragilis
Fusobacterium spp.
Clostridium spp.
perfringens
difficile
Mycoplasma spp.
Chlamydia spp.
Fungal
Candida spp.
albicans
other
Aspergillus spp.
Actinomyces spp.
fumigatus
Cryptococcus spp.
Fusarium spp.
Mucor spp.

ADVANCED OR CONFIRMATORY TESTING

- Small-volume lavage with culture or cytology of centrifuge pellet: Provides a more representative sample of the entire uterus
- Uterine biopsy for histopathology: Determines the presence or absence of endometritis when clinical and bacteriologic findings are inconclusive
- Uterine biopsy for culture: Has been suggested to be more diagnostic than a traditional culture
- Uterine biopsy for cytology: An alternative to traditional cytology sampling technique

TREATMENT

THERAPEUTIC GOAL(S)

- To aid the uterus in clearing infectious agents and inflammatory debris
- Administration of appropriate antibiotic or antifungal agent based on antimicrobial sensitivity determined from uterine culture

ACUTE GENERAL TREATMENT

- Aid in uterine clearance
- Uterine lavage
  - 0.9% saline or lactated Ringer's solution to reduce the numbers

TABLE 1 Common Intrauterine Antibiotics Used in the Treatment of Bacterial Endometritis

Antibiotic	Daily Recommended Intrauterine Dose	Spectrum
Amikacin should be buffered	1–2 g	Gram negative
Ampicillin	1–3 g	Gram positive
Gentamicin should be buffered	1–3 g	Gram negative
Potassium penicillin	5 million IU	Primarily *Streptococcus* spp.
Ticarcillin	3–6 g	Broad spectrum
Ticarcillin/clavulanic acid	3–6 g	Broad spectrum
Ceftiofur sodium	1 g	Broad spectrum

TABLE 2 Common Intrauterine Antibiotics Used in the Treatment of Fungal Endometritis

Antifungal	Daily Recommended Intrauterine Dose	Purpose
Amphotericin B	100–200 mg	Polyene antibiotic altering the permeability of the fungal cytoplasmic membrane; dilute in 100 mL
Nystatin	0.5–2.5 million U	Polyene antibiotic altering the permeability of the fungal cytoplasmic membrane; *do not* mix with saline, which may cause precipitation
Clotrimazole	500–700 mg	Disruption of nutrient exchange across the fungal cell wall and membrane
Fluconazole	100 mg	Disruption of nutrient exchange across the fungal cell wall and membrane
Miconazole	500–700 mg	Disruption of nutrient exchange across the fungal cell wall and membrane

ElibEVet.com

of infectious agents and remove inflammatory debris from the uterus
  - Enhances luminal defense mechanisms by inducing local irritation and influx of PMNs into the uterine lumen
  - Mycotic infections: Anecdotal evidence suggests the addition of dimethyl sulfoxide (10%–20%), dilute iodine (0.5%), or white vinegar (1%–2%) to the lavage solution may be beneficial.
- Ecbolics
  - Oxytocin: 5 to 20 IU administered IM or IV
  - Cloprostenol: 250 µg IM
- Appropriate intrauterine antibiotic or antifungal agent
- Bacterial infections are typically treated once daily for 3 to 5 days during estrus when the cervix is open.
- Fungal infections are also typically treated during estrus once daily for 7 to 10 days.
- Appropriate systemic antibiotics
- Often more expensive to reach minimum inhibitory concentrations within uterine tissues than with intrauterine administration
- May be used when antibiotic sensitivity warrants treatment with antibiotics not appropriate for intrauterine use (eg, enrofloxacin)

CHRONIC TREATMENT

- Repair of abnormal conformation or damaged reproductive anatomy. Common surgeries are a Caslick's procedure, perineal body reconstruction, or cervical laceration repair.
- Surgical repair should be performed before treatment with antibiotics.
- Good hygiene should be practiced by personnel and stallions when breeding mares.

POSSIBLE COMPLICATIONS

- Mares with repeated uterine infections may have an increase in development of uterine fibrosis (scar tissue). This has been shown to lead to decreased fertility rates.
- Enrofloxacin should not be used for intrauterine treatment.
- Avoid administration of prostaglandins after ovulation or during formation of the corpus luteum because it could adversely affect corpus luteum development and decrease pregnancy rates.

RECOMMENDED MONITORING

- Ultrasound examination as the mare comes back into estrus for the presence of intrauterine fluid
- Recheck uterine culture and cytology during posttreatment estrus.

PROGNOSIS AND OUTCOME

- Bacterial
  - If the initial inciting cause of the infection can be prevented, appropriate treatment will allow the mare to return to her previous level of fertility.
- Fungal
  - Treatment of fungal and more specifically yeast infections are often unrewarding. Reoccurrence of yeast infections is common. Also, the amount of intrauterine damage sustained during the infection leads to decreased fertility.
  - Mares with a fungal infection commonly have a secondary bacterial infection concurrently or after treatment for fungal organisms.

AUTHOR: **RYAN A. FERRIS**

EDITOR: **JUAN C. SAMPER**

Enteritis, Focal Eosinophilic

BASIC INFORMATION

DEFINITION

Recently described syndrome characterized by focal or circumferential regions of eosinophilic inflammatory infiltration in the small intestinal wall

SYNONYM

Idiopathic focal eosinophilic enteritis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Acute colic

PHYSICAL EXAM FINDINGS The initial evaluation of horses with focal eosinophilic enteritis is identical to that of horses presenting for other causes of nonstrangulating small intestinal obstruction, with moderate to severe abdominal pain, tachycardia, small intestinal distension on rectal examination, and gastric reflux.

ETIOLOGY AND PATHOPHYSIOLOGY

- The specific cause and the reason for the focal or circumferential nature of the inflammatory infiltrate are unknown.
- The inciting cause is likely similar to other causes of inflammatory bowel disease (see "Inflammatory Bowel Disease" in this section).
- Because of the predominance of eosinophils in the inflammatory infiltrate, a parasitic or allergic cause has been proposed, although evidence to support this is currently lacking.
- The inflammatory infiltrate and associated fibrosis creates an intramural mass or a circumferential mural band that obstructs the small intestinal lumen, resulting in acute colic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of nonstrangulating or strangulating small intestinal obstruction

INITIAL DATABASE

- No significant abnormalities other than mild dehydration are typically found on complete blood count.
- Serum biochemistry profile
  - Hypoproteinemia and hypoalbuminemia are frequently seen.
  - Globulin concentrations may be low, normal, or increased.
- Transabdominal ultrasonography: Moderate to severe small intestinal distension consistent with an obstructive pattern is frequently seen. A thickened small intestine is not usually appreciated.
- Peritoneal fluid analysis: Variable. In most cases, peritoneal fluid is either normal or has a mildly elevated nucle-

ElibeVet.com

ated cell count and total protein concentration.

ADVANCED OR CONFIRMATORY TESTING

- Exploratory celiotomy and histopathology
  - Reveal characteristic focal region or regions of intramural masses or mural bands in the small intestine with small intestinal distension oral to the lesion(s).
  - Resection of the affected regions is necessary. Histopathologic analysis reveals characteristic eosinophilic inflammatory infiltrates with variable fibrosis.

TREATMENT

THERAPEUTIC GOAL(S)

Surgical resection of affected intestine

ACUTE GENERAL TREATMENT

- Exploratory celiotomy is indicated because of colic signs associated with small intestinal obstruction that are refractory to medical management. Surgical resection of affected segments and anastomosis of unaffected jejunum is associated with a good prognosis.
- Medical management with immunosuppressive therapy as for other types of inflammatory bowel disease may have the potential to be effective but is usually not possible because of severe colic signs.
- Immunosuppressive therapy after surgery does not appear to be necessary because the lesions do not tend to recur.

POSSIBLE COMPLICATIONS

Small intestinal or gastric rupture if surgery is not performed

PROGNOSIS AND OUTCOME

Fair to good with surgical resection of affected intestine

PEARLS & CONSIDERATIONS

It is not clear whether this syndrome is an emerging phenomenon or is simply being recognized more frequently.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Enteritis, Proximal

BASIC INFORMATION

DEFINITION

Inflammatory disease of the duodenum and proximal jejunum resulting in excessive enteric fluid and electrolyte secretion and large-volume enterogastric reflux

SYNONYMS

- Anterior enteritis
- Duodenitis-proximal jejunitis (DPJ)

EPIDEMIOLOGY

CONTAGION AND ZOONOSIS Although infectious or toxic agents may contribute to proximal enteritis, the disease typically occurs in an individual horse on a farm rather than as an outbreak.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Depression, inappetence, fever, and variable signs of colic (mild to severe)

PHYSICAL EXAM FINDINGS

- Depression
- Pyrexia is commonly observed.
- Variable tachycardia and tachypnea
- Variable signs of colic, which are almost always relieved by passage of a nasogastric tube and gastric decompression
  - A significant volume of gastric reflux (5–25 L) is usually obtained initially. Reflux volume may increase with therapy when the patient is rehydrated.
  - The reflux may be orange to dark brown in color and often has a fetid odor. Hemorrhagic gastric reflux is occasionally encountered.
- Injected, hyperemic mucous membranes with a "toxic line" are usually encountered.
- Moderate to severe dehydration, with prolonged capillary refill time, prolonged skin tent, and poor jugular refill.
- Decreased to absent gastrointestinal borborygmi.
- Mild abdominal distension may be present.
- Rectal examination:
  - Mild to moderately distended or thickened small intestine is usually appreciated.
  - Concurrent large colonic gas distension is occasionally noted with severe, diffuse intestinal ileus.

ETIOLOGY AND PATHOPHYSIOLOGY

- The specific cause of proximal enteritis is unknown, although several infectious or toxic agents have been proposed. It is likely that a variety of causes result in a similar clinical syndrome.
  - Toxigenic *Clostridium difficile* is the pathogen most often isolated from horses with proximal enteritis, although *C. difficile* infection is not documented in all cases.
  - *Clostridium perfringens* and *Salmonella* spp. infection also occasionally manifest with signs consistent with proximal enteritis.
  - Cantharidin toxicity may result in small intestinal as well as colonic damage, and affected horses may present with clinical signs of proximal enteritis.
  - Lesions consistent with proximal enteritis have been produced experimentally in horses exposed to toxins produced by *Fusarium moniliforme*. However, neurologic signs and central nervous system lesions typical of leukoencephalomalacia were also observed in those horses and are not described in most cases of proximal enteritis.
- Regardless of the specific inciting cause, the gross pathologic findings in horses with proximal enteritis include duodenal and proximal jejunal serositis with mucosal and submucosal hyperemia and edema. Histopathologic findings include loss of intestinal villi and necrosis of epithelial cells with neutrophilic infiltration and sub-

ElibeVet.com

mucosal and serosal hemorrhages and fibrinopurulent exudates.
- Several factors may contribute to the large-volume enterogastric reflux in proximal enteritis.
  - With severe intestinal mural inflammation and epithelial cell necrosis, fluid, electrolytes, and plasma protein are lost passively through the damaged mucosa.
  - In addition, an active secretory component may be induced by bacterial toxins and likely plays a role in most cases, resulting in further enteric fluid and electrolyte loss.
  - Intestinal mural edema and inflammation and villus loss also decrease the small intestinal absorptive capacity and inhibit normal peristalsis, resulting in enterogastric reflux.
  - Finally, in some cases of proximal enteritis, pancreatic secretions are increased because of concurrent pancreatitis.
- Bacterial toxins enter the systemic circulation through the compromised enteric mucosal barrier or via the portal circulation, resulting in the clinical signs of endotoxemia and the systemic inflammatory response syndrome.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Strangulating or nonstrangulating small intestinal obstruction
- Ulcerative duodenitis or gastric outflow obstruction (see "Ulcerative Duodenitis" and "Pyloric Stenosis" in this section)

INITIAL DATABASE

- Complete blood count
  - Leukopenia characterized by a neutropenia with increased band neutrophils and toxic changes in neutrophils is typically seen.
  - The hematocrit varies with hydration status but can be markedly increased in severe cases (>60%).
  - Thrombocytopenia is occasionally present in severe cases with concurrent disseminated intravascular coagulation (DIC).
- Serum biochemistry profile
  - Variable electrolyte derangements are common, with hypokalemia, hyponatremia, hypochloremia, and hypocalcemia most common
  - Serum total protein (TP) concentration may be increased with dehydration or normal or low with enteric loss
  - Some degree of azotemia is common and may be caused by prerenal or renal causes (or both).
  - Metabolic acidosis and hyperlactatemia (>2 mmol/L) suggests impaired peripheral perfusion and tissue oxygenation caused by hypovolemia.
- Transabdominal ultrasonography
  - Mild to severe small intestinal distension with increased small intestinal mural thickness (>5 mm) is usually appreciated.
  - The duodenum is typically dilated and hypomotile with increased mural thickness (>5 mm).
- Peritoneal fluid analysis
  - Variable. In most cases, peritoneal fluid is grossly normal with a mildly increased nucleated cell count and TP concentration.
  - However, exudative fluid with a more substantially increased nucleated cell count may be seen if concurrent peritonitis has occurred because of bacterial translocation.
  - In severe cases, peritoneal fluid can be grossly serosanguineous, which may make it difficult to differentiate proximal enteritis from a strangulating intestinal obstruction.

ADVANCED OR CONFIRMATORY TESTING

- Diagnostic testing for specific causes of proximal enteritis should include the following.
  - Polymerase chain reaction or culture for *Salmonella* spp. on gastric reflux and feces
  - Gram stain and toxin assays for *C. perfringens* and *C. difficile* toxins on gastric reflux and feces.
  - ±Urine analysis for cantharidin if historical exposure
- Gastroduodenoscopy may be indicated to rule out ulcerative duodenitis and pyloric outflow obstruction, but visualization of the pylorus and duodenum may be difficult with large-volume gastric reflux.

TREATMENT

THERAPEUTIC GOAL(S)

Supportive care

ACUTE GENERAL TREATMENT

- An indwelling nasogastric tube should be maintained and the patient monitored for gastric reflux q2–3h to maintain gastric decompression and prevent gastric rupture. A careful record of gastric reflux volume can direct fluid therapy to meet ongoing fluid losses.
- IV fluid therapy
  - Fluid resuscitation with hypertonic saline (2–4 mL/kg IV bolus) or hydroxyethyl starch (5–10 mL/kg IV bolus) or both is indicated in severely dehydrated patients.
  - This should be followed by isotonic balanced polyionic crystalloid fluids (eg, Normosol-R or Plasmalyte) at 50 to 150 mL/kg/day, depending on the degree of dehydration and ongoing losses in gastric reflux.
  - Supplementation with potassium chloride (10–40 mEq/L with the rate not to exceed 0.5 mEq/kg/h), 23% calcium gluconate (1–2 mL/kg/day) or magnesium sulfate (20–25 g/450 kg horse/day) is often necessary to correct electrolyte derangements.
  - Colloidal support with equine plasma (20–40 mL/kg IV) or hydroxyethyl starch (5–10 mL/kg IV bolus q24–48h or 1 mL/kg/h IV continuous rate infusion [CRI]) is indicated in hypoproteinemic patients. (Note: Patients with initially normal TP concentrations may have hypoproteinemia after rehydration.)
  - Horses with inflammatory intestinal diseases such as proximal enteritis are particularly prone to thrombophlebitis. Long-term polyethylene IV catheters should be used and removed at the first sign of a problem with the catheter or vein.
- Antiinflammatory and analgesic therapy
  - Flunixin meglumine: 0.5 to 1.1 mg/kg IV q12h for analgesic and antiinflammatory effects; may be decreased to 0.25 mg/kg IV q6–8h
  - Lidocaine: 1.3 mg/kg IV as a slow bolus; then 0.05 mg/kg/min IV CRI for analgesic and prokinetic effects
  - ± Dimethylsulfoxide (90% solution): 20 to 100 mg/kg diluted to less than 10% solution in IV fluids q12h for 1 to 3 days (may scavenge free radicals and limit oxidative injury)
- Antiendotoxic therapy
  - Equine plasma (2–4 L IV or more if hypoproteinemic; regular equine plasma or hyperimmune plasma with antiendotoxin antibodies) or hyperimmune antiendotoxin serum (Endoserum, 1–2 mL/kg diluted in 3–5 L isotonic fluids IV)
  - Polymixin-B: 2000 to 6000 IU/kg (diluted in 500–1000 mL 0.9% saline) IV q12h for 1 to 3 days after the patient is hydrated and if renal function is adequate
- Laminitis prophylaxis
  - Placement of frog supports and maintenance in deep bedding should be initiated immediately.
  - Periodic or continuous maintenance in ice boots during initial therapy may be helpful in preventing laminitis, although this is not universally accepted.

ElibVet.com

- If signs of laminitis occur, treatment should be rapid and aggressive (see "Laminitis, Acute" in this section).
- Oral medications and intestinal absorbants should be avoided because of likely poor absorption and the risk of gastric rupture.
- Nutritional support
  - Addition of 1% to 2.5% dextrose to IV fluids during early therapy may help meet some of the patient's initial energy requirements.
  - Parenteral nutrition should be considered in protracted cases with persistent gastric reflux for several days or more.
- Antimicrobial therapy
  - Controversial because a specific infectious cause is often difficult to determine, and most horses recover without specific antimicrobial therapy.
  - Metronidazole (15–25 mg/kg by rectum) is indicated if clostridial toxin assay results are positive.
  - Broad-spectrum antimicrobial therapy is indicated in patients with peritonitis or in profoundly neutropenic patients (which are at greater risk of development of secondary infections such as pneumonia or septic thrombophlebitis). May include potassium penicillin 22,000 to 44,000 IU/kg IV q6h *and* gentamicin (6.6 mg/kg IV q24h) or enrofloxacin (5 mg/kg IV q24h)
- Other
  - Some evidence suggests that some horses with proximal enteritis may be hypercoagulable because of subclinical DIC and thus are at greater risk for thrombotic complications. Heparin (20–40 IU/kg IV or SC q8h) may be beneficial in these cases.
  - Some horses show signs of persistent abdominal pain despite gastric decompression and analgesic therapy. Exploratory celiotomy is warranted in these cases to rule out a small intestinal obstructive lesion.

POSSIBLE COMPLICATIONS

- Thrombophlebitis
- Laminitis
- Intestinal infarction
- Gastroduodenal ulcers with prolonged anorexia
- Increased risk of intraabdominal adhesions if laparotomy is necessary

PROGNOSIS AND OUTCOME

- Fair with normal peritoneal fluid, good response to supportive care, and avoidance of laminitis
- Guarded with concurrent peritonitis or serosanguineous peritoneal fluid, concurrent laminitis, or if laparotomy is necessary

PEARLS & CONSIDERATIONS

It can be difficult to differentiate between proximal enteritis and a strangulating small intestinal obstruction in some cases. Peritoneal fluid analysis should be performed in these cases and exploratory celiotomy considered if signs of colic persist after gastric decompression.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Enterolithiasis

BASIC INFORMATION

DEFINITION

Obstruction of the flow of ingesta or gas associated with the presence of an enterolith(s)

SYNONYMS

Stone, rock

EPIDEMIOLOGY

SPECIES, AGE, SEX Almost all reported cases of enterolithiasis are in horses >4 years, with most between 5 and 10 years of age. However, isolated reports of younger horses exist (eg, a 2-year-old Quarter Horse filly and an 11-month-old Miniature Horse).

GENETICS AND BREED PREDISPOSITION Arabians are overrepresented. Other breeds with reported predisposition include Arabian crosses, Morgans, American Saddlebreds, donkeys, and Miniature Horses.

RISK FACTORS Risk factors include diets high in alfalfa hay, wheat bran, and magnesium and phosphorus content and horses that are kept indoors more than 50% of the time.

GEOGRAPHY AND SEASONALITY States with high prevalence of enterolithiasis include California, Florida, and the Southern states.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of enterolithiasis are variable depending on the location and size of the enterolith(s). In general, horses present with mild to moderate abdominal pain (colic) and decreased or absent fecal production.
- Horses may have a history of repeated episodes of mild colic associated with intermittent partial obstruction.
- Diet, geographic location, and signalment consistent with enterolithiasis should be recognized.

PHYSICAL EXAM FINDINGS

- Horses with enterolithiasis have physical examination findings similar to horses with other simple obstructions of the large or small colon.
- If transmural pressure necrosis occurs, clinical signs will be consistent with intestinal perforation or rupture, including progression toward cardiovascular collapse, peracute peritonitis, and severe endotoxemia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Enteroliths form around small niduses (eg, pieces of wire, nails, sand, pebbles, rope).
- The dominant mineral within enteroliths is struvite (ammonium magnesium phosphate).
- Diets high in magnesium (water or feed; wheat bran, alfalfa) and protein (eg, alfalfa with high concentrations of ammonium and nitrogen in the large colon) have been implicated in the pathogenesis of enterolithiasis. However, other factors must play a role because horses fed similar diets in parts of the country where enteroliths are not prevalent do not develop them.
- The most common site of obstruction with enteroliths is the junction of the right dorsal colon and the transverse

ElibeVet.com

FIGURE 1 Enterolith being removed by colotomy in the right dorsal colon at exploratory laparotomy.

FIGURE 2 Typical appearance of enteroliths.

colon. Less frequently, obstruction occurs in the transverse colon or the small colon. Enteroliths have also been found in the right ventral colon and diaphragmatic flexure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain are simple or nonstrangulating obstructions of the gastrointestinal tract such as large colon impactions (feed and sand), large colon displacements, large intestinal intraluminal obstructions, tympany, small colon impactions, and ileal impactions.
- Other causes of large intestinal distension on examination per rectum include tympany, large colon impactions (feed and sand), large colon displacements, and other intraluminal obstructions.

INITIAL DATABASE

- Horses may pass small enteroliths in their feces, but this is not necessarily correlated with the presence of obstructive enteroliths.
- Findings on examination per rectum depend on the location of the impaction. Distension of the large colon and cecum is common with the addition of distension of the small colon if the enterolith is within the small colon. It is uncommon to palpate an enterolith per rectum.
- Nasogastric reflux is uncommon but can occur.
- Bloodwork may be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein [TP]). If transmural necrosis has occurred, the leukogram may reveal a leukopenia with or without a left shift.
- Abdominal fluid analysis is generally within normal limits. Elevations in TP and total nucleated cell counts indicate compromise to the intestinal wall.
- Abdominal radiography may be useful for identifying enteroliths. Radiographs are more likely to identify enteroliths in the large colon than the small colon and have a better positive predictive value than negative predictive value. Radiographs are likely more useful in areas with a high prevalence of enterolithiasis.

TREATMENT

THERAPEUTIC GOAL(S)

Remove the enterolith(s)

ACUTE GENERAL TREATMENT

- Surgical exploration and removal may be performed. If pressure necrosis is present, resection of the affected bowel may be required.
- Provide perioperative supportive care as required.

CHRONIC TREATMENT

- The recurrence rate of enteroliths is unknown.
- Prevention of recurrence focuses on dietary modifications. Recommendations include avoiding high-risk feeds such as alfalfa and wheat bran; preventing ingestion of material that may serve as a nidus, including sand and gravel; offering alternative water sources in areas with high mineral content in the water; and providing diets with a dietary cation-anion balance between 200 and 300 mEq/kg, such as grass hays and cereal grains. Acidification with cider vinegar (1 cup twice daily) and administration of psyllium has also been recommended.

PROGNOSIS AND OUTCOME

- Prognosis is considered excellent if surgical removal is pursued and no pressure necrosis has occurred.
- Prognosis with pressure necrosis depends on the location of the enterolith (ie, if resection and anastomosis are possible).

PEARLS & CONSIDERATIONS

COMMENTS

- Enterolithiasis should be considered as a differential diagnosis in horses with signs of simple obstruction of the large or small colon in regions with a high prevalence of the disease.
- Surgical removal is the recommended treatment for obstruction associated with an enterolith.

PREVENTION

Changes in management as described in chronic treatment may also serve as methods of prevention.

CLIENT EDUCATION

Client education may be useful in prevention.

Epiglottic Entrapment

BASIC INFORMATION

DEFINITION

Epiglottic entrapment occurs when aryepiglottic tissue envelops the epiglottis.

EPIDEMIOLOGY

SPECIES, AGE, SEX Most common in young racehorses

GENETICS AND BREED PREDISPOSITION The disorder is most commonly identified in Thoroughbred and Standardbred racehorses. Between 0.7% and 2% of racehorses have epiglottic entrapment, and as many as 8% of horses with upper airway obstruction have the disorder.

RISK FACTORS

- Racing or in race training
- Hypoplastic epiglottis
- Upper airway inflammation

ASSOCIATED CONDITIONS AND DISORDERS Affected horses are more likely to have concurrent epiglottic hypoplasia. Epiglottic flaccidity and dorsal displacement of the soft palate may also be noted.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Most affected horses are exercise intolerant and make an abnormal upper respiratory noise during exercise. Occasionally, epiglottic entrapment is an incidental finding. Rarely dysphagia, cough, or nasal discharge are noted.

PHYSICAL EXAM FINDINGS Normal

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause is unknown. Entrapment may be precipitated by inflammation of the redundant aryepiglottic tissue. Epiglottic hypoplasia may be a predisposing factor because as many as 30% of affected horses have some degree of epiglottic hypoplasia.
- Onset of hard work in racehorses has been incriminated.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dorsal displacement of the soft palate

INITIAL DATABASE

- The clinical pathology is normal.
- Examination of affected horse during exercise may elicit abnormal upper respiratory noise.

ADVANCED OR CONFIRMATORY TESTING

- Endoscopic evaluation of the upper airway confirms the diagnosis. The general shape of the epiglottis is visible; however, the normal serrated edge of the epiglottis and dorsal epiglottic vasculature are obscured by entrapping aryepiglottic tissue.
- Exercising endoscopic evaluation of the upper airway may be necessary for identification of intermittent or speed-induced disorder.
- Radiographic abnormalities of the larynx include excessive soft tissue density surrounding the epiglottis. Smaller thyroepiglottic length is common.

TREATMENT

THERAPEUTIC GOAL(S)

Relieve the entrapment by transecting or resecting the enveloping aryepiglottic tissue.

ACUTE GENERAL TREATMENT

- Surgical techniques for treatment include transendoscopic laser axial division, transnasal or transoral axial division using a curved bistoury, transendoscopic electrosurgical axial division, or excision through a laryngotomy or pharyngotomy.
- Phenylbutazone (4.4 mg/kg) and dexamethasone (0.04 mg/kg) should be given once before surgery.
- Topical antiinflammatory solution can be sprayed twice a day using a nasopharyngeal catheter after surgery.
- Stall confinement and handwalking are recommended for 7 days after surgical correction.

CHRONIC TREATMENT

Horses with excessively thickened, ulcerated, or fibrotic appearing entrapping aryepiglottic tissues may not be good candidates for axial division. Surgical excision of the affected tissue through a laryngotomy may be required.

POSSIBLE COMPLICATIONS

- The recurrence rate after surgical correction is 5% to 10%.
- Intermittent or permanent dorsal displacement of the soft palate occurs postoperatively in 5% to 15% of cases.
- Lacerations of the nasopharynx, soft palate, and epiglottis have occurred during transnasal axial transection of the entrapping membrane with a bistoury if the horse swallows or moves during the procedure.

RECOMMENDED MONITORING

- Endoscopic evaluation of the upper airway should be performed immediately after surgical correction and before resuming training.
- Endoscopic evaluation of the upper airway is recommended if clinical signs of exercise intolerance or abnormal upper respiratory noise recur.

PROGNOSIS AND OUTCOME

- Prognosis is very good after surgical correction, and the majority of horses will return to racing.
- Horses with concurrent epiglottic hypoplasia or dorsal displacement of the soft palate are less likely to race after surgery.
- Horses with severely ulcerated aryepiglottic tissue requiring resection through a laryngotomy have the worst prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Epiglottic entrapment is a common cause of poor performance and abnormal respiratory noise in horses. It is readily diagnosed during endoscopic evaluation of the upper airway. Most affected horses require surgical correction.

ElibVet.com

CLIENT EDUCATION

After identification during upper airway endoscopy, surgical correction is recommended, and the majority of horses will maintain or improve performance after surgery.

Equine Protozoal Myeloencephalitis

BASIC INFORMATION

DEFINITION

A central nervous system (CNS) disorder resulting from infection with a protozoan parasite, either *Sarcocystis neurona* or *Neospora hughesi*

SYNONYMS

EPM, protozoal myelitis, protozoal encephalomyelitis

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals <6 months old and adults >12 years appear to be more often affected.

RISK FACTORS

- Many horses are exposed to the causative organism for EPM, but very few become infected, and most horses exposed to *S. neurona* ultimately control or eliminate the parasite.
- Exposure to the definitive host, the opossum (*Didelphis virginiana*) is important, although the exact mechanism for how the organism enters the CNS as well as what factors related to the role of the equine immune system are not fully understood.
- The high levels of serum antibody in many horses showing signs of clinical disease suggest that antibody is not sufficient to prevent disease. Other risk factors include season of the year (fall more than spring, and summer more than winter), and the presence of opossums on the premises along with previous diagnosis of EPM on the premises.
- Stress from sales, transportation, and concurrent disease are other risk factors.

CONTAGION AND ZOONOSIS

- Infections take place in incidental hosts as a result of exposure to the causative organism from the definitive host. The definitive host becomes infected by ingestion of sarcocysts contained within the muscle tissues of intermediate hosts, including raccoons, armadillos, cats, skunks, and sea otters. The intermediate host may exhibit clinical neurologic symptoms from infection with *S. neurona.*
- The disease is not contagious from horse to horse, and horses are considered an aberrant host because sarcocysts are not formed in this species, failing to complete the life cycle.

GEOGRAPHY AND SEASONALITY The disease is observed most often during the warmer months of the year, likely as a result of travel and exposure to the organism. States that do not have opossums have many fewer horses infected with this organism. For example, in a study conducted on serum collected from wild horses in a state outside the range of wild opossums, there was a seroprevalence rate of only 6.5% using immunoblot assay.

ASSOCIATED CONDITIONS AND DISORDERS Horses that develop EPM are often under some sort of stress, either as a result of concurrent disease or immunosuppression secondary to transportation.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most EPM cases are sporadic cases with an insidious onset and often progressive signs of disease, although subclinical EPM is often suspected in horses that are not performing well or up to the expected level of training.
- Clinical signs in many horses may vary from mild to severe ataxia with muscle atrophy. Cranial nerve deficits may occur.

HISTORY, CHIEF COMPLAINT

- Ataxia (often asymmetrical)
- Cranial nerve deficits (dysphagia, head tilt, circling)
- Depression
- Paresis
- Recumbency
- Seizures (occasional)
- Muscle atrophy
- Nonspecific hindlimb lameness
- Most cases are insidious, although the disease may sometimes be rapidly progressive.

PHYSICAL EXAM FINDINGS

- Ataxia or paresis (often asymmetrical)
- Behavioral changes
- Cranial nerve deficits: Blindness, circling, dysphagia, head tilt
- Possible muscle atrophy

ETIOLOGY AND PATHOPHYSIOLOGY

- Clinical signs may result from direct damage to neural tissue or from resultant inflammatory response as a result of infection with either *S. neurona* or less commonly *N. hughesi.*
- The organism is sometimes found in the CNS of the horse in the asexual forms of schizonts or merozoites. Sarcocysts have never been identified in horse tissues after either natural or experimental infection.
- Infection of horses is via the oral route, and organisms can sometimes be found in the nervous tissues. In most cases, no organisms are identified, although histopathologic lesions may be detected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cervical vertebral malformation
- Equine degenerative myelopathy
- Equine herpesvirus-1 myelopathy
- Cerebrospinal nematodiasis
- Leukoencephalomalacia
- Meningitis
- Neoplasia
- Temporohyoid osteoarthropathy
- Trauma
- Viral encephalidities (Eastern equine myeloencephalitis, Western equine myeloencephalitis, Venezuelan equine myeloencephalitis, rabies, West Nile virus)

INITIAL DATABASE

- Complete blood count
- Serum chemistries
- Neurologic examination

 ElibeVet.com

- Cerebrospinal fluid (CSF) analysis
- Testing for IgG antibodies in serum, CSF, or both
  - Western blot
  - Modified Western blot
  - Indirect fluorescent antibody test
  - Enzyme-linked immunosorbent assay (ELISA) based on SAG-2 or a blend of SAG-4/3 antigens
  - ELISA based on SAG-1 antigen

ADVANCED OR CONFIRMATORY TESTING

- Radiography of the skull, cervical spine, or both to rule out other disorders
- CSF analysis and cytology to rule out other disorders and to test for EPM
- Magnetic resonance imaging: Lesions detected in a few cases of suspected EPM have been confirmed postmortem.
- Postmortem examination, histopathology, and microscopic identification of protozoal organisms are most useful for a definitive diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Kill protozoal parasites.
- Control and reduce CNS inflammation.
- Provide supportive care until the horse's neurologic function improves.

ACUTE GENERAL TREATMENT

- Ponazuril: 5 mg/kg PO q24h for 28 to 60 days
- Diclazuril: 1 mg/kg PO q24h for 28 days (pending Food and Drug Administration approval)
- Pyrimethamine (1 mg/kg) and sulfadiazine (20 mg/kg) PO q24h for 60 to 90 days
- Flunixin meglumine: 1.1 mg/kg IV q12–24h
- Dimethyl sulfoxide (0.5–1.0 g/kg IV q12–24h) must be diluted to a 10% solution or less in an isotonic balanced electrolyte solution
- IV fluids in recumbent, dehydrated, or dysphagic horses

CHRONIC TREATMENT

- Ponazuril, diclazuril, or pyrimethamine and sulfadiazine PO for longer periods.
- Horses that are unable to stand or get up on their own need to be placed into a sling periodically.

RECOMMENDED MONITORING

Periodic repeat neurologic examinations to assess response to therapy

PROGNOSIS AND OUTCOME

- The overall prognosis for complete recovery is guarded to good.
- Horses that are recumbent or unable to stand or support themselves in a sling for longer than 2 to 3 days are unlikely to recover.
- Horses that survive may have permanent neurologic deficits.

PEARLS & CONSIDERATIONS

COMMENTS

EPM remains an important cause of neurologic disease in horses, and diagnosis depends on careful and often repeated neurologic examinations along with evaluation of antibodies in the blood and CSF as well as response to treatment.

PREVENTION

- To date, no effective course of medication for prevention has been established.
- However, good and proper hygiene with regard feed storage along with elimination of dead carrion from the environment as well as avoidance of opossum exposure to feed and water areas used for horses are helpful.

AUTHOR & EDITOR: **STEPHEN M. REED**

Ergot-Related Toxicosis

BASIC INFORMATION

DEFINITION

Claviceps fungi ("ergot") produce a variety of toxins that can adversely affect the reproductive, circulatory, nervous, and musculoskeletal systems of horses. *Claviceps* fungi are visible as sclerotia or ergot bodies on susceptible grasses (Table 1) and small cereal grains such as wheat, barley, and oats (but not corn).

SYNONYMS

- Ergot, ergot poisoning, or ergotism
- Indole alkaloid mycotoxins
  - Ergot alkaloids (eg, ergocornine, ergocristine, ergocryptine, ergosine, ergotamine, ergovaline) and compounds related to lysergic acid (LSD) produced by *C. purpurea*
  - Indole-diterpene tremorgenic mycotoxins (ie, paspalinine; paspalitrems A, B, C) produced by *Claviceps paspali* and other species producing tremorgens

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Except for agalactia and pregnancy abnormalities, horses are much less susceptible to ergotism than are cattle.
- The species and age of exposed horses may influence the amount of toxin ingested.
- Aged animals, especially mares, may have concurrent disease that is exacerbated by toxin exposure.
- Age influences the likelihood of mares cycling or becoming pregnant.
- Mares are particularly susceptible to the reproductive effects of ergopeptine alkaloids.

GENETICS AND BREED PREDISPOSITION

- Anecdotal reports suggest that individual animal differences in susceptibility exist.

ElibeVet.com

TABLE 1 **Common Grasses Susceptible to *Claviceps* Infection**

Common Name of Susceptible Grasses	Latin Name of Susceptible Grasses	Claviceps spp.	Claviceps Toxins
Bahiagrass	*Paspalum notatum*	*Claviceps paspali*	Indole-diterpene alkaloids[a]
Bluegrasses	*Poa* spp.	*Claviceps purpurea*	Ergot alkaloids[b,c]
Bromegrasses	*Bromus* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Canarygrasses	*Phalaris* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Curlygrass[d]	*Hilaria jamesii*	*Claviceps cinerea*	Indole-diterpene alkaloids[a]
Dallisgrass	*Paspalum dilatatum*	*C. paspali*	Indole-diterpene alkaloids[a]
Fescue grasses	*Festuca* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Junegrasses	*Koeleria* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Lovegrasses	*Eragrostis* spp	*C. purpurea*	Ergot alkaloids[b,c]
Orchard grasses	*Dactylis* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Pearl millet	*Pennisetum glaucum*	*C. fusiformis*	Ergot alkaloids[e]
Quack grasses	*Agropyron* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Redtops	*Agrostis* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Ryegrasses	*Lolium* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Timothy grasses	*Phleum* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Wild barleys	*Hordeum* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Wild oats	*Avena* spp.	*C. purpurea*	Ergot alkaloids[b,c]
Wild ryes	*Elymus* spp.	*C. purpurea*	Ergot alkaloids[b,c]

[a]Especially the tremorgenic mycotoxins; paspalinine; and penitrems A, B, and C.
[b]Especially the ergopeptides, ergocornine, ergocristine, ergocryptine, ergosine, ergotamine, and ergovaline.
[c]LSD-related ergot alkaloids are also produced by *C. purpurea* and related species.
[d]Other *Hilaria* spp. can also be infected by *C. cinerea*.
[e]Somewhat different clinical signs in human outbreak; uncertain of specific ergot alkaloids.

- Possible differences in breed disposition might reflect influences of risk factors and geography.

RISK FACTORS

- Claviceps ergopeptine alkaloids:
  - Subacute to chronic consumption of the seed head stage of susceptible grasses or ergotized small grains or grass seed
  - Concurrent exposure to endophyte-infected tall fescue (see "Fescue-Related Toxicosis" in this section)
  - Early and particularly late gestation in mares
  - Mares in the spring transitional phase before the onset of normal cyclicity
  - "No till" farming practices
  - Cool, damp spring weather
  - Rye and triticale in horse rations
  - Pelletized rations, especially those incorporating screenings
  - History of laminitis
  - Hot or cold environmental temperatures
  - Forced exercise under hot and humid conditions
- *Claviceps* indole-diterpene tremorgenic mycotoxins
  - Several days' consumption of ergotized Dallisgrass (*Paspalum dilatatum*) or Bahiagrass (*Paspalum notatum*) in pasture or hay
  - Damp or wet disturbed soils favoring growth of *C. paspali* and related species
  - Concurrent exposure to endophyte (*Neotyphodium lolii*)-infected perennial ryegrass (*Lolium perenne*) hay or pasture or other tremorgenic mycotoxins
  - Forced exercise

CONTAGION AND ZOONOSIS Between grasses but not between animals and/or humans

GEOGRAPHY AND SEASONALITY

- *Claviceps* ergopeptine alkaloids
  - Seen worldwide, but predisposing weather conditions are common in the northern Great Plains and Pacific Northwest regions of North America (more sporadically in Midwestern and Atlantic coastal regions of the United States)
  - Cool, wet weather in the spring favors the *C. purpurea* life cycle.
  - Reproductive ergotism is most common in spring when mares are being bred and are foaling.
  - Hyperthermic ergotism is most common during hot and humid summers.
  - Gangrenous ergotism is most common during extremely cold winters.
- *Claviceps* indole-diterpene tremorgenic mycotoxins
  - Southeastern United States, Central and South America, parts of Europe, Africa, Australia, and New Zealand
  - Clinical signs of nervous ergotism or "grass staggers" are most common when rainy or humid summers and autumns favor the *C. paspali* life cycle

ASSOCIATED CONDITIONS AND DISORDERS

- *Claviceps* ergopeptine alkaloids: Fescue toxicosis
- *Claviceps* indole–diterpene tremorgenic mycotoxins
  - Other "grass staggers" syndromes
  - Other tremorgenic mycotoxins

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- *C. purpurea* ergopeptine alkaloids
  - Reproductive ergotism: Most common form in horses; observed at low dosages of toxins
  - Hyperthermic ergotism: Less common in horses; observed at higher toxin doses than reproductive ergotism
  - Gangrenous or cutaneous ergotism: Less common in horses; observed at higher toxin doses than reproductive ergotism
- *C. purpurea* LSD-like ergot alkaloids, especially *C. paspali* indole-diterpene tremorgenic mycotoxins: Nervous or convulsive ergotism

HISTORY, CHIEF COMPLAINT

- Generally, multiple animals are affected in instances of ergotism.
- Reproductive ergotism (indistinguishable from most common form of equine fescue toxicosis)
  - Agalactia or dysgalactia (may be observed in absence of any other clinical signs)
  - Prolonged gestation
  - Retained fetal membranes
  - Dystocia, premature placental separation (ie, "red bag")
  - Fetal dysmaturity/overmaturity
  - Abortion/stillbirth
  - Prolonged transitional phase before the first ovulation or abnormal cyclicity in the spring
  - Conception failure or early embryonic loss
- Hyperthermic ergotism
  - Heat intolerance
  - Increased sweating
  - Decreased feed intake and growth
  - Impaired athletic performance
  - Mortality
- Gangrenous or cutaneous ergotism
  - Lameness or possible laminitis characterized by ischemic necrosis of the hooves, as well as associated bones, joints, and soft tissues
  - Dry gangrene of the tips of the ears and tail
  - Mortality
- Nervous or convulsive ergotism
  - Confusion and ataxia with LSD-like ergot alkaloids
  - Exercise-exacerbated ataxia, tremors, convulsions, and occasional

ElibeVet.com

deaths caused by misadventure associated with indole-diterpene tremorgens

PHYSICAL EXAM FINDINGS

- Reproductive ergotism
  - Little or no udder development within 14 days of the due date; this may be the only clinical sign seen
  - Aborted fetus or stillbirth
  - Dystocia with an abnormally large or malpositioned foal
  - Premature separation of the chorioallantois ("red bag" presentation)
  - Thickened, edematous fetal membranes, possibly retained
  - Dysmature or overmature foal unable to suckle
  - Failure of passive transfer
  - Multiple, anovulatory follicles; failure to ovulate in a timely fashion
- Hyperthermic ergotism
  - Elevated body temperature and respiratory rate
  - Increased sweating
  - Mortality
- Gangrenous or cutaneous ergotism
  - Multiple limb lameness and possible laminitis, often beginning with swelling or reddening at the coronary band
  - Shifting leg lameness
  - Inflammation and ischemic necrosis in distal limbs, with possible secondary bacterial infections
  - Dry gangrene of the tips of the ears and tail
  - Mortality, generally because of complications
- Nervous or convulsive ergotism
  - Altered mentation and ataxic gait with *Claviceps* LSD-related ergot alkaloids
  - Nervousness or a belligerent attitude, as well as exercise-exacerbated tremors, ataxia, or convulsions associated with *Claviceps* indole-diterpene tremorgens
  - Mortality, generally through misadventure or trauma secondary to central nervous system effects

ETIOLOGY AND PATHOPHYSIOLOGY

- Reproductive ergotism caused by *C. purpurea* ergopeptine alkaloids: D2 dopamine receptor agonism-induced hypoprolactinemia (decreased prolactin secretion by the anterior pituitary) and altered uterofetoplacental progestagen metabolism
- Hyperthermic and gangrenous ergotism: Vasoconstriction caused by D1 dopaminergic receptor inhibition and partial adrenergic and serotoninergic receptor agonism
- *C. purpurea* LSD-related ergot alkaloids: Neurotransmitter imbalance in the pituitary and pineal glands
- *C. paspali* indole-diterpene tremorgenic mycotoxins: Impairment of γ-aminobutyric acid and glycine-mediated inhibitory pathways

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Reproductive ergotism: Fescue toxicosis (horses are very sensitive to agalactia and pregnancy abnormalities)
- Hyperthermic ergotism
  - Fescue toxicosis (horses require higher dosages of toxins than cattle)
  - Noninfectious respiratory disease
  - Viral or bacterial respiratory diseases
  - Other potential causes of impaired athletic performance
- Gangrenous or cutaneous ergotism
  - Fescue toxicosis (potential association with laminitis)
  - Other causes of laminitis, cellulitis, or vasculitis
  - Thromboembolic events
  - Strangulating trauma to the distal limbs
  - Frostbite
- Nervous or convulsive ergotism
  - Other "staggers" or "grass staggers" syndromes (eg, Bermuda grass staggers, perennial rye grass staggers, stagger syndromes associated with the consumption of Tares [*Lolium temulentum*]
  - Other tremorgenic mycotoxins (eg, penitrem A, verruculogen) in contaminated feedstuffs
  - Plants associated with gait abnormalities and ataxia (sorghum ataxia, locoism, lathyrism)
  - Plants associated with tremorgenic or convulsive syndromes: Water hemlock, blue-green algae, poison hemlock, tobacco
  - Equine protozoal myelopathy
  - Equine herpes viral infections
  - Viral encephalitides
  - Pesticide exposures
  - Cervical vertebral instability ("wobblers" syndrome)
  - Trauma

INITIAL DATABASE

- Claviceps ergopeptine alkaloids
  - Agalactia or dysgalactia; failure to "wax"; no increase in calcium in mammary secretions before foaling; little or no milk production
  - Failure of passive transfer
  - Hemograms and biochemical profiles: Vary depending on the complicating secondary conditions
  - Sensitivity to hoof testers over tip of the coffin bone, frequently in more than one foot, indicative of laminitis
  - Radiographic evidence of rotation of the coffin bone, osteomyelitis, or other bony changes
- *Claviceps* LSD-related ergot alkaloids and *Claviceps* indole-diterpene tremorgenic mycotoxins: Changes in hemograms and routine biochemical profiles reflect secondary physiological abnormalities.

ADVANCED OR CONFIRMATORY TESTING

- Endocrine analyses
  - Hypoprolactinemia, especially in late-gestational mares
  - Decreased maternal progestagen concentrations in late-gestational mares (use cross-reactive progesterone radioimmunoassay to detect 5α-pregnanes)
  - Decreased maternal relaxin; variable alterations in circulating maternal estrogens in late-gestational mares
- Detection of *Claviceps* indole alkaloid mycotoxins in feedstuffs
- Pathologic findings for reproductive ergotism
  - Gross findings in foals are consistent with prolonged gestation (oversized foal, eruption of the foal's incisors, increased eponychium on the foal's hooves, angular limb deformities), dystocia (limb trauma, meconium staining, possible ruptured bladder), agalactia, or failure of passive transfer (absence of colostrum or milk in the gastrointestinal tract, joint or umbilical cord infections).
  - Histopathologic findings in foals that are characteristic of ergopeptine alkaloid exposure, such as distended thyroid follicles lined by flat cuboidal epithelial cells, may be observed.
  - Nonspecific histopathologic findings in foals consistent with prolonged gestation
  - Fetal membranes grossly thickened, edematous, and possibly retained or prematurely separated
  - Gross findings in mares consistent with agalactia, dystocia (trauma to the reproductive and urinary tracts, retained fetal membranes, possible laminitis)
  - Histopathologic findings in mares consistent with sepsis and laminitis

TREATMENT

THERAPEUTIC GOAL(S)

- *Claviceps* ergopeptine alkaloids
  - Prevent further exposure to contaminated feedstuffs.
  - Counteract the mechanisms of action of ergopeptine alkaloids.
  - Provide supportive care and prevent complications.

ElibVet.com

- *Claviceps* LSD-related ergot alkaloids and *C. paspali* diterpene tremorgenic mycotoxins
  - Prevent further exposure to contaminated feedstuffs.
  - Decrease absorption of tremorgenic mycotoxins.
  - Control tremors and convulsions.
  - Provide supportive care and prevent complications.
  - Prevent death from misadventure.

ACUTE GENERAL TREATMENT

- Removal from source of toxins
- For agalactia, prolonged gestation, and cycling abnormalities: Antidotal treatment with domperidone, a D2 dopamine receptor antagonist (Equidone; Equi-tox, Inc., Central, SC), at 1.1 mg/kg PO q24h
- Need to adjust dosage or frequency of administration of domperidone if dripping of milk or leaking of colostrum occurs
- Potential extrapyramidal neurologic side effects with other D2 dopamine antagonists, such as fluphenazine and perphenazine
- Administration of activated charcoal in cases of LSD-related ergot alkaloids and tremorgens
- Supportive care for inflammation, infections, wounds, or pain caused by ergopeptine alkaloids
- Supportive care for tremors and convulsions caused by LSD-related ergot alkaloids or indole-diterpene tremorgenic mycotoxins

CHRONIC TREATMENT

Varies depending on the possible complications described below

POSSIBLE COMPLICATIONS

- Reproductive ergotism
  - In mares, trauma or rupture of the reproductive tract or its vasculature; bladder or bowel displacement; subsequent laminitis
  - Sepsis in mares or foals
  - Ruptured urinary bladder in foals secondary to dystocia
- Gangrenous ergotism: Chronic laminitis, lameness, and infections of bones and soft tissues
- Hyperthermic ergotism: Heat stroke; chronically impaired athletic performance
- Nervous ergotism: Trauma

RECOMMENDED MONITORING

- Depends on the observed clinical signs and complications
- Monitor udder development in pregnant mares; attend and assist with foaling.

PROGNOSIS AND OUTCOME

- Depend on the duration and level of toxin exposure, as well as concurrent risk factors and complications
- Possible mortality

PEARLS & CONSIDERATIONS

COMMENTS

Agalactia is the most sensitive indicator of ergopeptine alkaloid exposure in horses. Signs of hyperthermic or gangrenous ergotism are rarely seen in horses.

PREVENTION

- Mow pastures to prevent seed head stage of ergotized grasses.
- Ensure there are no grain or grass seed screenings in rations.
- Maintain careful breeding records and confirm pregnancy in regions where ergopeptine alkaloid exposure is common.
- Carefully inspect animals, especially udder development in late-gestational mares.
- Provide daily oral treatment with domperidone 10 to 14 days before the foaling due date.
- Attend and assist with foaling

CLIENT EDUCATION

Increased awareness of risk to horses from exposure to ergot-related toxins

Esophageal Cysts, Intramural

BASIC INFORMATION

DEFINITION

Inclusion cysts of the esophageal wall. Inclusion cysts are defined as a cyst formed by the implantation of epithelial tissue into another structure.

SYNONYM(S)

Intramural inclusion cysts

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals and young adult horses

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of esophageal obstruction, including hypersalivation and esophageal dysphagia
- Regurgitation
- Progressive swelling of the cervical esophagus as the cysts enlarge

PHYSICAL EXAM FINDINGS

- The findings of physical examination confirm the presenting signs, including dysphagia, hypersalivation, and retching.
- A visible or palpable soft tissue swelling of the cervical esophagus may be present.

ETIOLOGY AND PATHOPHYSIOLOGY Congenital inclusion cyst

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition): Pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophageal stricture, esophageal rupture, equine grass sickness
- Other cysts involving the esophagus: Esophageal duplication cysts

ElibVet.com

INITIAL DATABASE

- The leukogram and hematology are likely to be normal.
- Confirmation of the intramural inclusion cyst is achieved by endoscopic examination (esophagoscopy reveals focal compression of the esophageal lumen) and radiography (positive or double-contrast esophagraphy). A filling defect is present on radiography.
- Ultrasonography demonstrates a soft tissue cystic structure in the esophageal wall.

TREATMENT

THERAPEUTIC GOAL(S)

Surgical excision of the cysts

ACUTE GENERAL TREATMENT

- Surgical removal of the cyst in its entirety is required. The cyst can be dissected from the esophageal wall after esophagomyotomy.
- Alternatively, the cyst can be marsupialized to the skin. (This procedure reduces the risk of inadvertently entering the esophageal lumen.)

CHRONIC TREATMENT

Frequent small meals of moistened pellets or fresh grass should be fed.

POSSIBLE COMPLICATIONS

- Complications of surgery include inadvertent esophagotomy and esophageal fistula formation.
- Other complications of surgical excision have included surgical trauma to the recurrent laryngeal nerve (resulting in laryngeal hemiplegia).

PROGNOSIS AND OUTCOME

The prognosis appears to be fair to good with surgery.

PEARLS & CONSIDERATIONS

Persistent or recurrent signs of esophageal obstruction in a young horse should alert the clinician to the possibility of an intramural esophageal cyst.

Esophageal Diverticulum

BASIC INFORMATION

DEFINITION

Outpouching of the lumen of the esophagus

EPIDEMIOLOGY

RISK FACTORS

- Esophageal obstruction
- Trauma

ASSOCIATED CONDITIONS AND DISORDERS Esophageal diverticula may occur after esophageal obstruction, especially chronic obstruction, or trauma to the neck.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Some esophageal diverticula may be asymptomatic. Others can become impacted with food material and cause esophageal obstruction.

PHYSICAL EXAM FINDINGS The findings of physical examination are identical to those of esophageal obstruction. A moveable mass in the mid to distal cervical region may be noticeable before the onset of complete obstruction. The mass may enlarge and reduce repeatedly over a long period of time.

ETIOLOGY AND PATHOPHYSIOLOGY

- There are two types of esophageal diverticula:
  - Traction or true diverticulum resulting from periesophageal fibrous scar tissue often secondary to a wound or previous surgery. This results in tenting of the wall of the esophagus. This condition is usually asymptomatic and appears as a wide neck on barium swallow esophagraphy.
  - Pulsion or false diverticulum, resulting from protrusion of mucosa and submucosa through a defect in the esophageal musculature. These diverticuli may be caused by external trauma or by some fluctuation in esophageal intraluminal pressure and overstretch damage to the esophageal muscle fibers by impacted feed stuff. A pulsion diverticulum appears spherical and flasklike on an esophagram. They may enlarge over time and may become impacted with food material.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition), including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophagitis, intramural esophageal cysts, esophageal rupture, and equine grass sickness.
- Repeated bouts of esophageal obstruction should increase the suspicion of an underlying esophageal stricture or esophageal diverticulum.

INITIAL DATABASE

- The leukogram and hematology results are likely to be normal unless there is dehydration from chronic esophageal obstruction.
- The presence of a focal, firm, and moveable swelling over the esophagus is suspicious of a pulsion diverticulum.
- Confirmation of esophageal diverticulum can be made in some cases by

ElibeVet.com

endoscopic examination (esophagoscopy).

ADVANCED OR CONFIRMATORY TESTING

Radiography, including contrast radiography or double-contrast radiography, may be necessary to identify an esophageal diverticulum. A traction diverticulum appears as a wide neck on a barium swallow esophagram. A pulsion diverticulum appears spherical and flasklike on an esophagram.

TREATMENT

THERAPEUTIC GOAL(S)

- Horses with traction diverticula rarely require any specific treatment.
- Horses with pulsion diverticula may require surgical closure.

ACUTE GENERAL TREATMENT

Acute treatment is required only in horses that develop complete esophageal obstruction (see treatment under "Esophageal Obstruction" in this section).

CHRONIC TREATMENT

- Pulsion diverticula may be corrected surgically by inverting or resecting the prolapsed mucosa and closing the underlying defect in the esophageal wall.
- Diverticulectomy is the treatment of choice for a large pulsion diverticulum that has a narrow communication with the esophageal lumen or for a diverticulum that is inflamed and necrotic.

POSSIBLE COMPLICATIONS

Complications of esophageal surgery include esophageal impaction, stricture, and postsurgical dehiscence.

RECOMMENDED MONITORING

After surgical treatment, horses should be monitored for signs of infection or surgical dehiscence.

PROGNOSIS AND OUTCOME

- The prognosis for horses with traction diverticuli is generally good, and they rarely require specific treatment.
- The prognosis for a pulsion diverticulum depends on its size.
- After surgical treatment, the prognosis is generally fair to good.

PEARLS & CONSIDERATIONS

- Traction diverticuli are usually asymptomatic and do not require treatment.
- Pulsion diverticuli are usually amenable to surgical treatment.

Esophageal Duplication Cyst

BASIC INFORMATION

DEFINITION

A congenital cystic formation attached to or originating from the esophagus that has the same structure as the esophagus

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals and young adult horses

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of esophageal obstruction, including hypersalivation, esophageal dysphagia, and regurgitation.
- There is progressive swelling of the cervical esophagus as the cysts enlarge.

PHYSICAL EXAM FINDINGS

- The findings of physical examination confirm the presenting signs, including dysphagia, hypersalivation, and retching. A visible or palpable soft tissue swelling of the cervical esophagus may be present.

ETIOLOGY AND PATHOPHYSIOLOGY Congenital malformation

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition), including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophageal stricture, esophageal rupture, and equine grass sickness
- Other cysts involving the esophagus, including intramural esophageal cysts

INITIAL DATABASE

- The leukogram and hematology results are likely to be normal.
- Confirmation of the esophageal duplication cyst is achieved by endoscopic examination (esophagoscopy) and radiography (positive or double-contrast esophagraphy). On endoscopic examination, compression of the esophageal lumen may be identified; in some cases, a communication to the cyst may be demonstrated. A filling defect is present on radiography.
- Ultrasonography shows the presence of a soft tissue cystic lesion adjacent to the esophageal wall.

TREATMENT

THERAPEUTIC GOAL(S)

Surgical excision of the cyst

ACUTE GENERAL TREATMENT

- Surgical removal of the cyst in its entirety is required. The cyst can be dissected from the esophageal wall after esophagomyotomy.
- Alternatively, the cyst can be marsupialized to the skin. This procedure reduces the risk of inadvertently entering the esophageal lumen.

CHRONIC TREATMENT

Frequent small meals of moistened pellets or fresh grass should be fed.

ElibVet.com

POSSIBLE COMPLICATIONS

- Complications of surgery include inadvertent esophagotomy and esophageal fistula formation.
- Surgical damage to the recurrent laryngeal nerve or sympathetic trunk may result in laryngeal hemiplegia and Horner's syndrome, respectively.

PROGNOSIS AND OUTCOME

Prognosis appears to be fair to good with surgery.

PEARLS & CONSIDERATIONS

Persistent or recurrent signs of esophageal obstruction in a young horse should alert the clinician to the possibility of an esophageal duplication cyst.

Esophageal Fistula

BASIC INFORMATION

DEFINITION

Permanent opening of esophagus draining to the skin surface

EPIDEMIOLOGY

RISK FACTORS

- Esophageal rupture
- Esophageal surgery

ASSOCIATED CONDITIONS AND DISORDERS Esophageal fistula may occur after esophageal surgery (failure of an esophagostomy incision to heal appropriately) or after esophageal rupture.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT A chronic draining tract at the skin surface overlying the esophagus from which saliva and food drains

PHYSICAL EXAM FINDINGS Affected horses are usually normal apart from the presence of the draining tract. In the case of large fistulae, signs of dehydration and weight loss may occur. There may be localized cellulitis or swelling of the neck and excoriation of the skin around the fistula.

ETIOLOGY AND PATHOPHYSIOLOGY

- Inappropriate healing after esophageal perforation
- Inappropriate healing after esophageal surgery (esophagotomy)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Abscess or chronic draining tract caused by a foreign body
- Other causes of cellulitis of the neck

INITIAL DATABASE

- Bloodwork is usually normal, but for large fistulae, hemoconcentration, electrolyte abnormalities (hyponatremia, hypochloremia), and metabolic acidosis may be present.
- Physical examination confirms drainage of saliva from the tract. Saliva (with or without food material) will spontaneously drain if the horse is offered food. Water will drain when the horse drinks.

ADVANCED OR CONFIRMATORY TESTING

The presence of an esophageal fistula may be confirmed by esophagoscopy and contrast radiography (administration of barium suspension under pressure).

TREATMENT

THERAPEUTIC GOAL(S)

Facilitate healing of the damaged esophageal wall and surrounding tissues.

ACUTE GENERAL TREATMENT

Surgical treatment: Resection of the sinus tract and closure of the stoma

POSSIBLE COMPLICATIONS

Complications include esophageal stricture, breakdown of the surgical repair, and reformation of esophageal fistula.

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of dehydration, weight loss, and electrolyte abnormalities.

PROGNOSIS AND OUTCOME

Prognosis appears to be fair to good after surgical resection.

PEARLS & CONSIDERATIONS

Failure to repair the fistula is likely to result in weight loss and fluid and electrolyte abnormalities.

SUGGESTED READING

Fubini SL: Esophageal diseases. In Mair T, Divers T, Ducharme N, editors: *Manual of equine gastroenterology*. London, 2002, Saunders Elsevier, pp 89–98.

ElibeVet.com

Esophageal Obstruction

BASIC INFORMATION

DEFINITION
Obstruction of the esophageal lumen

SYNONYM
Choke

EPIDEMIOLOGY
RISK FACTORS
- Horses and ponies that have ravenous appetites or "bolt" their feed may be at increased risk.
- Older horses and ponies with poor dentition and young horses with erupting teeth may be at an increased risk because of poor mastication of food.
- A previous episode of esophageal obstruction may predispose to further episodes; some horses are affected by repeated episodes of esophageal obstruction as a result of stricture or diverticulum formation.

ASSOCIATED CONDITIONS AND DISORDERS Dental diseases, esophageal neoplasia, thyroid tumors, external compressive masses (eg, mediastinal lymphoma), and congenital abnormalities (eg, duplication cysts, megaesophagus, neuromuscular disorders) may predispose horses to esophageal obstruction.

CLINICAL PRESENTATION
DISEASE FORMS/SUBTYPES Esophageal obstructions may be caused by a primary intraluminal obstruction, or they may arise secondary to an extraluminal compressive mass or functional problem.

HISTORY, CHIEF COMPLAINT The most common presenting signs are acute onset of excessive salivation, retching (repeated flexion and extension of the neck), coughing, and copious discharge of saliva from the nostrils.

PHYSICAL EXAM FINDINGS
- Affected horses often sweat excessively and appear distressed, but the body temperature is usually normal.
- The heart rate may be mildly elevated.
- Mucous membranes may be mildly congested.
- There may be a palpable swelling in neck in the jugular groove or over the trachea (if the obstruction is in the cervical region). If the obstruction is in the cervical part of the esophagus, most affected horses will retch immediately after attempting to swallow. (There is often a 10- to 12-second delay between the swallow and the onset of retching if the obstruction is in the distal esophagus.)

ETIOLOGY AND PATHOPHYSIOLOGY
- The obstructing mass is usually food, especially dry pelleted food or dry sugar beet pulp. The dry, fibrous material swells with the absorption of saliva, and an expanding bolus occludes the esophageal lumen. Subsequent boluses compound the obstruction.
- Primary feed impactions may also be composed of roughage, especially leafy alfalfa hay, coarse grass hay, bedding, and even grass.
- Occasionally, foals and young horses may eat foreign bodies that lodge in the esophagus and initiate an obstruction.
- Eating too soon after sedation or general anesthesia (when coordinated muscular activity of the esophagus has not yet returned) may predispose horses to obstruction.
- The most common sites of esophageal obstruction are the proximal esophagus and just cranial to the thoracic inlet.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Other causes of dysphagia, especially abnormalities affecting the pharyngeal and esophageal phases of deglutition, including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, megaesophagus, esophageal stricture, intramural esophageal cysts, esophageal rupture, and equine grass sickness

INITIAL DATABASE
- Bloodwork may be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
- Mucous membranes may be mildly congested.
- Passage of a nasogastric tube is impeded by an obstruction in the esophagus. The horse may become distressed when attempting to swallow the nasogastric tube.

ADVANCED OR CONFIRMATORY TESTING
- Esophageal endoscopy allows identification of the type of material that is causing the obstruction. (Remember that any food that the horse has swallowed subsequent to the occurrence of the obstruction will be visualized by endoscopy, so the initial obstructing mass may not be visible.)
- Ultrasound examination can be used to confirm an obstruction and to identify any extraluminal masses (in the cervical region).
- Radiography (including contrast radiography) can be used to confirm the presence of an obstruction but is more useful in investigating possible strictures or diverticuli.

TREATMENT

THERAPEUTIC GOAL(S)
Treatments are aimed at relieving the obstruction and preventing secondary complications such as inhalation pneumonia.

ACUTE GENERAL TREATMENT
- If choke is suspected, the owners should be advised to remove all food and water immediately.
- Many "chokes" can be relieved by heavy sedation and the repeated administration of spasmolytic agents. This treatment can be continued for several hours or even days, but the distressed state of the patient and the likelihood of serious respiratory complications demand that conservative management should not be prolonged.
- The horse should be tranquillized with acepromazine, and further sedation should be provided with xylazine, detomidine, or romifidine to lower the animal's head (to allow drainage of feed and saliva from the nostrils and prevent aspiration).
- *N*-butylscopolammonium bromide (Buscopan; 0.3 mg/kg IV) may be used to relax the esophagus.
- Oxytocin (0.11–0.22 IU/kg IV q6h) may reduce esophageal smooth muscle tone (do not administer to pregnant mares).
- Lidocaine (30–100 mL of 2% solution) may be administered via nasogastric tube to aid relaxing the esophageal musculature.

CHRONIC TREATMENT
- Conservative treatments are frequently sufficient to relax the esophagus and allow the obstruction to pass within 4 to 6 hours. If conservative therapy fails

ElibVet.com

to relieve the obstruction after 24 hours, most clinicians advocate lavage under sedation (with the patient's head kept low) or general anaesthesia. Gentle lavage is performed via a nasogastric tube. Warm water is gently pumped or administered by gravity flow. The nasogastric tube must be maneuvered carefully to avoid iatrogenic damage to the esophagus.
- Intravenously administered crystalloids may be required in long-standing cases to prevent dehydration.
- Prophylactic antibiotics should be administered to prevent the development of inhalation pneumonia.
- After the obstruction has been resolved, the horse should be allowed access to water only for 24 to 48 hours before being fed a soft diet.
- If all attempts to resolve the obstruction fail, surgical intervention (esophagotomy) may be necessary.

POSSIBLE COMPLICATIONS

Inhalation pneumonia, esophageal rupture, esophageal stricture, esophageal diverticulum, reobstruction

RECOMMENDED MONITORING

During treatment, horses should be monitored for nasal discharge of saliva and retching. Resolution of these signs suggests that the obstruction has cleared. Passage of a nasogastric tube confirms clearance of the obstruction. Endoscopic examination may be helpful in identifying mucosal damage after resolution of the impaction.

PROGNOSIS AND OUTCOME

The prognosis for horses with simple esophageal obstruction is good, but the prognosis is poor if an esophageal stricture occurs.

PEARLS & CONSIDERATIONS

COMMENTS

- Do not leave food or water in the stall after esophageal obstruction occurs.
- Do not use mineral oil as a lubricant to lavage esophageal obstructions because of the risk of aspiration.
- Do not attempt to lavage the esophagus unless the horse's head is lowered.

CLIENT EDUCATION

Never feed dried beet pulp. Ensure that horses cannot gain access to dried beet pulp.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Esophageal Rupture

BASIC INFORMATION

DEFINITION

Rupture of the wall of the esophagus

SYNONYM

Esophageal perforation

EPIDEMIOLOGY

RISK FACTORS
- Chronic esophageal obstruction
- Kick wounds to the neck region

ASSOCIATED CONDITIONS AND DISORDERS Esophageal rupture may occur after esophageal obstruction, especially chronic obstruction, or as an extension of infection or injury from surrounding tissues.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Clinical signs of esophageal rupture include cervical swelling, cellulitis, abscess formation, and subcutaneous emphysema. With open perforations, there is a wound from which saliva and food may drain.

PHYSICAL EXAM FINDINGS In addition to the presenting signs listed above, affected horses may be febrile and have congested mucous membranes. Dyspnea may develop because of tracheal compression or obstruction or pleuritis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Chronic obstruction of the esophagus may cause pressure-induced necrosis of the esophageal wall.
- Swallowed perforating foreign body
- Penetrating external wounds, especially kick wounds
- Repeated traumatic nasogastric intubation

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of cellulitis of the neck
- Other causes of subcutaneous emphysema (eg, thoracic wounds)
- Other causes of dyspnea

INITIAL DATABASE

- The leukogram may reveal a leukopenia with or without a left shift and hypoproteinemia.
- Confirmation of esophageal rupture may be aided by endoscopic examination (esophagoscopy). Ruptures of the cranial esophageal sphincter may be very difficult to visualize with esophagoscopy. The more distal esophageal ruptures are easier to see using esophagoscopy.

ADVANCED OR CONFIRMATORY TESTING

- Diagnosis can be aided by radiography and ultrasound examination. Survey radiographs may reveal emphysema and gas tracking along the fascial planes around the esophagus.
- Contrast radiography may show leakage of liquid contrast agents into the tissues surrounding the esophagus.
- Thoracic radiography may show pneumomediastinum or pneumothorax.

TREATMENT

THERAPEUTIC GOAL(S)

- Maintain a patent airway and treat dyspnea.
- Control infection.
- Facilitate healing of the damaged esophageal wall and surrounding tissues.

ACUTE GENERAL TREATMENT

- Acute (6–12 hours) perforations may be amenable to debridement and primary surgical closure if sufficient healthy esophageal tissue is present.
- Horses should receive nothing by mouth for 48 to 72 hours after surgery.

ElibVet.com

- Administer balanced polyionic fluids intravenously until the horse is eating and drinking again.
- Nonsteroidal antiinflammatory drugs should be administered.
- Tetanus prophylaxis should be administered if required.
- The horse may be so dyspneic (because of compression of the trachea by cellulitis or emphysema) that a tracheotomy is required.
- If pneumothorax is present, drainage of pleural air by a chest drain may be required.
- Broad-spectrum antibiotic treatment is indicated. A suitable antibiotic combination is sodium or potassium penicillin (22,000–44,000 IU/kg IV q6h) and gentamicin (6.6 mg/kg IV q24h). Metronidazole (15–25 mg/kg PO q6h) may be useful in treating anaerobic infections.

CHRONIC TREATMENT

- Most esophageal perforations have to heal by secondary intention. Adequate ventral drainage is essential to prevent migration of the infection to the thoracic inlet, and the wound is allowed to heal by contraction and epithelialization.
- The horse can be fed by placing an esophagotomy tube through the rupture site, allowing tissues to contract down around the tube.
- Alternatively, the patient can be fed through a tube placed distally to the esophageal perforation in a normal area of the esophagus.
- Some horses take a long time to granulate the wound and allow migration of esophageal mucosa over the granulating bed.
- Intermittent fluid therapy may be necessary.

POSSIBLE COMPLICATIONS

Complications include esophageal stricture, failure to heal with formation of esophageal fistula, esophageal impaction, septic mediastinitis, and pleuritis.

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of dehydration, weight loss, and septic pleuritis.

PROGNOSIS AND OUTCOME

- Prognosis appears to be fair for horses with acute esophageal perforation if aggressive therapy is instituted early and the perforation is amenable to surgical closure.
- In chronic cases, the prognosis is more guarded because of the risk of complications.

PEARLS & CONSIDERATIONS

Prompt, aggressive treatment offers the best chance of complete healing without complications.

AUTHOR: **TIM MAIR**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Esophageal Stricture

BASIC INFORMATION

DEFINITION

Stricture (narrowing of the lumen) of the esophagus

SYNONYMS

Esophageal webs or rings

EPIDEMIOLOGY

RISK FACTORS

- Esophageal obstruction
- Esophagitis

ASSOCIATED CONDITIONS AND DISORDERS Esophageal stricture may occur after esophageal obstruction, especially chronic obstruction, or circumferential esophageal erosion or ulceration. Stricture may also occur after trauma to the neck. Congenital strictures have been reported rarely.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Clinical signs of esophageal stricture are similar to those of esophageal obstruction, including acute onset of excessive salivation, retching (repeated flexion and extension of the neck), coughing, and copious discharge of saliva from the nostrils. Repeated bouts of esophageal obstruction may occur.

PHYSICAL EXAM FINDINGS The findings of physical examination are identical to those of esophageal obstruction.

ETIOLOGY AND PATHOPHYSIOLOGY

- Esophageal strictures may develop in three forms:
  - Mural lesions that involve only the adventitia and muscularis
  - Esophageal rings or webs that involve only the mucosa or submucosa
  - Annular stenosis that involves all layers of the esophageal wall

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition), including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophagitis, intramural esophageal cysts, esophageal rupture, and equine grass sickness
- Repeated bouts of esophageal obstruction should increase the suspicion of an underlying esophageal stricture.

INITIAL DATABASE

- The leukogram and hematology results are likely to be normal unless there is dehydration from chronic esophageal obstruction.
- Confirmation of esophageal stricture can be made in some cases by endoscopic examination (esophagoscopy). Esophageal webs and rings can often be detected by endoscopy, but mural strictures or annular stenosis may not be visible.

ADVANCED OR CONFIRMATORY TESTING

Radiography, including contrast radiography or double-contrast radiography, may be necessary to identify an esophageal stricture.

ElibEVet.com

TREATMENT

THERAPEUTIC GOAL(S)

Resolution of the stricture

ACUTE GENERAL TREATMENT

- Clinical and experimental studies indicate that stricture formation may occur as soon as 15 days after circumferential mucosal loss. There is little change in lumen diameter for the next 15 days.
- Between 30 and 60 days postinjury, the lumen diameter increases, with the largest change occurring between 30 and 45 days. Surgical treatment of a stricture should, therefore, be delayed until at least 60 days after the traumatic incident.
- Medical management (feeding a slurry diet and administration of nonsteroidal antiinflammatory drugs) may allow some strictures to resolve without the need for surgery. Pelleted mash has been found to be the most palatable feed. Alternatives include IV total parenteral or partial parenteral nutrition or extraoral alimentation using an esophagostomy tube.

CHRONIC TREATMENT

- Surgical therapy is indicated in cases in which the stricture fails to resolve and recurrent obstructions develop. The surgical management of an esophageal stricture depends on the layer of the esophagus that is involved, although this may not be known before surgery.
- Esophagomyotomy is indicated for an esophageal stricture confined to the muscularis and adventitia. A longitudinal incision is made through the adventitia and muscle, allowing mucosa and submucosa to bulge through the incision. A stomach tube is gently advanced to determine if the lumen will allow passage easily across the strictured site. In most instances, the myotomy is left open, and the rest of the surgical incision is drained and sutured in a routine manner.
- Partial esophageal resection is most appropriate for lesions confined to the mucosa and submucosa. The muscularis and adventitia are incised in a longitudinal manner, and the strictured area of mucosa and submucosa is dissected free and resected. The mucosa is closed only if it is possible to do so without excessive tension. The muscularis is closed because it serves as a muscular tube upon which the mucosal defect can regenerate. It may be necessary to feed the horse through a separate esophagotomy site or via extraoral alimentation.
- Complete esophageal resection: Transection of the esophagus is performed in healthy tissue cranial and caudal to the lesion, and a two-layer anastomosis is performed. Extraoral alimentation or feeding by esophagostomy after surgery can be advantageous.
- Esophagoplasty: A longitudinal incision in the esophagus is closed in a transverse manner. This is only recommended for very small lesions (<2 cm in length).
- Patch grafting with local musculature has been described. A patch graft of the sternocephalicus tendon can be apposed to the mucosal defect left after resection of the stricture.
- Fenestration through a cicatrix: The esophagus is isolated, and an esophagotomy is performed through the strictured area followed by fenestration of the mucosal and submucosal cicatrix. An esophagostomy tube is passed through the defect and left in place until the site constricts down enough for the tube to be removed. The wound will heal with a small traction diverticulum.
- Bougienage is used in humans and small animals for treatment of esophageal stricture, but horses do not tolerate the technique well.

POSSIBLE COMPLICATIONS

Complications of esophageal surgery are common and include esophageal impaction, recurrence of stricture, and postsurgical dehiscence.

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of dehydration, weight loss, infection, and surgical dehiscence

PROGNOSIS AND OUTCOME

- The prognosis depends on the severity of the stricture.
- In strictures that fail to resolve with medical therapy, the prognosis is better if surgery is performed than if continued conservative management is attempted.

PEARLS & CONSIDERATIONS

Medical management of esophageal strictures early in the course of the disease (the first 60 days) is frequently successful.

ElibeVet.com

Esophagitis

BASIC INFORMATION

DEFINITION
Inflammation of the wall of the esophagus; may be ulcerative or nonulcerative

SYNONYM
Reflux esophagitis

EPIDEMIOLOGY
RISK FACTORS
- Esophageal obstruction
- Gastric fluid regurgitation into the esophagus

ASSOCIATED CONDITIONS AND DISORDERS Esophagitis may occur after esophageal obstruction, especially chronic obstruction, or as a result of reflux of gastric fluid into the esophagus.

CLINICAL PRESENTATION
HISTORY, CHIEF COMPLAINT Clinical signs of esophagitis are nonspecific and are similar to those of esophageal obstruction and gastric ulcer disease. Affected horses present with signs of dysphagia or discomfort when swallowing, hypersalivation, bruxism, and inappetence.

PHYSICAL EXAM FINDINGS The findings of physical examination confirm the presenting signs, which include dysphagia, hypersalivation, and bruxism. Weight loss may occur in chronic cases.

ETIOLOGY AND PATHOPHYSIOLOGY
- Chronic obstruction of the esophagus may cause pressure-induced necrosis of the esophageal wall.
- Swallowed perforating foreign body
- Penetrating external wounds, especially kick wounds
- Repeated traumatic nasogastric intubation
- Repeated episodes of gastric fluid reflux into the distal esophagus (secondary to gastric ulcer disease, motility disorders, gastric outflow obstruction, intestinal ileus, proximal enteritis)
- Chemical injury from swallowed irritant substances

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition), including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophageal stricture, intramural esophageal cysts, esophageal rupture, and equine grass sickness

INITIAL DATABASE
- The leukogram and hematology results are likely to be normal unless there is dehydration from chronic esophagitis or changes secondary to any underlying disease.
- Confirmation of esophagitis is achieved by endoscopic examination (esophagoscopy). Diffuse, patchy, linear, or coalescing areas of inflammation, erosion, or ulceration may be observed.

ADVANCED OR CONFIRMATORY TESTING
- Investigations should be undertaken to establish whether there is a primary underlying disease causing secondary esophagitis. The stomach should be examined endoscopically to establish the presence of gastritis, gastric ulceration, or gastric outflow abnormalities.
- Radiography, including contrast radiography, may be helpful in assessing esophageal motility and transit time.

TREATMENT

THERAPEUTIC GOAL(S)
- Control infection.
- Facilitate healing of the damaged esophageal wall and surrounding tissues.
- Treat any underlying primary disease.

ACUTE GENERAL TREATMENT
- Decrease or discontinue nonsteroidal antiinflammatory drug therapy if at all possible.
- Gastric acid suppression
  - Proton pump inhibitors
    - Omeprazole: 4 mg/kg PO q24h
    - Pantoprazole (1.5 mg/kg IV q24h) is available for patients in which oral omeprazole cannot be used but may be cost prohibitive
  - Histamine H2-receptor antagonists
    - Cimetidine: 16 to 25 mg/kg PO or 6.6 mg/kg IV q6–8h
    - Ranitidine: 6.6 mg/kg PO or 1.5 mg/kg IV q8h
    - Famotidine: 2.8 to 4.0 mg/kg PO or 0.23 to 0.5 mg/kg IV q8–12h
  - Antacids: Magnesium hydroxide, aluminum hydroxide
    - Require frequent administration (q2–4h) to have any effect on increasing gastric pH; thus, they are not recommended
- Mucosal protectants: Sucralfate (20 mg/kg PO q6–8h). Efficacy has not been proven for esophageal ulcers.
- Broad-spectrum antibiotic treatment is indicated if there is infection of the esophageal wall or periesophageal tissues. A suitable antibiotic combination is sodium or potassium penicillin (22,000–44,000 IU/kg IV q6h) and gentamicin (6.6 mg/kg IV q24h). Metronidazole (15–25 mg/kg PO q6h) may be useful for treating anaerobic infections.
- Horses with reflux esophagitis caused by gastroduodenal ulcer disease, gastric paresis, or proximal enteritis may benefit from prokinetic drugs that act on the proximal gastrointestinal tract (eg, metoclopramide, 0.02–0.10 mg/kg SC q4–12h, or bethanechol, 0.025–0.035 mg/kg SC q4–24h)

CHRONIC TREATMENT
- Frequent small meals of moistened pellets or fresh grass should be fed.
- Severe esophagitis may require withholding food completely for several days.

POSSIBLE COMPLICATIONS
Complications include esophageal stricture and esophageal impaction.

RECOMMENDED MONITORING
During treatment, horses should be monitored for signs of dehydration and weight loss.

PROGNOSIS AND OUTCOME
- The prognosis depends on the presence and nature of any underlying primary disease.
- The prognosis appears to be fair to good for horses with acute esophagitis without any underlying primary disease.
- In chronic cases, the prognosis is more guarded because of the risk of complications.

PEARLS & CONSIDERATIONS
- Esophagitis is frequently secondary to an underlying

ElibEVet.com

disease affecting the stomach or proximal intestinal tract.
- The nature and severity of any underlying primary disease is most important in determining the prognosis.

Esophagus: Idiopathic Muscular Hypertrophy

BASIC INFORMATION

DEFINITION

Muscular hypertrophy of the small muscle layers of the distal esophagus

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS Idiopathic muscular hypertrophy of other regions of the gastrointestinal tract

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT In most cases, the disease is asymptomatic and is discovered as an incidental postmortem finding. In a small number of cases, the disease may be associated with esophageal dysphagia (hypersalivation, nasal discharge of saliva or food) or recurrent esophageal obstructions by feed. Affected horses may also present with weight loss.

PHYSICAL EXAM FINDINGS The findings of physical examination confirm the presenting signs, which include dysphagia, hypersalivation, and nasal discharge containing food material. Distension of the cervical esophagus may be visible or palpable.

ETIOLOGY AND PATHOPHYSIOLOGY Unknown cause. There is muscular hypertrophy of the tunica muscularis of the distal esophagus without fibrosis or inflammation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition): Pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, esophageal stricture, esophageal rupture, megaesophagus, and equine grass sickness
- Other obstructions of the esophagus: Intramural esophageal cysts, duplication cysts of the esophagus, esophageal neoplasia

INITIAL DATABASE

- The leukogram, hematology, and blood chemistry results are likely to be normal unless they reflect abnormalities associated with secondary aspiration pneumonia.
- Endoscopic examination (esophagoscopy) may reveal reduced esophageal peristaltic activity and dilatation of the lumen. There may be evidence of esophagitis.
- Fluoroscopy and contrast radiography can be used to demonstrate prolonged transit time of a bolus from the cervical esophagus to the stomach. Contrast radiography also demonstrates dilatation of the esophageal lumen and a thickened esophageal wall.

ADVANCED OR CONFIRMATORY TESTING

Confirmation is achieved by postmortem examination.

TREATMENT

THERAPEUTIC GOAL(S)

- Treat any secondary inhalation pneumonia
- Aid transit of food along the esophagus

ACUTE GENERAL TREATMENT

- Treat any secondary aspiration pneumonia with broad-spectrum antibiotics.
- Dietary modification may help esophageal transit of food boluses to the stomach. Feeding slurries of pellets and feeding from an elevated position may help.
- Metoclopramide or bethanechol may benefit patients with reflux esophagitis by increasing lower esophageal tone, increasing gastric emptying, and reducing gastroesophageal reflux.

CHRONIC TREATMENT

Frequent small meals of slurries or fresh grass should be fed.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Weight loss

PROGNOSIS AND OUTCOME

The prognosis is poor in most cases.

PEARLS & CONSIDERATIONS

Idiopathic muscular hypertrophy of the esophagus should be considered as a rare cause of chronic signs of esophageal dysphagia.

SUGGESTED READING

Benders NA, Veldhuis Kroeze EJ, van der Kolk JH: Idiopathic muscular hypertrophy of the oesophagus in the horse: a retrospective study of 31 cases. *Equine Vet J* 36:46, 2004.

ElibeVet.com

Estrus, Prolonged

BASIC INFORMATION

DEFINITION

Estrous behavior lasting more than 12 days

SYNONYM(S)

Persistent estrus, nymphomania

EPIDEMIOLOGY

SPECIES, AGE, SEX Sexually mature mares

RISK FACTORS Endometritis

GEOGRAPHY AND SEASONALITY

- Prolonged estrus during spring transition between January and April (Northern Hemisphere)
- Hemorrhagic anovulatory follicles are more common during the fall

ASSOCIATED CONDITIONS AND DISORDERS

- Endometritis
- Ovarian disorders

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Signs of estrus for >12 days (normal duration 5–7 days with a range of 2–12 days)

PHYSICAL EXAM FINDINGS Body condition generally good

ETIOLOGY AND PATHOPHYSIOLOGY

- Seasonality: Prolonged estrous behavior during spring transition or winter anestrus
- Granulosa theca cell tumor (GTCT): Increased production of estrogens or lack of progesterone
- Gonadal dysgenesis: 63,XO; 65,XXX; 64,XY mares
- Hormone imbalance: Older mares may fail to ovulate and exhibit prolonged estrus; possibly due to insufficient or ineffective leutinizing hormone release
- Previous ovariectomy
- Hemorrhagic anovulatory follicles (HAF): 14.3% remain as follicular structures with consequent signs of persistent estrus

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Frequent urination
  - Cystitis/urethritis
  - Bladder atony
- Frequent posturing and straining
  - Urovagina
  - Vaginitis
  - Pneumovagina
- Submissive behavior
- Missed shortened interestrus
- Psychogenic behavioral problem not associated with physiologic or pathologic causes of prolonged estrus

INITIAL DATABASE

- Teasing: Estrous behavior
- Transrectal palpation and ultrasound: Serial examinations may be needed to evaluate the estrous cycle and its association with behavior.
  - Anestrus: Small inactive ovaries, no uterine edema, relaxed cervix.
  - Spring transition: Active ovaries, 20 mm follicles, ±uterine edema, relaxed cervix.
  - GTCT: Asymmetric ovaries, no uterine edema, relaxed cervix; the affected ovary presents a multicystic or honeycombed appearance, with loss of ovulation fossa, but also could appear as a solid mass or a single large cyst. The contralateral ovary is generally inactive and small.
  - Gonadal dysgenesis: Small inactive ovaries, no uterine edema, relaxed cervix.
  - Hormone imbalance: Active ovaries with follicles, uterine edema, relaxed cervix.
  - HAF: Asymmetric ovaries, uterine edema, relaxed cervix. HAFs may be 5 to 15 cm in diameter and persist for up to 2 months. Fibrous (hyperechoic) bands or strands traversing the follicular lumen may be seen on ultrasound, but in some cases the only feature observed is a thickening of the follicular wall. The contralateral ovary is generally active.
- Speculum vaginal examination
  - Urovagina: Presence of urine in the lumen
  - Vaginitis: Irritation of the vaginal walls

ADVANCED OR CONFIRMATORY TESTING

- Inhibin, testosterone, and progesterone serum concentrations for GTCT
- Inhibin >0.7 ng/mL, testosterone >50 to 100 pg/mL, and progesterone <1 ng/mL
- Urinalysis to rule out cystitis
- Karyotyping for gonadal dysgenesis

TREATMENT

THERAPEUTIC GOAL(S)

Treat underlying cause

ACUTE GENERAL TREATMENT

- Winter anestrus: Progestogens will abolish estrous signs (Altrenogest 0.044 mg/kg PO q24h or progesterone in oil 150 mg IM q24h)
- Spring transition
  - Hastening the first ovulation of the year
    - Artificial lighting (14.5–16h of light daily, starting in December, extending the natural light in the evening, with an intensity of 10 lux or 1 foot-candle)
    - Progestogens will shorten and ease the transitional signs (Altrenogest 0.044 mg/kg PO q24h or progesterone in oil 150 mg IM q24h for 10–15 days during late transition; ovulation is expected 12–15 days after discontinuation of treatment)
- Estrus suppression
- GTCT: Unilateral ovariectomy.
- No known efficacious treatment for hormone imbalance. Induction of ovulation can be attempted by administration of human chorionic gonadotropin (hCG; 1500–3500 IU, IM, or IV) or Deslorelin (gonadotropin-releasing hormone analog; 1.5 mg IM) when a >35 mm follicle is present.
- HAF: Administration of hCG (1500–3500 IU, IM, or IV) or Deslorelin (1.5 mg IM) to induce ovulation or luteinization of the follicles (although they may not respond to such treatment) followed by administration of prostaglandin $F_{2\alpha}$ (Dinoprost 5–10 mg IM) 7 to 10 days later to induce luteolysis (repeated doses may be needed). Most HAFs regress spontaneously without treatment.
- Previous ovariectomy: Progestogens will abolish estrous signs (Altrenogest 0.044 mg/kg PO q24h or progesterone in oil 150 mg IM q24h).

POSSIBLE COMPLICATIONS

- Treatment with progestagens may decrease uterine defenses and lead to endometritis.
- Injections of progesterone may produce muscle soreness.

RECOMMENDED MONITORING

GTCT: Ultrasound examination to check for return to cyclicity of the remaining ovary starting 2 months after ovariectomy

PROGNOSIS AND OUTCOME

- GTCT: Good prognosis for life and fertility. Time to return to cyclicity of the contralat-

ElibVet.com

eral ovary is 6 months on average (2–12 months)
- Guarded for fertility for hormonal imbalance
- Poor prognosis for fertility in mares with congenital disorders
- Once winter anestrus and spring transition are over, the mare is expected to cycle normally

PEARLS & CONSIDERATIONS

COMMENTS

- One complaint is that the mare constantly shows a behavior, interpreted as estrus, that interferes with the mare's performance. Often this complaint is not associated with an abnormality in cyclicity.
- Signs of discomfort, agitation, or submission can be confused with signs of estrus.
- Deslorelin is only available through compounding pharmacies in the United States.

CLIENT EDUCATION

Human safety must be considered when handling Altrenogest. Gloves must be worn while handling this product. Pregnant women or women who suspect they are pregnant should not handle this drug. Women of child-bearing age should exercise extreme caution when handling this product. Accidental absorption could lead to a disruption of the menstrual cycle or prolongation of pregnancy, uterine or abdominal cramping, increased or decreased uterine bleeding, and headaches.

AUTHOR: **MARIA CLARA SARDOY**

EDITOR: **JUAN C. SAMPER**

Ethmoid Hematoma, Progressive

BASIC INFORMATION

DEFINITION

- A well-encapsulated, non-neoplastic, and slowly growing mass that originates in the ethmoid turbinate region and less often within the paranasal sinuses
- The condition is most often unilateral, although 15% to 20% of reported cases have bilateral disease.

SYNONYM(S)

Ethmoid hematoma

EPIDEMIOLOGY

SPECIES, AGE AND SEX Although progressive ethmoid hematoma (PEH) is often considered a disease of middle-aged horses (10–12 years old), reported age ranges from <1 year to 20 years old.

GENETICS AND BREED PREDISPOSITION

- Any breed can be affected, although the condition is overrepresented in Thoroughbreds and Arabians.
- Standardbreds appear underrepresented.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Based on the origin of the PEH:
- Ethmoid turbinate
- Sphenopalatine sinus
- Maxillary sinus
- Other location within the paranasal sinus

HISTORY, CHIEF COMPLAINT
- Unilateral epistaxis, which is often mild and intermittent in nature.
- May occur spontaneously or after exercise.
- A respiratory noise may be heard at rest but more often during exercise.

PHYSICAL EXAM FINDINGS
- Epistaxis alone or mixed with mucopurulent nasal discharge.
- Respiratory noise may be present.
- Some uncommon findings during physical examination include coughing, halitosis, facial deformity, head shyness or shaking, dyspnea, and visualization of the mass at the level of the nostril.
- Small PEHs may not show any clinical signs.

ETIOLOGY AND PATHOPHYSIOLOGY
- The initiating cause is unknown.
- PEHs form because of an episode of hemorrhage in the submucosa of either an ethmoid turbinate or paranasal sinus, causing the mucosa to stretch and secondarily thicken creating a capsule.
- As the hematoma expands, the capsule becomes necrotic, which can leak or rupture, leading to episodes of mild and often intermittent epistaxis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Guttural pouch mycosis
- Paranasal sinus cysts
- Neoplasia of the ethmoids, paranasal sinuses, or guttural pouch
- Ulcerative or fungal rhinitis
- Skull fracture
- Foreign body
- Pulmonary abscess or pleuropneumonia

INITIAL DATABASE

- Physical examination
- Resting endoscopic examination will reveal a glistening yellow- to green-tinged mass either at the ethmoid turbinate or through the nasomaxillary opening. The absence of a mass in the nasal passages does not rule out PEH because PEHs can be found within the paranasal sinuses.
- Radiographs of the sinuses and nasal passage may reveal a smooth-walled and well-demarcated soft tissue density within the sinus cavity or in the nasal passage at times impinging on the nasal septum. Fluid lines within the sinuses may be present in some cases.
- Small lesions may fail to be identified radiographically.
- Bloodwork (complete blood count and chemistry profile) is usually normal, although it may reveal anemia in some cases.

ADVANCED OR CONFIRMATORY TESTING

- Computed tomography may provide an exact location, origin, and extent of the PEHs, as well as providing information regarding all other soft tissue structures within the skull. It can be

ElibeVet.com

very useful to accurately diagnose bilateral lesions as well.
- Nuclear scintigraphy may help differentiate a PEH from a cyst or a carcinoma. PEH typically appears scintigraphically as a poorly defined region of radioisotope uptake within the sinus or ethmoidal region. Cysts are usually well defined and within the maxillary or frontal sinus, and carcinomas invade bone, which will be shown scintigraphically as another region of radioisotope uptake.
- Biopsies taken transendoscopically in cases of PEH are typically of limited or no diagnostic benefit because of their thick capsule. Biopsies are usually more beneficial to rule in other conditions such as granulomas and carcinomas.

TREATMENT

THERAPEUTIC GOAL(S)

To eliminate the PEHs and to minimize the chance of recurrence

ACUTE GENERAL TREATMENT

- Photoablation of the PEH with an Nd:YAG laser under endoscopic guidance
  - May be done with the horse standing or under general anesthesia.
  - Intranasal portion of the PEH.
  - The goal is to create thermal necrosis and obliteration of the mass.
  - Noncontact fiber.
  - May be necessary to perform several treatment sessions depending on the size of the lesion, usually 1 to 2 weeks apart to allow for the charred and necrotic material to slough.
- Chemical ablation of the PEH using 10% formalin (4% formaldehyde solution) under endoscopic guidance
  - Standing procedure.
  - Although used mostly for PEH with a nasal component, it may be used in PEHs within the sinus using a trephine opening.
  - Between 30 and 50 mL of formalin is injected using a commercially available catheter with guarded needle tip (Cook Veterinary Products, Spencer, IN) or homemade.
- PEH is injected until it begins to leak.
  - The method of action is desiccation and coagulation of the tissue by protein hydrolysis.
  - Several treatments are likely needed (range, 1–18) every 3 to 4 weeks.
- PEH removal via frontonasal bone flap
  - The goal is to remove the entire hematoma, including its origin.
  - May be done in combination with Nd:YAG laser.
  - Because of the need to access the ethmoid labyrinth or base of the sphenopalatine sinus, hemorrhage can be severe.
  - After removal of the PEH, the sinuses are packed with sterile gauze, exiting through a corner of the flap or through the nasal cavity and secured to the nostril. The packing is removed approximately 72 hours after surgery.

CHRONIC TREATMENT

Ablation of the PEH using either Nd:YAG laser or formalin injections usually requires several treatments spaced every week or 3 to 4 weeks, respectively, until the lesion is fully destroyed.

POSSIBLE COMPLICATIONS

- Although rare, there have been reports of significant complications after the use of intralesional formalin such as severe laminitis and erosion of the cribiform plate, allowing formalin to come in contact with the brain. In addition, formalin can induce significant nasal edema, which can lead to complete obstruction if bilateral lesions are simultaneously treated.
- Thermal damage to surrounding structures, including the brain, is possible when using the Nd:YAG laser. For this reason, it is very important to aim the laser beam at the center of the lesion and monitor the amount of energy used.
- Severe hemorrhage during surgical removal through a frontonasal bone flap is possible and should be discussed with the owner before surgery.

RECOMMENDED MONITORING

Repeat endoscopy or radiography of the skull is recommended every 6 months.

PROGNOSIS AND OUTCOME

- Long-term prognosis is fair to guarded.
- The incidence of recurrence has been reported in up to 45% of cases.
- Bilateral lesions (43%) seem to have a significantly worse prognosis compared with unilateral lesions (8%) regarding long-term remission.

PEARLS & CONSIDERATIONS

COMMENTS

- It is important to examine both nasal passages to assess whether there is unilateral or bilateral involvement.
- Because of the chance of significant hemorrhage during surgical extirpation of the PEH, it is always recommended to have donor blood available. Alternatively, if a donor is not available, it is recommended to collect blood from the patient 2 to 4 weeks before surgery for an autotransfusion.
- In cases of mild to moderate hemorrhage, IV administration of aminocaproic acid (10–20 mg/kg) diluted in 100 mL of saline can be beneficial. The treatment can be given q6h for several days. It is important to monitor the hematocrit because it will artificially decrease (reason unknown, potentially rouleaux formation).
- Aminocaproic acid is an antifibrinolytic or antiproteolytic drug that works by blocking plasminogen activator factor. This keeps plasmin from being activated, which then cannot split fibrin.

CLIENT EDUCATION

Horse owners must be advised about the potential for several treatments and long-term regular follow-up to enhance the chances for a good long-term outcome.

EDITOR: **ERIC J. PARENTE**

ElibeVet.com

Ethylene Glycol Toxicosis

BASIC INFORMATION

DEFINITION

Condition caused by intoxication with ethylene glycol (EG) characterized by neurologic, acid-base, and renal disturbances

SYNONYM(S)

EG poisoning, antifreeze poisoning

EPIDEMIOLOGY

SPECIES, AGE, SEX The paucity of case reports suggests that EG toxicosis is uncommon in horses.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Early acute onset of neurologic dysfunction and acidosis followed by renal insufficiency or failure.

HISTORY, CHIEF COMPLAINT Acute onset (10–30 minutes) of central nervous system (CNS) depression and ataxia, progression to profound CNS depression, subsequent polyuria, oliguria, or anuria may develop.

PHYSICAL EXAM FINDINGS Signs developing soon after ingestion include ataxia, CNS depression, tachypnea, sweating, tachycardia, hypothermia, decreased gut motility, colic, and seizure. Development of renal insufficiency occurs within 24 to 36 hours after exposure.

ETIOLOGY AND PATHOPHYSIOLOGY EG is metabolized via alcohol dehydrogenase to glycoaldehyde, glycolic acid, glyoxylic acid, and oxalic acid, resulting in severe systemic acidosis. Oxalic acid combines with serum calcium to form calcium oxalate crystals, which precipitate in the kidney and contribute to the renal injury caused directly from other EG metabolites.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of acute onset of neurologic dysfunction: Viral and bacterial encephalidities, fumonisins, hepatic encephalopathy, and propylene glycol
- Other causes of renal injury: Soluble oxalate-containing plants, nonsteroidal antiinflammatory drug toxicosis, enterotoxemia, aminoglycoside toxicosis, myoglobinuria, and hemoglobinuria

INITIAL DATABASE

- Baseline serum chemistry and blood gases followed by repeat testing of renal function and serum calcium levels
  - Expect metabolic acidosis, increased anion gap, hypocalcemia, increased blood urea nitrogen, increased creatinine, and possibly hyperkalemia.
- EG levels can be measured in the blood with in-house test kits.

ADVANCED OR CONFIRMATORY TESTING

- Qualitative and quantitative testing for EG can be done at most diagnostic laboratories and at human hospitals.
- Gritty texture upon cutting the kidney at necropsy.
- Uremic ulcers in the oral cavity; gastric mucosal mineralization.
- Histopathologic examination of the kidney reveals proximal tubular necrosis associated with the presence of birefringent crystals in the lumens of tubules.

TREATMENT

THERAPEUTIC GOAL(S)

Manage acidosis, provide supportive care, enhance elimination, and prevent formation of toxic metabolites.

ACUTE GENERAL TREATMENT

- IV fluid diuresis at twice to three times maintenance rate (8.0–12.0 mL/kg/h IV) to enhance elimination of EG and metabolites.
- Ethanol: 4.4 mL/kg of 25% solution followed by 2.0 mL/kg IV q4h for 4 days.
- Administration of sodium bicarbonate IV as needed based on blood gas results.
- Provide a quiet, padded environment with minimal sensory stimuli.

CHRONIC TREATMENT

Long-term dietary alteration may be necessary if residual kidney dysfunction occurs.

POSSIBLE COMPLICATIONS

Pulmonary edema is possible.

RECOMMENDED MONITORING

Acid-base status, oxygen saturation, urine output (fluid ins/outs), renal values, serum calcium

PROGNOSIS AND OUTCOME

Prognosis is guarded to poor if there is evidence of renal dysfunction.

PEARLS & CONSIDERATIONS

COMMENTS

- Although some sources suggest the use of activated charcoal to adsorb glycols, the current consensus is that activated charcoal is a poor adsorbent for small molecules such as these and is of little benefit in EG exposures.
- There is no information on the efficacy (or lack thereof) of fomepizole causing inhibition of equine alcohol dehydrogenase; therefore, the usefulness of this modality in treating equine EG intoxication is not known.
- Some car antifreeze products contain fluorescein dye, which may cause fluorescence when a wood's lamp is used to visualize urine. Because not all EG products contain fluorescein, absence of urine fluorescence should not be construed as a negative test for EG.

PREVENTION

Keep horses away from areas where EG is being used.

ElibeVet.com

Exercise-Induced Pulmonary Hemorrhage

BASIC INFORMATION

DEFINITION

Hemorrhage originating from small pulmonary vessels associated with strenuous exercise.

SYNONYM(S)

- EIPH
- Bleeders

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Females are thought to have a slightly increased risk of epistaxis associated with EIPH.
- The incidence of EIPH is increased in older horses doing strenuous work.

RISK FACTORS

- Increased exercise intensity
- Previous EIPH episodes
- Extended time in training
- Existing airway inflammation
- Cardiac arrhythmias such as atrial fibrillation
- Significant upper airway obstruction

GEOGRAPHY AND SEASONALITY

Anecdotally, seasonal association with extreme environmental conditions (ie, cold, dry winter or hot, humid summer)

ASSOCIATED CONDITIONS AND DISORDERS

- Upper airway obstruction
- Lower airway inflammation: Infectious or noninfectious
- Cardiac dysrhythmia (especially atrial fibrillation)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Blood visualized in trachea with endoscope. This is the most common method of diagnosing EIPH. The severity of EIPH is quantified by scores from 0 to 4.
  - Grade 0: No blood in the trachea
  - Grade 1: Small droplets of blood in the trachea
  - Grade 2: Narrow stream of blood (<5 mm wide) in the trachea
  - Grade 3: Confluent wider streams of blood in the trachea
  - Grade 4: Pooling of blood occupying the majority of the tracheal circumference
- Red blood cells (RBCs) seen microscopically in bronchoalveolar lavage (BAL) fluid in the absence of blood visible endoscopically in the trachea
- Epistaxis: Uncommonly observed (<1% of race starts); some association with higher bleeding scores

HISTORY, CHIEF COMPLAINT

- Reduced athletic performance
- Frank hemorrhage in trachea
- Epistaxis (rarely)

PHYSICAL EXAM FINDINGS

- None specific
- Epistaxis (rarely)

ETIOLOGY AND PATHOPHYSIOLOGY

- Horses undergoing strenuous exercise have very high pulmonary vascular and left atrial pressures. This predisposes the smaller vessels in the lungs to damage.
- Stress failure of pulmonary capillaries results when transmural forces exceed the strength of the capillary walls.
- Increased transmural forces can occur from both elevated pulmonary vascular pressures or increased swings in airway pressures during intense exercise.
- When this occurs, protein-rich fluid and then RBCs (hemorrhage) leak into the interstitium and alveoli.
- The blood in the alveoli eventually migrates to the trachea, where it may be seen with endoscopy. This blood can be engulfed and cleared by alveolar macrophages, which are seen on cytologic evaluation of BAL fluid as hemosiderophages. Very rarely, blood is seen at the nose (epistaxis). It may also be coughed up and swallowed.
- The RBCs remaining in the interstitium likely set up an inflammatory response in the lung parenchyma and may be responsible for ongoing damage and fibrosis in the lung.
- The capillaries in the dorsocaudal region of the lung are the most prominently affected, particularly in early episodes of EIPH.
- With time, the vessels in more cranial portions of the lung are affected, especially noted at the periphery of prior lesions. The ventral aspect of the lung is much less commonly involved.
- Other factors, including airway inflammation, limb loading and hoof impact, and cardiac disease, are thought to modify the extent or frequency of hemorrhage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Airway hemorrhage from other sources (eg, larynx, pharynx, nasal passages, ethmoids, guttural pouches, sinuses)
- Pulmonary hemorrhage not associated with exercise

INITIAL DATABASE

- Airway endoscopy for blood in the trachea or bronchi
- BAL for enumeration of erythrocytes in BAL fluid. RBCs may persist for at least 7 days after an episode in BAL fluid. Nucleated cell count and differential analysis or cytology to assess degree of airway inflammation are also important.
- The presence of hemosiderophages in BAL fluid indicates hemorrhage occurred sometime in the past (generally persist up to 3 weeks after an episode).
- The complete blood count is likely to be normal.
- Thoracic radiographs may show characteristic lesions (increased interstitial density) in the caudodorsal lung field. With chronicity, a bronchial pattern may be seen superimposed over the interstitial pattern; however, this is not a sensitive indicator of EIPH.
- Thoracic ultrasonography may show increased numbers of "comet tail" artifacts in the caudodorsal lung fields. This is neither sensitive nor specific for EIPH, but may be a way to monitor EIPH severity or pulmonary damage in horses with repeated episodes over time.

ADVANCED OR CONFIRMATORY TESTING

Scintigraphy with labeled RBCs may be used, but this is very technically demanding, not readily available, and may not accurately distinguish between hemorrhage and RBCs within vessels.

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate factors that may predispose the horse to increased severity of EIPH or increased number of episodes (eg, cardiac arrhythmias, airway inflammation, and upper airway obstruction)
- Rest to allow time for pulmonary lesions to heal

ACUTE GENERAL TREATMENT

- Many treatments have been used to limit EIPH or its severity; however, few have met with consistent success. Although some treatments do seem to work in individual horses under certain circumstances, none has been found to consistently decrease or prevent EIPH. Treatments fall under general categories of reduction of

ElibVet.com

pulmonary artery (PA) pressures, decreasing airway resistance, procoagulants, antiinflammatory agents, and other.

- Furosemide (Lasix, Salix): This is the only race day medication approved in all racing jurisdictions in the United States. Its primary mechanism is to reduce PA pressures (and body weight) through diuresis; however, it also has bronchodilatory as well as other effects. It is permitted a minimum of 4 hours before racing, using a dose range of 100 to 500 mg (variable between jurisdictions). There is no agreement that furosemide overall prevents EIPH, although anecdotally it may decrease severity in some situations. Studies report conflicting results as to its efficacy.
- Endothelin receptor antagonists: No effect on PA pressures or EIPH
- Nitric oxide (NO), NO donors, NO with type 5 phosphodiesterase (PDE) inhibitors: Conflicting results as to efficacy; most promising is a combination of NO and a selective type 5 PDE inhibitor; not commercially available or approved for race day use
- Nasal strip: Mechanism is to decrease nasal resistance. Studies show conflicting results regarding the ability to decrease EIPH.
- Bronchodilatory agents: Mechanism is to decrease airway resistance. However, airways of healthy horses are fully dilated during maximal exercise. These agents do not appear to directly influence EIPH. If a horse has inflammatory airway disease, these agents may affect EIPH; however, they are not approved as a race day medication.
- Various procoagulants (eg, herbal remedies, aminocaproic acid, conjugated estrogens, vitamin K) have not been shown to be efficacious.
- Antiinflammatory agents: The mechanism is to decrease airway inflammation; does not have a direct effect on EIPH; not approved as race day medication

CHRONIC TREATMENT

- Chronic treatment is aimed at reducing predisposing causes contributing to EIPH occurrence or severity.
- Management practices designed to decrease airway inflammation such as decreasing dust, irritants, and allergens in environment and use of corticosteroids may help to control EIPH if it is exacerbated by inflammation.
- Correction of upper airway obstructions that may contribute to increased inspiratory airway resistance
- Ensuring that cardiac function is normal
- Rest to allow time for pulmonary lesions to heal

POSSIBLE COMPLICATIONS

- Decreased pulmonary function over time if repeated episodes of severe bleeding with parenchymal damage and fibrosis occur.
- Bronchitis or pneumonia

PROGNOSIS AND OUTCOME

- Horses that are "severe" bleeders are likely to continue to have episodes. These horses are usually retired because of poor athletic performance related to EIPH.
- Horses that bleed more severely (grade 3 or 4) do not perform as well on the racetrack.
- All horses undergoing intense exercise on a regular basis bleed at some time during their athletic career. If the episodes are mild, this may not be a performance-limiting factor.

PEARLS & CONSIDERATIONS

COMMENTS

All athletic horses participating in intense exercise will bleed, although not all horses have detectable blood every time they exercise. Factors contributing to the variability seen in the diagnosis of EIPH are not known. This makes it difficult to assess treatment efficacy.

PREVENTION

- None
- As noted above, medications are used to attempt to limit EIPH, although their efficacy is mostly unproven.

EDITOR: **MELISSA R. MAZAN**

Failure of Passive Transfer

BASIC INFORMATION

DEFINITION

- Failure of transfer of passive immunity (FPT) from the dam's colostrum to the foal. The most widely accepted definition of FPT is measurement of serum immunoglobulin G (IgG) concentrations less than 400 mg/dL at or after 24 hours of age.
- Partial failure of passive transfer (PFPT) is commonly defined as IgG concentrations between 400 and 800 mg/dL.
- Adequate transfer of passive immunity is generally defined as IgG of 800 mg/dL or greater.

SYNONYM(S)

Failure of transfer of passive immunity

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals younger than 1 month.

RISK FACTORS Prematurity, rejection by dam, peripartum asphyxia syndrome, geriatric dam, colostrum lost before parturition

ASSOCIATED CONDITIONS AND DISORDERS Sepsis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- FPT with secondary sepsis
- FPT without disease

ElibeVet.com

HISTORY, CHIEF COMPLAINT
- Detection at routine new foal examination
- Foals that have not nursed adequately
- Foals rejected by dam
- Premature lactation of dam
- Weak, poor affinity for dam

PHYSICAL EXAM FINDINGS
- FPT without other illness: No abnormalities on physical examination
- FPT with illness: Signs of generalized disease (weakness, lethargy, poor affinity for dam) or localized disease (swollen joint, lameness) (see "Neonatal Sepsis" in this section)

ETIOLOGY AND PATHOPHYSIOLOGY
- Insufficient production
  - Premature birth of foal
  - Serious illness of dam
  - Ingestion of endophyte-infected fescue during third trimester of gestation
  - Premature lactation (as with placentitis, premature placental separation, twinning)
  - Variation of IgG concentration of colostrum among mares
- Insufficient ingestion
  - Weak foal
  - Congenital musculoskeletal abnormalities of foal
  - Rejection by dam
  - Separation of dam and foal (eg, foal rolls under a fence)
- Insufficient absorption
  - Concurrent disease
  - Hypoxic ischemic insult to enterocytes

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Sepsis with adequate transfer of passive immunity

INITIAL DATABASE

- Whole blood or serum for estimation of IgG concentration
  - Quantitative immunoassay (DVM stat) or semiquantitative (SNAP, IDEXX Laboratories, Westbrook, ME) immunoassays
  - Zinc sulphate turbidity (Equine FPT Test Kit, VmRD, Inc., Pullman, Wash.) or glutaraldehyde coagulation (Gamma-Check E, Plasvacc USA, Templeton, CA)
- Complete blood count (CBC): Aids in distinguishing FPT alone from FPT and sepsis

ADVANCED OR CONFIRMATORY TESTING

- Turbidimetric immunoassay (TIA)
- Single radial immunodiffusion: Most quantitatively accurate but requires 18 to 24 hours of incubation time

TREATMENT

THERAPEUTIC GOAL(S)

- Increase blood concentration of IgG to a value above 800 mg/dL.
- Prevent infection in the lag time between the time of exposure to pathogens (at birth) and the development of a protective immune response.

ACUTE GENERAL TREATMENT

- Plasma is recommended for all foals older than 12 hours with IgG below 800 mg/dL.
- Foals with IgG between 400 and 800 mg/dL may not require treatment if a clean environment is maintained and the foal shows no physical or laboratory (CBC) abnormalities.
- Foals younger than 12 hours of age with inadequate nursing: Equine colostrum
  - Begin with 200 to 400 mL colostrum to ensure the gastrointestinal tract will tolerate feedings.
  - Feed via nasogastric tube to weak foals.
  - Total of 1 to 2 L of good-quality colostrum is recommended for the average 45-kg foal.
- Foals older than 12 hours of age: IV equine plasma
  - Administer United States Department of Agriculture–licensed products or plasma obtained from a local donor.
  - Administer slowly through a whole-blood filter set.

CHRONIC TREATMENT

- FPT with sepsis: See "Neonatal Sepsis" in this section for specific treatment recommendations.
- FPT without illness: Broad-spectrum oral or intramuscular antibiotics may be used prophylactically.

POSSIBLE COMPLICATIONS

- Transfusion reaction to plasma: Slow rate or stop transfusion; start at slower rate; or switch to another plasma donor if the patient is still reacting
- Focal infection
- Sepsis

RECOMMENDED MONITORING

- Recheck IgG after administering treatment to ensure sufficient concentration achieved. This can be done immediately after transfusion.
- Check septic foals IgG approximately weekly. Catabolism and distribution of immunoglobulins may differ from those of nonseptic foals.

PROGNOSIS AND OUTCOME

- FPT without illness: Excellent prognosis with treatment
- FPT with illness: Varied depending on the specific illness

PEARLS & CONSIDERATIONS

COMMENTS

- The appearance of colostrum is not reliably a good indicator of quality or IgG concentration.
- Colostrometers are available for measuring IgG (good-quality colostrum contains >3000 mg/dL IgG).
- Consumption of ingested IgG in sick foals may result in inadequate circulating concentrations.
- Immunoglobulins in plasma or serum are poorly absorbed when given orally.

CLIENT EDUCATION

The cost of testing for FPT is minimal compared with treating an infected foal with FPT.

ElibeVet.com

Failure to Cycle

BASIC INFORMATION

DEFINITION

Failure to show estrous behavior when expected during the breeding season

SYNONYMS

- Noncycling mare
- Anestrus

EPIDEMIOLOGY

SPECIES, AGE, SEX Sexually mature mares

RISK FACTORS

- Iatrogenic from the use of hormones
- Long-term chronic infections, such as pyometra

GEOGRAPHY AND SEASONALITY

- From October to February (Northern Hemisphere), most mares present physiologic anestrus.
- Mares that foal between January and early March under the natural photoperiod (Northern Hemisphere) are more predisposed to lactational anestrus, especially if they are in poor body condition.

ASSOCIATED CONDITIONS AND DISORDERS Poor body condition, negative energy balance, endometritis, photoperiod, pregnancy loss, pyometra

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Lack of ovarian activity
- Prolonged luteal activity
- Behavioral
- Iatrogenic

HISTORY, CHIEF COMPLAINT

- Absence of estrous behavior when expected during the breeding season
- Absence of follicular development during the breeding season

PHYSICAL EXAM FINDINGS Good/poor body condition, ± vulvar discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- Lack of ovarian activity
  - Seasonality (winter anestrus): Decreased gonadotropin-releasing hormone (GnRH) secretion from increased melatonin secretion during darkness
  - Lactational anestrus: In mares that foal from January to March under the natural photoperiod and/or that are in poor body condition, the condition is likely related to the suppressive effect of the photoperiod on GnRH secretion and/or negative energy balance
  - Gonadal dysgenesis (63,XO; 65,XXX, 64,XY)
  - Ovarian tumors (eg, granulosa theca cell tumor [GTCT]): Production of inhibin suppresses follicular activity through follicle-stimulating hormone suppression
  - Anabolic steroid treatment: Suppresses pituitary gonadotropin secretion
- Prolonged luteal activity
  - Persistent corpus luteum (CL): Can remain functional for up to 60 to 90 days if untreated
    - Pyometra: Failure to release prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) because of extensive damage to the endometrium
    - Insensitivity to released $PGF_{2\alpha}$: Diestrus ovulation after the tenth day postovulation
    - Pseudopregnancy: Embryonic death after the first luteal response to pregnancy (typically days 14 to 15 days postovulation)
  - Pregnancy: Persistent progesterone production by the CL after maternal recognition of pregnancy or progestogens from the fetoplacental unit
- Behavioral
  - Silent estrus: Absence of estrous behavior in spite of normal cyclicity
- Iatrogenic
  - Progestins: Suppress estrous behavior by inhibition at the level of the brain
  - Oxytocin treatment for estrus suppression: Prolongs luteal activity

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See Etiology above

INITIAL DATABASE

- Teasing: No signs of estrous behavior
- Transrectal palpation and ultrasound:
  - Follicular activity, CL, no uterine edema, tight cervix: Prolonged luteal function
  - Small inactive ovaries, no uterine edema, no CL, relaxed cervix: Lack of ovarian activity
  - Asymmetric ovaries, no uterine edema, cervix relaxed: GTCT
  - Follicular activity, uterine edema, relaxed cervix: Silent estrus
  - Uterine contents
    - Conceptus: Pregnancy
    - Intrauterine fluid: Pyometra or endometritis

ADVANCED OR CONFIRMATORY TESTING

- Inhibin, testosterone, and progesterone serum concentrations for GTCT
  - Inhibin >0.7 ng/mL, testosterone >50 to 100 pg/mL, and progesterone <1 ng/mL in a nonpregnant mare are suggestive of GTCT
- Uterine culture and cytology for pyometra/endometritis
- Karyotyping for gonadal dysgenesis
- Progesterone test for detection of an active corpus luteum

TREATMENT

THERAPEUTIC GOALS

- Treat the underlying cause
- Induce ovarian activity
- Eliminate source of progesterone
- Induce estrous behavior

ACUTE GENERAL TREATMENT

- Induction of ovarian activity
  - Artificial lighting for advancing first ovulation of the year
    - 14.5 to 16 hours of light daily added after sunset, starting in December, with an intensity of 10 lux or 1 foot-candle.
    - Transition may last 40 to 60 days. Traditionally, it was advised to keep mares under lights until late spring, but it has been shown that mares resume cyclicity with only 35 days of light starting at winter solstice.
  - GnRH for induction of ovulation in anestrus mares
    - GnRH
      - Hourly infusion for 28 days (100 ng/kg SC via an osmotic minipump) induced ovulation and fertile estrus in 50% of mares. Mares in shallow seasonal anestrus were more likely to respond to GnRH infusion.
      - Administration of GnRH 167 µg q8h for 7 or 7.5 days induced normal follicular growth and luteinization in anestrous mares.
    - GnRH analogs (Cystorelin, Merial)
      - 10 to 40 µg, IM or SC, q12h for 3 to 4 weeks has been associated with ovulation rates of 26% in deep anestrus and 45% in transitional mares. The resulting pregnancies may be jeopardized because of the potential for dysfunctional primary CL.
      - The subcutaneous GnRH analogue implant (Ovuplant Peptech, Sydney, Australia)

ElibeVet.com

designed to release 100 µg/day administered to transitional mares for 28 days resulted in 60% of mares ovulating 4 to 30 days after implant treatment.
  - Dopamine antagonists for lactational anestrus
    - Sulpiride (200 mg IM q12h) or domperidone (440 mg PO q24h) and 16 hours of daylight previous to starting the treatment. Treatment is unlikely to be effective if the mare has not presented estrous by 18 days.
  - No treatment for gonadal dysgenesis
  - Unilateral ovariectomy for GTCT
  - Discontinuation of treatment for exogenous anabolic steroids
- Elimination of source of progesterone
  - Persistent CL
    - Dinoprost (5–10 mg IM), or cloprostenol (100–250 µg IM). Return to estrus is expected in 3 to 5 days (range, 2–12 days). Cloprostenol is not labeled for use in horses.
    - Pyometra: Several uterine lavages with saline or lactated Ringer's solution may be necessary to eliminate the uterine contents. Oxytocin and $PGF_{2\alpha}$ can be used to induce myometrial contractions.
  - Termination of pregnancy: Method selected for termination of pregnancy depends on the stage of pregnancy
    - 5 to 33 days postovulation:
      - Dinoprost (5–10 mg IM) or cloprostenol (100–250 µg IM; not labeled for horses).
      - Before day 11 to 15, a single injection is generally effective. More injections may be needed later. Estrous behavior appears on average 3 to 5 days (range, 2–12 days) after treatment.
      - Intrauterine infusions of 100 mL saline or lavage with 1 to 3 L saline
      - Manual crushing of the vesicle (days 16–25)
      - Transvaginal ultrasound guided aspiration of fetal fluids (>20 days)
    - 34 to 120 days postovulation:
      - $PGF_{2\alpha}$ q6–24h for 3 to 5 days until pregnancy loss
      - Manual invasion of the cervix
      - Rupture of the chorioallantois
      - Manual extraction of the fetus and membranes
      - Transvaginal ultrasound guided aspiration of allantoic fluid (days 40–65)
    - ≥120 days postovulation:
      - Multiple injections of $PGF_{2\alpha}$
      - Manual disruption of the fetal membranes and removal of the fetus after cervical dilatation with 17β-estradiol (6–10 mg IM 24 hours before induction of abortion) or PGE_1/misoprostol (200 µg, intracervical, once)
      - Oxytocin 10 to 20 IU IM or IV in 5-IU increments q15–20 min
      - Transabdominal ultrasound-guided fetal-cardiac puncture and injection of potassium chloride or potassium penicillin
      - Transcervical intra-allantoic injection of dexamethasone induced abortion within 3 days in treated mares
- Silent estrus
  - Frequent transrectal palpation and ultrasound examination to monitor estrous cycles.
  - Attempt change in estrus detection methods.
  - The use of estradiol has been suggested for mares not allowing the stallion to mount, but studies on effect on fertility are not available. It is advised to use as last resource.
    - 0.5 to 10 mg 17β-estradiol IM 6 hours before breeding
    - 10 mg of estradiol cipionate IM 2 to 3 days before breeding
    - Cipionate is available through compounding pharmacies in the United States and needs to be administered 2 to 3 days in advance; estrous behavior starts in 2 to 3 days and persists for 3 to 4 days after injection
- Discontinuation of treatment for exogenous progestins

POSSIBLE COMPLICATIONS

- Endometritis from invasion of the uterus during pregnancy termination
- Dystocia, retained fetal membranes, trauma to the genital tract with termination of late pregnancy
- Treatment with $PGF_{2\alpha}$ or its analogues can produce undesirable side effects, including sweating, trembling, increased heart rate, and even signs of colic. These signs present within 15 minutes of administration and resolve within 1 hour.

RECOMMENDED MONITORING

- Anestrus and transitional mares should be monitored weekly until a CL is detected, indicative of the first ovulation of the year
- Return to estrus is expected in 3 to 5 days (range, 2–12 days) after $PGF_{2\alpha}$ administration
- Perform ultrasound examinations to check for return to cyclicity of the remaining ovary starting 2 months after ovariectomy for GTCT
- Estrus occurs 4 to 5 days after withdrawal of progestogens
- Return to cyclicity may be affected for up to 6 months after cessation of anabolic steroid administration

PROGNOSIS AND OUTCOME

- Pyometra has guarded prognosis for fertility from damage to the endometrium and good prognosis for life.
- Good prognosis for return to cyclicity for prolonged diestrus, winter anestrus, lactational anestrus.
- Poor prognosis for fertility in mares with congenital disorders.
- GTCT: Good prognosis for life and fertility. Time to return to cyclicity of the contralateral ovary averages 6 months (range, 2–12 months).

PEARLS & CONSIDERATIONS

COMMENTS

- Winter anestrus is a physiologic reproductive stage in mares, although 20% of mares do not undergo anestrus.
- Prolonged luteal phase may occur in 4% to 18% of cycles; in these cases the luteal phase may be prolonged for up to 60 days.

PREVENTION

Lactational anestrus: Mares with expected foaling dates before March 15 can be placed under artificial lights at the beginning of December; adequate feed intake should be available and monitored.

False Dandelion/Flat Weed Toxicosis

BASIC INFORMATION

DEFINITION

- Stringhalt, a unique disease of horses characterized by spasmodic hyperflexion of one or both hind legs, has been associated with horses eating *Hypochaeris radicata* (cat's ear, flat weed).
- Other plants that have been associated with stringhalt include sweet peas (*Lathyrus* spp.), dandelion (*Taraxacum officinale*), and mallow (*Malva parviflora*).

SYNONYM(S)

- *H. radicata* is commonly known as cat's ear, hairy cat's ear, false dandelion, and flat weed.
- "Australian stringhalt" refers to a similar condition in horses in Australia associated with grazing the same plant.

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION All breeds may be affected, with Thoroughbreds being commonly affected and ponies rarely.

RISK FACTORS

- Overgrazed pastures with heavy infestation of false dandelion (flat weed)
- Poisoning is most common in late summer.

GEOGRAPHY AND SEASONALITY

- False dandelion is a perennial, native plant of most of North America, Australia, and New Zealand that has become a nuisance weed in some areas.
- Closely resembling the common dandelion, *H. radicata* has a rosette of basal leaves and multiple branching flower stems (Figure 1) in contrast to the single-flowered stems of the dandelion.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Stringhalt may be intermittent and vary from mild to severe, resulting in an abnormal gait and lameness.

HISTORY, CHIEF COMPLAINT Unusual movement of one or both hindlimbs

PHYSICAL EXAM FINDINGS

- Hyperflexion of one or both hock joints
- In extreme cases, the foot is drawn up sharply to the abdomen and is then slapped to the ground.
- Turning, backing, and excitement exacerbate signs.
- The horse may have a hopping gait when both hind legs are affected.
- Atrophy of the lateral thigh muscles may occur in chronic cases.
- Laryngeal hemiplegia resulting in "roaring" may occur in some affected horses

ETIOLOGY AND PATHOPHYSIOLOGY

- The specific toxin in *H. radicata* responsible for stringhalt is not known.
- The condition can be reproduced experimentally by feeding horses a mean of 9.8 kg of green plant daily for 50 days.
- The toxin affects conduction in the long nerves in the body.
- Increased electromyographic activity is reported in the long digital extensor muscle.

FIGURE 1 False dandelion, or flat weed (*Hypochaeris radicata*).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Upward fixation of the patella
- Injury to the lower pastern area or hind limb laminitis may mimic stringhalt.

INITIAL DATABASE

- Physical examination: Normal
- Hematology: Normal
- Serum biochemistry profile: Normal

ADVANCED OR CONFIRMATORY TESTING

- Electromyography of long digital extensor muscle
- Axonal degeneration of peripheral nerves histologically

TREATMENT

ACUTE GENERAL TREATMENT

- Phenytoin (15 mg/kg body weight PO for 2 weeks) may help shorten the recovery period.
- Thiamine has helped in recovery of Australian stringhalt.

CHRONIC TREATMENT

Horses with persisting signs may benefit from tenectomy of the lateral digital extensor(s).

PROGNOSIS AND OUTCOME

- There is a good prognosis with early diagnosis and removal of the plant from the horse's diet.
- Recovery may take a few weeks up to 18 months after horses are removed from the flat weed.
- Most horses recover after flat weed is removed from their diets.

PEARLS & CONSIDERATIONS

PREVENTION

Pasture management to prevent overgrazing in late summer when weeds such as *H. radicata* are abundant will prevent the occurrence of the stringhalt syndrome.

 ElibVet.com

CLIENT EDUCATION

- Owner recognition of the plant and herbicides can be useful in controlling the plant.

Fescue-Related Toxicosis

BASIC INFORMATION

DEFINITION

Toxins, such as ergovaline, produced by the tall fescue endophyte (*Neotyphodium coenophialum*; formerly *Acremonium coenophialum*), which is not externally visible on infected plants and grows symbiotically within the fescue grass (*Lolium arundinaceum*; formerly *Festuca arundinacea*)

SYNONYM(S)

- Fescue toxicosis
- Tall fescue toxicosis
- Ergopeptine alkaloid (ergovaline) toxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Except for agalactia and pregnancy abnormalities, horses are less susceptible to fescue toxicosis than are cattle.
- There are possible differences between Equid species.

GENETICS AND BREED PREDISPOSITION There have been anecdotal reports of individual differences in susceptibility, perhaps reflecting the influences of risk factors and geography

RISK FACTORS

- Generally subacute to chronic consumption of endophyte-infected fescue in pastures or hay
- Late-gestational mares (~270–300 days)
- Early-gestational mares
- Mares in the spring transitional phase before the onset of normal cyclicity
- Endophyte-infected fescue in the seed head stage
- Aberrant weather conditions (eg, flood, drought) that favor growth of endophyte-infected fescue
- High rate of application of nitrogen-containing fertilizers
- Concurrent exposure to *Claviceps purpurea* ergot in pastures, hay, grain, and especially pelletized rations incorporating "screenings" (see "Ergot-Related Toxicosis" in this section)

GEOGRAPHY AND SEASONALITY

- Upper Southeastern and lower Midwestern United States; the area of distribution is increasing in size
- Worldwide distribution in parts of South America, Europe, Africa, and Asia
- Spring when mares are cycling and being bred and when foals are being born
- Seasonal variation in toxin concentration occurs, with the riskiest time of year being late spring when the grass is in the seed head stage.

ASSOCIATED CONDITIONS AND DISORDERS Ergot, ergot poisoning, or ergotism (see "Ergot-Related Toxicosis" in this section)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Fescue toxicosis in mares
- "Summer slump": Much less common and less severe in horses than in cattle (see "Ergot-Related Toxins" in this section)
- "Fescue foot": Much less common and less severe in horses than in cattle (see "Ergot-Related Toxins" in this section)

HISTORY, CHIEF COMPLAINT

- Agalactia or dysgalactia may be observed in the absence of any other clinical signs.
- Prolonged gestation
- Retained fetal membranes
- Dystocia or premature placental separation (ie, "red bag")
- Fetal dysmaturity or overmaturity
- Abortion or stillbirth
- Prolonged transitional phase before the first ovulation or abnormal cyclicity in the spring
- Conception failure or early embryonic loss
- Impaired athletic performance in hot weather
- Laminitis
- See "Ergot-Related Toxicosis" in this section for other hyperthermic and gangrenous effects (uncommon in horses).

PHYSICAL EXAM FINDINGS

- Little or no udder development within 14 days of the due date; this may be the only clinical sign seen
- Aborted fetus or stillbirth
- Dystocia with an abnormally large or malpositioned foal
- Premature separation of the chorioallantois ("red bag" presentation)
- Thickened, edematous fetal membranes, possibly retained
- Dysmature or overmature foal unable to suckle
- Failure of passive transfer
- Multiple, anovulatory follicles; failure to ovulate in a timely fashion
- Increased sweating and heat intolerance during exercise in hot weather
- Multiple limb lameness or laminitis
- See "Ergot-Related Toxicosis" in this section for other hyperthermic and gangrenous effects (uncommon in horses).

ETIOLOGY AND PATHOPHYSIOLOGY

- Fescue toxins consist of a number of ergopeptine alkaloids, including ergovaline (the ergopeptine of highest concentration), and ergoline alkaloids, including lysergic acid.
- In mares, these toxins cause the following:
  - Decreased prolactin secretion by the anterior pituitary via D2 dopamine receptor agonism
  - Altered uterofetoplacental progestagen metabolism
  - Speculated direct or indirect inhibition of corticotropes in the fetal anterior pituitary
- See "Ergot-Related Toxicosis" in this section for hyperthermic and gangrenous effects.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Reproductive signs
  - Reproductive ergotism
  - Idiopathic agalactia, prolonged gestation, or dystocia not associated with ergot alkaloid exposure

ElibeVet.com

- Delayed fetal development for gestational age
- Infectious causes of abortion or stillbirth, placental abnormalities, or fetal septicemia
- Foal dysmaturity unrelated to ergot alkaloid exposure

- "Summer slump" (horses require higher dosages of ergovaline than cattle)
  - Hyperthermic ergotism
  - Other causes of altered athletic performance
- "Fescue foot" (horses require higher dosages of ergovaline than cattle; laminitis is most likely)
  - Gangrenous ergotism
  - Other causes of laminitis

INITIAL DATABASE

- Confirmation of prolonged gestation
- Agalactia or dysgalactia; failure to "wax"; no increase in calcium in mammary secretions before foaling; little or no milk production
- Failure of passive transfer
- Hemograms or biochemical profiles: Vary depending on the complicating secondary conditions

ADVANCED OR CONFIRMATORY TESTING

- Endocrine analyses
  - Hypoprolactinemia, especially in late-gestational mares
  - Decreased maternal progestagen concentrations in late-gestational mares (use cross-reactive progesterone radioimmunoassay to detect 5α-pregnanes)
  - Decreased maternal relaxin; variable alterations in circulating maternal estrogens in late-gestational mares
- Ultrasound imaging results
  - Placental thickening
  - Anovulatory ovarian follicles when mares should be cycling
  - Conception failure or embryonic loss
- Chemical analyses
  - Detection of ergopeptine alkaloids, especially ergovaline, in pasture or hay using a variety of analytical methods. Total dietary concentrations of ergopeptine alkaloids as low as 100 ppb have been associated with clinical cases of fescue toxicosis in late gestational mares, with some reports of concenratins as low as 50 ppb being associaed with agalactia.
  - ELISA analyses (Agrinostics, Inc., Watkinsville, GA) for ergot alkaloids (greater affinity for ergoline alkaloids than ergopeptine alkaloids) in forages or in urine samples from exposed animals. Ergot alkaloids are rapidly excreted after removal from the source.
- Pathology
  - Gross findings in foals consistent with prolonged gestation (oversized foal, eruption of the foal's incisors, increased eponychium on the foal's hooves, angular limb deformities), dystocia (limb trauma, meconium staining, possible ruptured bladder), agalactia or failure of passive transfer (absence of colostrum or milk in the gastrointestinal tract, joint or umbilical cord infections)
  - Histopathologic finding of distended thyroid follicles lined by flat, cuboidal epithelial cells
  - Grossly thickened or edematous, possibly retained or prematurely separated fetal membranes
  - Edematous fetal membranes
  - Gross findings in mares consistent with agalactia and dystocia (trauma to the reproductive and urinary tracts, retained fetal membranes, possible laminitis)
  - Histopathologic findings in mares consistent with sepsis and laminitis

TREATMENT

THERAPEUTIC GOALS

- Prevent further exposure to endophyte-infected fescue.
- Counteract the mechanisms of action of ergopeptine alkaloids.
- Provide supportive care.
- Prevent complications.

ACUTE GENERAL TREATMENT

- Removal of source of toxins
- For agalactia, prolonged gestation, and cycling abnormalities: Antidotal treatment with domperidone, a D2 dopamine receptor antagonist (Equidone; Equi-tox, Inc., Central, SC) at 1.1 mg/kg body weight q24h PO
- Need to adjust the dosage or frequency of administration of domperidone if dripping of milk or leaking of colostrum occurs
- Potential extrapyramidal neurologic side effects with other D2 dopamine antagonists, such as fluphenazine and perphenazine
- See "Ergot-Related Toxins" in this section for other hyperthermic and gangrenous effects.

CHRONIC TREATMENT

Depends on complications associated with fescue toxicosis

POSSIBLE COMPLICATIONS

- In mares, trauma or rupture of the reproductive tract or its vasculature; bladder or bowel displacement; subsequent laminitis
- Sepsis in mares or foals
- Ruptured urinary bladder in foals secondary to dystocia
- See "Ergot-Related Toxins" in this section for possible hyperthermic or gangrenous complications.

RECOMMENDED MONITORING

- Depends on the observed clinical signs and complications
- Monitor udder development in pregnant mares; attend and assist with foaling.

PROGNOSIS AND OUTCOME

Depend on the duration and level of toxin exposure, as well as concurrent risk factors and complications; possible death of the mare, foal, or both

PEARLS & CONSIDERATIONS

COMMENTS

- Agalactia is the most sensitive indicator of ergopeptine alkaloid exposure in horses; it may be observed in the absence of any other signs.
- With ergopeptine alkaloid toxicosis, parturition cannot be predicted by "waxing" or increased calcium concentrations in mammary secretions.
- Consider domperidone treatment in cases of prolonged pregnancies that are 345 days or longer with little or no udder development in regions where ergopeptine alkaloid exposure is common.
- Dystocia in late-gestational, agalactic mares is highly suggestive of exposure to ergopeptine alkaloids.

PREVENTION

- Maintain careful breeding records and confirmation of pregnancy in regions where ergopeptine alkaloid exposure is common.
- Withdraw pregnant mares from endophyte-infected fescue pasture or hay at least 30 days before the foaling due date (60–90 days before foaling is preferable, if possible).
- Carefully inspect animals, especially udder development in late-gestational mares.
- Provide oral treatment with domperidone 1.1 mg/kg q24h 10 to 14 days before the foaling due date, especially if the mare has agalactia or withdrawal from fescue is not possible.
- Attend and assist at the time of foaling.
- Keep pastures mowed to prevent seed head stage of tall fescue.

ElibVet.com

- Inspect pastures and hay for fescue and ergot.
- Overseed fescue pastures with legumes.
- Replace toxic endophyte-infected fescue with tall fescue infected with a genetically modified, "nontoxic" endophyte.

CLIENT EDUCATION

Increased awareness of risks to horses, especially late-gestational mares, associated with exposure to fescue-related endophytic toxins

Fibrotic Myopathy

BASIC INFORMATION

DEFINITION

A mechanical lameness characterized by an abrupt shortening of the forward swing of one or both pelvic limbs with a characteristic "slapping" of the affected hoof onto the ground

SYNONYM(S)

Ossifying myopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Horses: Average age of 8.7 years in one study and 11.8 years in another study
- Mares are overrepresented in one study

GENETICS AND BREED PREDISPOSITION Quarter Horse–related breeds are predisposed because of Western performance activities.

RISK FACTORS

- Overstretching trauma to the thigh musculature associated with reining maneuvers such as sliding stops
- Abscesses, injection reactions, or wounds in the semitendinosus muscle

ASSOCIATED CONDITIONS AND DISORDERS An identical gait can be seen with hind limb denervating disease such as equine motor neuron disease and peripheral neuropathy and with myopathies such as polysaccharide storage myopathy.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most often affects the distal semitendinosus muscle with occasional involvement of the gracilis, biceps femoris, and semimembranosus muscles.
- Unilateral signs are most often caused by trauma, although early peripheral neuropathy is still possible.
- If bilateral, consider an underlying denervation or myopathy.

HISTORY, CHIEF COMPLAINT Prior trauma resulting in increased muscle tension (eg, sliding stops, slipping, catching a hind leg in a halter) or localized muscle damage caused by wounds or injections

PHYSICAL EXAM FINDINGS

- The abnormal gait is characteristic. The gait abnormality is most obvious at a walk, becomes less noticeable to absent at a trot, and is rarely seen at a canter.
- Palpable abnormalities such as fibrous to bony thickening may be present in the affected muscle, most often the distal semitendinosus muscle.

ETIOLOGY AND PATHOPHYSIOLOGY Reduced muscle elasticity from fibrosis secondary to physical trauma or chronic denervation or caused by myopathy, results in abnormal limb biomechanics.

DIAGNOSIS

INITIAL DATABASE

- Observation of gait
- Palpation of the hind limb musculature

TREATMENT

THERAPEUTIC GOAL(S)

Increase muscle elasticity to improve limb biomechanics

ACUTE GENERAL TREATMENT

Antiinflammatory (eg, nonsteroidal antiinflammatory drug) therapy if treated immediately after predisposing injury

CHRONIC TREATMENT

- Horses with traumatic injury resulting in fibrosis often respond to surgery (eg, semitendinosus myotenectomy, myotomy, or tenotomy).
- Cases caused by neuropathy or myopathy are less likely to respond to surgery.
- Horses with polysaccharide storage myopathy can be treated with diet and exercise (see "Polysaccharide Storage Myopathy" in this section).
- Horses with neuropathy caused by equine motor neuron disease can be treated with high doses (≥10,000 IU) of vitamin E.

POSSIBLE COMPLICATIONS

Wound dehiscence or infection after surgery

RECOMMENDED MONITORING

Regular examination

PROGNOSIS AND OUTCOME

- More than 90% of horses with only semitendinosus muscle damage caused by trauma improve to some degree after surgery, but residual gait deficits are common.
- Horses with traumatic damage to multiple muscles may not respond as well to surgery.
- Horses with polysaccharide storage myopathy improve with diet change.
- Horses with neuropathy are unlikely to respond to any therapy, and the disease process may progress.

PEARLS & CONSIDERATIONS

COMMENTS

Fibrotic myopathy is not a diagnosis; rather, it is a clinical sign of a mechanical lameness that may have a variety of causes.

ElibeVet.com

PREVENTION

Minimize trauma to the caudal thigh muscles.

CLIENT EDUCATION

Fibrotic myopathy does not appear to be painful. Some degree of gait deficit may persist despite therapy, but horses can still be functional.

Flail Chest

BASIC INFORMATION

DEFINITION

Three or more consecutive fractured ribs, allowing a section of the rib cage to float freely

SYNONYM(S)

Multiple rib fractures

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in adult horses because of the magnitude of force required to fracture multiple ribs
- Foals may develop a flail segment secondary to rib fractures sustained in parturition.
- Flail chest is rare in foals; rib fractures are usually singular (one per rib).

ASSOCIATED CONDITIONS AND DISORDERS

- Pneumothorax
- Pneumomediastinum
- Hemothorax
- Pulmonary contusions
- Pleuritis
- Cardiac contusions

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History
  - Trauma (eg, hit by car)
  - Dystocia
  - Thoracic wounds
- Chief complaint: Increased respiratory rate and effort

PHYSICAL EXAM FINDINGS

- Paradoxical movement of the flail segment
  - In with inspiration
  - Out with expiration
- Tachypnea, dyspnea
- Tachycardia, arrhythmias
- Circulatory compromise (pale mucous membranes, cool extremities, poor pulse quality)
- Crepitus or depression at the site of the fractures
- Wounds or other injuries related to the inciting cause

ETIOLOGY AND PATHOPHYSIOLOGY

- Fractured ribs are caused by trauma (external blunt force, penetrating injuries) or compression because of abnormal presentation during parturition.
- Respiratory dysfunction is likely caused by a pulmonary contusion, pneumothorax, or pleural effusion secondary to the initiating trauma rather than the flail segment itself.
- Pulmonary trauma results in atelectasis, edema, and hypoventilation, which results in hypoxemia through decreased diffusion of oxygen and ventilation-perfusion mismatching.
- Pain amplifies hypoxia through decreased tidal volume and hypoventilation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Rib fractures without a flail chest

INITIAL DATABASE

- Physical examination, rebreathing exam, thoracic ultrasonography, arterial blood gas, serum lactate
- Complete blood count, serum chemistry indicated for evaluation of concurrent injury or infection

ADVANCED OR CONFIRMATORY TESTING

- Electrocardiography (ECG) for cardiac arrhythmias caused by cardiac contusion
- Thoracic radiographs are insensitive in identifying fractures in horses.

TREATMENT

THERAPEUTIC GOAL(S)

- Relieve pain
- Improve oxygenation
- Treat concurrent traumatic injuries

ACUTE GENERAL TREATMENT

- Analgesia
  - Nonsteroidal antiinflammatory drugs
    - Flunixin meglumine: 1.1 mg/kg IV q12h
    - Phenylbutazone: 2.2 mg/kg IV q12h
  - Opioids (may cause ileus)
    - Morphine: 0.05 to 0.1 mg/kg IV q12–24h up to q6h if IM
    - Combine with detomidine (5 µg/kg) or acepromazine (0.02–0.05 mg/kg) to reduce excitement
    - Butorphanol (13 µg/kg/h continuous rate infusion)
    - Variable pain relief
    - Fentanyl patch: Two to three 100-µg/h patches per 1000 lb
    - Absorption not consistent
  - Local anesthetic infusion: Caudal to rib; dorsal to fractures
    - Bupivacaine
    - Mepivacaine
- Respiratory and circulatory support
  - Nasal oxygen (5–15 L/min): Provides an FiO_2 of up to 40%
  - Mechanical ventilation: Indicated if PaO_2 remains below 60 mm Hg or SpO_2 remains below 90% despite oxygen therapy
  - Thoracocentesis for removal of pneumothorax or hemothorax
    - Required only if inhibiting oxygenation
    - Drainage of hemothorax may induce acute hemorrhage caused by clot disruption
  - Fluid therapy for cardiovascular shock (crystalloids, colloids, hypertonic saline)
- Wound management
  - Debridement, suturing, packing
  - Seal open chest wounds with stent bandages or plastic occlusive bandages or plastic wrap
  - Antibiotics
  - Tetanus prophylaxis

ElibVet.com

- Fracture stabilization in foals
  - Required only for fractures that risk cardiac perforation
  - Plate fixation ± cerclage wires

POSSIBLE COMPLICATIONS

- Concurrent head injury may necessitate ventilation because of central respiratory depression.

RECOMMENDED MONITORING

- Monitor for respiratory fatigue as an indication for mechanical ventilation.
  - Tachypnea or bradypnea
  - PaO_2 below 60 mm Hg on nasal oxygen
  - $PaCO_2$ above 60 mm Hg on nasal oxygen
  - PaO_2/FiO_2 ratio below 200
- Monitor arrhythmias with continuous ECG

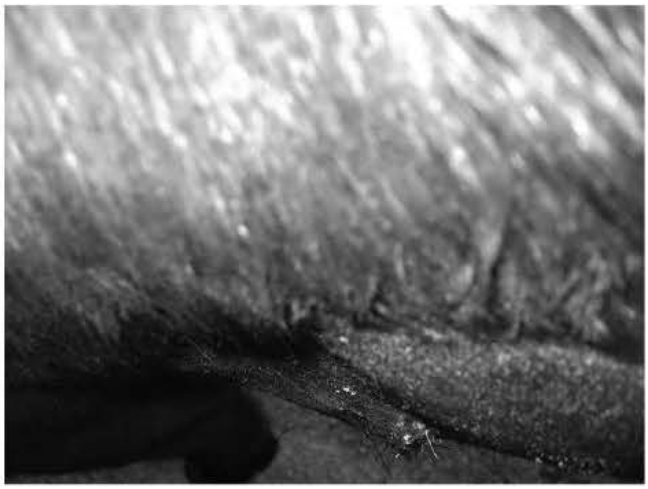

FIGURE 1 Flail chest. In this image of the left thorax, taken from above, note the depression where the flail segment lies.

PROGNOSIS AND OUTCOME

- Adult horses have a poor prognosis. The majority of adult horses succumb to the extensive trauma that caused the flail chest.
- Foals have a good prognosis with therapy. The extent of concurrent injuries may decrease the prognosis.

PEARLS & CONSIDERATIONS

Thoracic bandages may limit chest excursion and increase hypoxemia.

AUTHOR: **AMELIA MUNSTERMAN**

EDITORS: **REED HANSON** and **AMELIA MUNSTERMANN**

Fractures: Mandible and Maxilla

BASIC INFORMATION

DEFINITION

- Mandibular fractures are the most common type of fracture of the equine head. The incisive plate (rostral portion of the mandible), interdental space, horizontal ramus (caudal), and vertical ramus or the mandibular condyle (within the temporomandibular joint) can all be affected. Anatomical considerations when assessing these fractures should include the position of the parotid duct (emptying into the mouth adjacent to the fourth premolar (third cheek tooth, X08), the facial vein and artery, and the mental nerve foramen.
- Maxillary fractures are less common than mandibular fractures. Involvement of the premaxilla (incisive), frontal, nasal, and maxillary bones are most common. Paranasal sinus involvement may also complicate case management.

CLINICAL PRESENTATION

CLINICAL SIGNS

- Anorexia, difficulty prehending feed, quidding, ptyalism, halitosis, swelling, heat, pain
- In the case of maxillary fractures, there may only be a puncture wound or depression in the contour of the skull.

PHYSICAL EXAM FINDINGS

- Visual examination of incisor occlusion: In some fractures, disruption of the integrity of the mandible results in offset incisors (laterally), tipped lower incisors (relative to the maxilla), or missing teeth.
- Complete oral examination (sedation, full-mouth speculum, light source, and mirror): In some cases, because of the presence of significant pain, this can only be achieved using general anesthesia. Fractures are frequently open and significantly contaminated. It is important that injuries are not exacerbated during oral examination.

DIAGNOSIS

INITIAL DATABASE

Imaging Modalities

- Radiography: Adequately exposed radiographs should include at a minimum the lateromedial, dorsoventral, and two oblique projections. An offset dorsoventral projection is sometimes useful, especially in rostral fractures. This is achieved by moving the mandible across the midline immediately before exposure. This places the rostral portion of the horizontal ramus and incisor teeth in the middle of the radiograph to minimize the overlap by other bony anatomy. An intraoral ventrodorsal projection may also be of use.
- Computed tomography (CT): In complex fractures in which significant dental involvement is predicted by clinical and radiographic examination, CT examination before surgical intervention may augment surgical planning.

ElibeVet.com

- Ultrasonography: Marginal and body fractures of the mandibular ramus as well as those of the maxilla can be imaged using ultrasonography. This is particularly useful where deep musculature may have splinted the fracture, leading to minimal swelling despite clinical and historical evidence of pain and anorexia. A 10-MHz linear probe is used by the author.

TREATMENT

ACUTE GENERAL TREATMENT

Fracture stabilization:

- Unilateral, nondisplaced fractures may be managed conservatively.
- Surgical intervention is required when the fracture fragments are displaced and there is instability. Techniques used include intraoral wiring, wiring combined with intramedullary pins or lag screws, and intraoral U-bar or polymethylmethacrylate (PMMA) splints. Type I or II external fixator, lag screw, or orthopedic plate fixations may also be used.
- Involved teeth should not be automatically removed. They may provide essential stability to the resultant fracture fixation. Additionally (especially with incisor teeth), inclusion in a repair may result in dental retention. Every attempt should be made to *not* place an implant through the structure of a tooth (eg, a bone screw) during the fixation process. The hypsodont nature of the equine dentition is such that the process of continued eruption will be compromised, and future pathology is likely to occur.
- Maxillary fractures involving the paranasal sinuses: In some cases, minimally invasive elevation of fractured fragments may confer normality to the contour of the skull. In more extensive cases, repair can be achieved using cuttable bone plates.

POSSIBLE COMPLICATIONS

- Implant infection and loosening
- Sequestrum formation
- Dental loss and opposing tooth overgrowth

RECOMMENDED MONITORING

Recheck in 3 to 6 months. Ensure dental viability and eruption. Implant removal should be done if infected.

PROGNOSIS AND OUTCOME

Good, assuming stability has been conferred to the fractures

AUTHOR & EDITOR: **JAMES L. CARMALT**

Fractures: Metacarpal/Metatarsal Condyles

BASIC INFORMATION

DEFINITION

Fractures of the distal condyles of the third metacarpus/metatarsus (MC/MT-III). Fractures originate at the distal articular surface and propagate proximally in the sagittal plane.

SYNONYMS

These fractures are simply referred to as *condylar fractures* or longitudinal fractures of the third metacarpal/metatarsal condyles.

EPIDEMIOLOGY

SPECIES, AGE, SEX Condylar fractures occur predominantly in young racehorses.

GENETICS AND BREED PREDISPOSITION Condylar fractures are most commonly seen in Thoroughbred racehorses. They also occur in Standardbred racehorses; racing Arabians; and occasionally polo ponies, steeplechasers, and eventers.

RISK FACTORS Racing plates with long toe grabs and harder dirt surfaces have been proposed as risk factors based on results of epidemiologic studies.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Fractures may involve either the lateral or medial condyle.
  - Lateral condylar fractures are either incomplete or complete (exit the ipsilateral cortex). The majority of complete fractures are displaced.
  - Medial condylar fractures rarely exit the ipsilateral cortex and instead have a propensity to propagate proximally into the diaphysis or proximal metaphysis. They do so in either a spiral configuration or in a sagittal plane that changes abruptly in mid-diaphysis to take on a Y-shaped configuration. This type (Y configuration) is at risk of catastrophic failure.

HISTORY, CHIEF COMPLAINT

- Most horses present with an acute onset of moderate to severe lameness during or shortly after a race or a workout. In some cases, horses finish the race well with no "bad step" perceived by the rider. With some incomplete fractures, lameness is not noted until the following day.
- Some horses have a history of pain ("soreness") and inflammation (heat and effusion) in the associated fetlock joint at some point in the days or weeks leading up to fracture.

PHYSICAL EXAM FINDINGS

- Horses with condylar fractures generally bear full weight on the limb and exhibit mild to severe lameness at the walk. Lameness in many cases improves rapidly so that by 24 to 48 hours, there may be minimal lameness at the walk (most evident on turns).
- Fetlock effusion is invariably present and is typically marked. Horses with complete lateral condylar fractures often have noticeable soft tissue swelling along the lateral aspect of the distal metaphysis. Pain on lower limb (fetlock) flexion is typically moderate to severe in the acute stage.

ETIOLOGY AND PATHOPHYSIOLOGY

- Condylar fractures are fatigue fractures resulting from accumulated high-speed cyclic strains.
- Subchondral microdamage develops where stress is concentrated along the condylar groove (junction between the condyle and sagittal ridge).
- Overt fracture occurs acutely and begins in the distal palmar/plantar aspect of the articular surface and propagates proximally between or along the sagitally oriented "plates" of trabecular bone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other intraarticular fractures of the fetlock joint

INITIAL DATABASE

- Physical examination in the vast majority of cases reliably identifies the fetlock joint as the site of injury.

ElibeVet.com

FIGURE 1 Dorsopalmar radiograph of the metacarpophalangeal joint of a horse with an incomplete lateral condylar fracture.

FIGURE 3 Dorsopalmar radiograph of the metacarpus of a horse with a medial condylar fracture.

FIGURE 2 Dorsopalmar radiograph of the metacarpophalangeal joint of a horse with a complete, displaced, lateral condyle fracture.

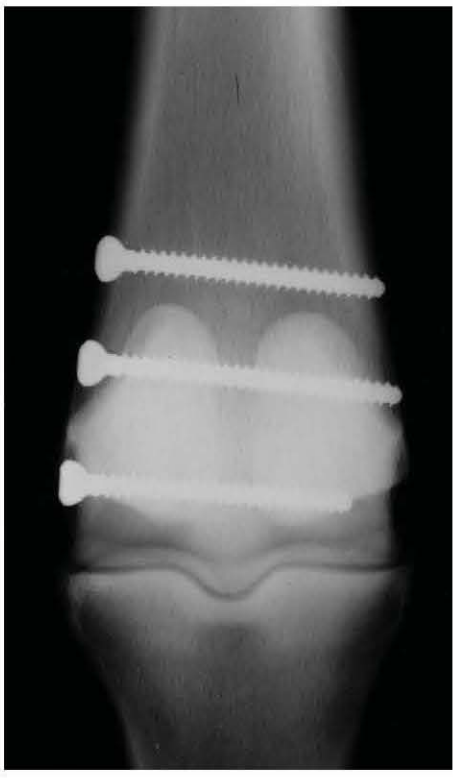

FIGURE 4 Postoperative dorsopalmar radiograph of the metacarpophalangeal joint of a horse following screw fixation of a lateral condylar fracture.

- Radiographs confirm the diagnosis.
- Radiographs should include the four standard views as well as a flexed dorsopalmar/plantar projection to aid in detection of articular comminution (Figures 1 to 3).

ADVANCED OR CONFIRMATORY TESTING

- In rare cases (typically short, chronic, incomplete fractures) diagnostic analgesia (low four-point block or IA anesthesia) is helpful to confirm the fetlock as the site of pain.
- Nuclear scintigraphy may prove useful in these same cases.

ElibVet.com

TREATMENT

THERAPEUTIC GOALS

- Promote fracture healing and minimize degenerative changes in the affected joint.
- With medial condylar fractures, avoiding catastrophic failure is also paramount.

ACUTE GENERAL TREATMENT

- Stall confinement, bandaging, and systemic antiinflammatory drugs.
- Rigid, full-limb external coaptation is indicated after diagnosis of any propagating medial condylar fracture.

CHRONIC TREATMENT

- Surgical repair using cortical screws in a lag fashion (Figure 4).
- Screws in lateral condylar fractures are inserted through individual stab incisions.
- Complete lateral condylar fractures are reduced under arthroscopic control.
- All medial condylar fractures with a mid-diaphyseal Y configuration or those with fracture lines that do not spiral and end abruptly in the mid-diaphysis should be repaired with a combination of lag screws and application of a dynamic compression plate or locking compression plate.
- Medial condylar fractures with a radiographically confirmed spiral configuration may be repaired with lag screws alone, but many surgeons opt for plate stabilization as added security.
- Nonsurgical management is an option for selected incomplete fractures.

POSSIBLE COMPLICATIONS

- The most devastating complication is a catastrophic failure in cases of medial condylar fracture.
- Insufficient fracture reduction and failure to accurately realign the articular surface in repairing displaced fractures invariably results in debilitating arthritis.

RECOMMENDED MONITORING

Follow-up radiographs are taken to monitor fracture healing.

PROGNOSIS AND OUTCOME

- The prognosis for nondisplaced condylar fractures is generally good to very good (70%–90% return to athletic soundness).
- The prognosis for displaced condylar fractures in the forelimbs of Thoroughbred racehorses is guarded to fair (<50% return to athletic soundness).
- The presence of degenerative joint disease, concurrent proximal sesamoid fracture, or other significant IA pathology imparts a lower prognosis.
- Concurrent axial fracture of a proximal sesamoid bone is almost always associated with a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Most horses can resume training 4 to 5 months after surgical repair.
- The author does not routinely remove screws before training commences, although some surgeons do.
- Plates must be removed from cases of medial condylar fracture if athletic use is anticipated.

PREVENTION

- Carefully monitor for early detection of pathology in and around the fetlock.
- Avoid shoes with long toe grabs.
- Have the horse race and train on grass or synthetic surfaces.

Fractures: Middle Phalanx

BASIC INFORMATION

DEFINITION

Fractures of the middle phalanx may be classified as osteochondral chip fractures, uniaxial or biaxial fracture of the medial or lateral eminence of the middle phalanx, axial fractures, or comminuted middle phalanx fractures

SYNONYM(S)

P2 fracture

EPIDEMIOLOGY

SPECIES, AGE, SEX Fractures of the middle phalanx occur in horses of all ages, including foals. However, fractures at this location happen most commonly in the hindlimbs of middle-aged (4–10 years) Western performance horses and polo horses.

GENETICS AND BREED PREDISPOSITION Quarter Horses are the most commonly represented breed, although all breeds may be affected.

RISK FACTORS Athletic activities that involve abrupt stops or turns such as those that occur during cutting, roping, barrel racing, pole bending, and polo

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Acute moderate to severe lameness that may occur during athletic activity or in paddock turnout

PHYSICAL EXAM FINDINGS

- Osteochondral chip fractures
  - Mild to moderate lameness
  - May be an incidental finding
  - Respond to diagnostic anesthesia of the proximal interphalangeal joint
- Uniaxial palmar or plantar eminence fractures
  - Moderate to severe lameness
  - Pain on manipulation
  - Instability or crepitus (usually not present)
- Biaxial palmar or plantar eminence and comminuted fractures
  - Severe non–weight-bearing lameness
  - Pain on manipulation
  - Joint instability and crepitus

ETIOLOGY AND PATHOPHYSIOLOGY

- The hind limbs are more likely to sustain a fracture than the forelimbs.
- Comminuted fractures are the most common fracture type.
- Comminuted fractures result from the complex forces that occur when the horse pivots on the hind limb with the foot fixed relative to the digit.
- Eminence fractures may result from avulsion of the bony insertion of the superficial digital flexor tendon.

ElibEVet.com

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Fracture of the proximal or distal phalanx
- Luxation of the proximal interphalangeal joint
- Sole abscess

INITIAL DATABASE

- Localization of the lameness with physical examination and manipulation of the distal limb
- Complete radiographic evaluation of the middle phalanx
- Complete blood count and serum biochemistry panel

ADVANCED OR CONFIRMATORY TESTING

Computed tomography or magnetic resonance imaging may help define fracture configuration and aid in fracture repair planning.

TREATMENT

THERAPEUTIC GOALS

- Restoration of limb function
- Restoration of the normal pastern joint angle
- Limit development of osteoarthritis in the distal interphalangeal joint

ACUTE GENERAL TREATMENT

First aid stabilization:

- With the limb held off the ground, a light padded bandage is applied from the proximal metacarpus/metatarsus to just distal to the coronary band. A rigid splint (polyvinyl chloride) is taped to the dorsum (forelimb) or plantar surface (hindlimb) of the bandage to maintain axial alignment of the dorsal cortices of the metacarpus/metatarsus and phalanges. The bandage and foot are then encased in fiberglass cast material to temporarily stabilize the fracture for transport.
- Osteochondral chip fractures are treated by removal of the osteochondral fragments with arthroscopy or an open technique.
- All other fracture types are best treated with internal fixation and arthrodesis of the proximal interphalangeal joint.
- Arthrodesis is generally recommended because of the high likelihood of developing performance limiting osteoarthritis.
- With comminuted fractures the aim of surgical repair is reconstruction of the proximal and distal articular surfaces of the middle phalanx to preserve the distal interphalangeal joint.
- Select cases of comminuted fractures may be treated with transfixation pin casting.

CHRONIC TREATMENT

- After internal fixation, the horse is maintained in a distal limb cast for 4 to 6 weeks.
- After cast removal, the horse is supported with either a heavy bandage or a bandage cast.
- The horse is stall confined for a total of 3 to 4 months until there is radiographic evidence of fracture healing and arthrodesis of the joint.
- Handwalking usually begins at 2 to 3 months after surgery depending on the degree of lameness.
- Complete healing generally requires 6 to 8 months.

POSSIBLE COMPLICATIONS

- Implant failure
- Osteoarthritis of the distal interphalangeal joint
- Infection
- Persistent lameness
- Contra-limb laminitis

RECOMMENDED MONITORING

Radiographic evaluation at intervals until healing is complete

PROGNOSIS AND OUTCOME

- Based on the severity of injury and presence or absence of complications (eg, infections, contralateral limb laminitis).
- Horses with osteochondral chip fractures have a good prognosis for return to soundness.
- Horses with uniaxial eminence fractures have a fair to favorable prognosis for return to athletic activity.
- Horses with biaxial eminence fractures have a fair prognosis for return to some level of athletic activity after arthrodesis.
- Horses with comminuted fractures have a guarded prognosis. Horses have returned to athletic activity, although some residual lameness is anticipated if there is inadequate reduction of the fracture fragments entering the distal interphalangeal joint.

PEARLS & CONSIDERATIONS

Comminuted unstable fractures are the most common fracture configuration and require early diagnosis and first aid and stabilization for transport to increase the likelihood of restoring some degree of athletic activity.

EDITOR: **ANDRIS J. KANEPS**

Fractures: Physeal

BASIC INFORMATION

DEFINITION

Fractures of any bone involving the physis or growth plate

SYNONYM(S)

- Growth plate fracture
- Salter-Harris–type fracture

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS

- Angular limb deformity
- Juvenile arthritis
- Support limb breakdown
- Growth plate infection

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

The Salter-Harris fracture classification is a guide for determination of prognosis and treatment options:

- Type I: Fracture through the physis (involves only the zone of hypertrophied chondrocytes); most common

ElibeVet.com

- Type II: Fracture across the physis and extends into a portion of the metaphysis
- Type III: Fracture involving the physis and epiphysis (this type extends into the joint)
- Type IV: Fracture involving the physis, epiphysis, and metaphysis (this type also extends into the joint)
- Type V: Compression injury of the physis
- Type VI: Periosteal bridging between the metaphysis and epiphysis

HISTORY, CHIEF COMPLAINT

- Lameness, swelling, limb deviation, recumbency, and reluctance to stand or bear weight on the affected limb

PHYSICAL EXAM FINDINGS

- Varying degree of lameness, but usually grade 3 to 5 of 5
- Pain upon palpation of the injured area
- Swelling
- Possible instability of the limb
- Possible angular deviation of the limb distal to the fracture

ETIOLOGY AND PATHOPHYSIOLOGY The vast majority of physeal fractures are traumatic in origin. The physis is weaker than bone, ligament, tendons, and joint capsule. Therefore, the growth plate is the most vulnerable aspect of the immature musculoskeletal system. Bending, shearing, torsional, tensile, or compressive forces are sufficient to result in physeal fractures.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious physitis
- Infectious arthritis
- Joint luxation or subluxation
- Foot abscess

INITIAL DATABASE

- Physical examination and digital palpation
- Examination of locomotion

ADVANCED OR CONFIRMATORY TESTING

Radiographic evaluation

TREATMENT

THERAPEUTIC GOALS

- Stabilization of the fracture
- Immediate improvement of comfort level
- Even weight bearing across all limbs
- Minimal limb deformity

ACUTE GENERAL TREATMENT

- The neonate limb responds poorly to external coaptation; therefore, internal fixation is preferred.
- A major difficulty in surgical stabilization may be the small size of the epiphysis for implant purchase. This problem has been partially overcome with the use of cross pins, transfixation pins, tension-band wiring, or T-plates.
- Conservative management with external coaptation is often unsuccessful because it results in extreme limb laxity. Also, it is not possible in foals with femoral and proximal tibial physeal fractures.
- Returning a fractured limb to weight bearing as soon as possible is important to protect the other limbs (especially the contralateral limb) from overload. Young bones are very susceptible to maldevelopment if overloaded.

CHRONIC TREATMENT

- Monitor for signs of infection. Treat quickly and aggressively if suspected.
- Monitor for signs of inappropriate stabilization and remedy immediately if suspected.
- Assist in maintaining even weight bearing and appropriate levels of comfort (pain management drugs, including nonsteroidal antiinflammatory drugs and opioids).

POSSIBLE COMPLICATIONS

- Fracture fixation or implant failure
- Infection (septic physitis or osteomyelitis)
- Cast sores
- Residual lameness
- Muscle atrophy
- Tendon contracture or laxity
- Angular limb deformity of the contralateral limb
- Angular limb deformity of affected limb (rare)
- Limb length discrepancy (rare)

RECOMMENDED MONITORING

Monitor for signs of residual lameness, angular limb deformity, flexural limb deformity, and limb length discrepancy. Also monitor for signs of gastrointestinal discomfort caused by the stress and use of nonsteroidal drugs.

PROGNOSIS AND OUTCOME

- If adequate reduction of the fracture and stabilization is achieved, the prognosis for future soundness is good.
- Types I and II Salter-Harris fractures are most common and involve the third metacarpal or metatarsal bones. The prognosis is good for healing without lameness.
- In general, prognosis decreases if the Salter-Harris classification number increases. However, other factors essential to prognosis include the severity of the trauma to the growth plate, the foal's age, the location of the injury, the time elapsed before treatment, the level of displacement, whether the injury is open or closed, and the integrity of the vasculature and accompanying soft tissue structures.

PEARLS & CONSIDERATIONS

COMMENTS

- Physeal fractures are the most common fracture in foals.
- Physeal fractures should be considered serious and addressed immediately because of the risk for abnormal or retarded growth patterns.

CLIENT EDUCATION

- Physeal fractures heal in approximately 50% of the time necessary for metaphyseal fractures.
- Younger foals appear to tolerate injury to the physis better than older foals.

ElibEVet.com

Fractures: Proximal Phalanx

BASIC INFORMATION

DEFINITION

Fractures of the proximal phalanx may be broadly classified as proximal intraarticular osteochondral fractures and fractures involving the diaphyseal region of the proximal phalanx.

SYNONYM(S)

- P1 fractures
- Long pastern fractures

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Osteochondral fractures involving the proximal dorsal rim of the proximal phalanx are common in racehorses.
- Osteochondral fractures involving the proximopalmar/plantar aspect of P1 are seen in young athletic horses and are classified as type 1 when they are avulsed from the axial portion of proximal P1 and are mostly articular. Type 2 lesions are abaxial, larger, and have limited articular cartilage and are most commonly seen in the hindlimbs.
- Diaphyseal fractures are seen in horses of all ages and are typically the result of trauma.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Osteochondral fractures involving the proximal dorsal rim of P1 typically present with a history of several days of moderate lameness that may improve with rest.
- Type 1 osteochondral fractures involving the proximopalmar/plantar aspect of P1 typically present for mild lameness that may only be evident at higher speeds.
- Type 2 lesions are often found only on radiographic evaluation, and most do not cause lameness.
- Horses with diaphyseal fractures most often have a history of trauma or acute injury.

PHYSICAL EXAM FINDINGS

- Small osteochondral fractures demonstrate significant joint effusion and moderate pain on flexion.
- Horses with diaphyseal fractures present for moderate to severe lameness depending on the severity of the fracture and the instability of the limb.

ETIOLOGY AND PATHOPHYSIOLOGY

- Osteochondral fractures involving the proximal dorsal rim of the P1 are seen most commonly in racehorses and result from hyperextension of the metacarpophalangeal joint with impact on the dorsal region of the metacarpus.
- Osteochondral fractures involving the proximopalmar/plantar aspect of P1 were thought to be the result of osteochondrosis; however, recent evidence supports a fracture etiology.
- Diaphyseal fractures result from compressive and torsional forces transmitted from the sagittal ridge of the cannon bone through the sagittal groove propagating distally.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Proximal sesamoid fractures
- Middle phalanx fractures
- Condylar fractures

INITIAL DATABASE

- Clinical examination localizing the lesion to the area.
- Complete radiographic evaluation.

ADVANCED OR CONFIRMATORY TESTING

Computed tomography may help with determining fracture configuration for surgical planning.

TREATMENT

THERAPEUTIC GOAL(S)

- Restore limb function.
- Restore the normal metacarpophalangeal joint angle.
- Limit development of osteoarthritis.

ACUTE GENERAL TREATMENT

- Horses with osteochondral fractures involving the proximal dorsal rim of P1 are treated with arthroscopic removal of the fragments and cartilage debris.
- Horses with type 1 osteochondral fractures involving the proximopalmar/plantar aspect of P1 are treated with arthroscopic removal of the fragment when the lesions cause clinical lameness.
- Horses with type 2 lesions rarely require surgery; however, in select cases, surgical fixation of the fragment with a screw placed in lag fashion may be required.
- First aid stabilization of diaphyseal fractures
- With the limb held off the ground, a light padded bandage is applied from the proximal metacarpus or metatarsus to just distal to the coronary band. A rigid splint (polyvinyl chloride) is taped to the dorsum (forelimb) or plantar surface (hindlimb) of the bandage to maintain alignment of the dorsal cortices of the metacarpus or metatarsus and phalanges. The bandage and foot are then encased in fiberglass cast material to temporarily stabilize the fracture for transport.
- Diaphyseal fractures require treatment with internal fixation, external fixation, or a combination of both in many cases.
- Reconstruction of comminuted diaphyseal fractures requires at least one piece of intact bone spanning its length (also referred to as a *strut*) to which other fragments can be anchored.
- In severely comminuted fractures, external fixation alone may provide the best option.

PROGNOSIS AND OUTCOME

- Horses with small osteochondral fractures have a good prognosis for return to athletic activity after surgical removal.
- The prognosis for diaphyseal fractures depends on the fracture configuration and amount of displacement.
- Horses with minimally displaced fractures have a good prognosis for survival and return to work.
- Horses with displaced comminuted fractures have a guarded prognosis for survival and a poor prognosis for athletic activity.

PEARLS & CONSIDERATIONS

- Always evaluate the blood supply to the digit in cases of comminuted unstable diaphyseal fractures.
- Osteoarthritis is the likely sequela of any fracture where the joint surface cannot be perfectly reconstructed and may be the limiting factor in return to soundness.

AUTHOR: **KELLY FARNSWORTH**

EDITOR: **ANDRIS J. KANEPS**

Fractures: Proximal Sesamoid Bones

BASIC INFORMATION

DEFINITION

Fractures of the proximal sesamoid bones may be classified as apical, midbody, basilar, abaxial, axial, sagittal, or comminuted.

EPIDEMIOLOGY

SPECIES, AGE, SEX Common injuries in racing Thoroughbreds, Standardbreds, and Quarter Horses. The forelimbs are most commonly affected in Thoroughbreds (right front) and Quarter Horses. The hind limbs are most frequently affected in Standardbreds (left hind).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Moderate to severe lameness developing either during exercise or racing or within 24 hours
- Lameness may or may not improve with rest.

PHYSICAL EXAM FINDINGS

- All except abaxial nonarticular fractures result in metacarpophalangeal or metatarsophalangeal joint effusion and moderate to severe lameness.
- The horse may have soft tissue swelling around the sesamoid bones.
- Weight bearing on the toe is common.
- Mild to moderate pain on flexion of the fetlock joint is seen.

ETIOLOGY AND PATHOPHYSIOLOGY

- Occur as a result of excessive tension on the suspensory apparatus
- Hyperextension during maximal loading may produce tensile forces on the sesamoid bones, exceeding their internal strength.
- Sufficient exercise results in increased strength of the suspensory ligament, increasing the likelihood of sesamoid fractures versus injury to the suspensory ligament in unfit horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Proximal phalanx fracture
- Third metacarpal or metatarsal condylar fracture
- Suspensory ligament injury

INITIAL DATABASE

- Complete radiographic evaluation, including standard dorsopalmar, lateral medial, and oblique projections
- Other views to consider include flexed lateral and a skyline view of the abaxial surface of the sesamoid bones.
- Evaluation of the blood supply to the digit if breakdown of the suspensory apparatus (identified as a dropped fetlock joint on weight bearing) is apparent

TREATMENT

THERAPEUTIC GOAL(S)

- Restoration of limb function
- Return to soundness

ACUTE GENERAL TREATMENT

- Most horses not intended for further athletic careers may be treated conservatively with support bandages, splinting, or casting with stall rest.
- Severe injuries in these horses may require use of a splint such as the Kimzey leg saver that places the horse on its toe and relieves suspensory tension.
- Apical fractures are almost always articular and treated with removal of the apical fragment up to one third of the proximodistal dimension via either arthroscopy or arthrotomy.
- Midbody fractures are repaired with internal fixation with either lag screw placement or circumferential wiring.
- Basilar fractures are repaired with internal fixation using circumferential wiring when they involve the entire base or by fragment removal when they are small.
- Abaxial fractures are usually nonarticular and do not require surgery. Articular abaxial fractures are treated with arthroscopic removal of the fragments.
- Sagittal fractures tend to occur in conjunction with other injuries to the fetlock joint; they are treated with lag screw fixation.
- Comminuted and biaxial fractures are best treated with fetlock arthrodesis.

CHRONIC TREATMENT

- Horses with apical fractures treated by removal of osteochondral fragments are typically stall confined for 30 to 60 days, depending on the amount of suspensory ligament disruption, followed by a slow return to exercise.
- Internal fixation is usually supplemented with a lower limb cast for 1 to 4 weeks with a total convalescence of 10 to 12 months.

POSSIBLE COMPLICATIONS

- Implant failure
- Persistent lameness

RECOMMENDED MONITORING

- Periodic radiographic follow-up to determine the degree of repair if internal fixation was used
- Ultrasonographic evaluation of the suspensory ligament before initiating rehabilitative exercise

PROGNOSIS AND OUTCOME

- Horses with apical fractures have a good prognosis (~65%) for return to some degree of athletic activity with surgery.
- Horses with midbody fractures repaired with internal fixation also have a good chance of returning to athletic activity.
- Horses with basilar fractures that involve less than 25% of the base and can be removed surgically also have almost a 60% chance of returning to soundness.
- Horses with larger basilar fractures have a guarded prognosis for return to athletic activity.
- Horses with comminuted and biaxial fractures have a poor prognosis for return to soundness and typically require fetlock arthrodesis to salvage the animals as pets or for breeding.

PEARLS & CONSIDERATIONS

The suspensory ligament should be carefully evaluated with ultrasonography in all cases to determine the amount of damage to the ligament because suspensory desmitis may ulti-

 ElibEVet.com

mately become the limiting factor in the horse's return to soundness.

EDITOR: **ANDRIS J. KANEPS**

Fractures: Rib in the Neonate

BASIC INFORMATION

DEFINITION

Separation of a rib into two or more pieces under stress

SYNONYM(S)

- Broken rib
- Flail chest

EPIDEMIOLOGY

SPECIES, AGE, SEX Most occurrences are at the time of parturition.

RISK FACTORS

- Large birth weight of foal
- Dystocia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Rib fractures detected during routine well foal examination
- Tachypnea, flail chest
- Attitude and appetite are often normal.

PHYSICAL EXAM FINDINGS

- Groaning or grunting by the foal, subcutaneous edema over the ribs and axilla near the elbows, pain and crepitus on palpation of the affected rib(s)
- Flail chest: Paradoxical movement of a segment of the chest wall separated from the rest by multiple adjacent fractured ribs

ETIOLOGY AND PATHOPHYSIOLOGY

- Trauma to the ribcage during parturition is believed to be the most significant factor associated with rib fractures. Postnatal trauma could also result in rib fractures.
- Most fractures are located very near the costochondral junction. The distal piece of the fragmented rib typically displaces axially.
- Laceration of the myocardium and or great vessels is fatal.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Displaced versus nondisplaced rib fractures

INITIAL DATABASE

- Careful palpation of the ribcage
- Thoracic ultrasonography: More sensitive than radiography in detecting rib fractures; hemothorax may be present if the rib fragment lacerates pulmonary tissue

TREATMENT

THERAPEUTIC GOALS

- Prevent fatal laceration by rib fragment.
- Prevent respiratory distress.
- Minimize pulmonary contusion.
- Prevent infection.

ACUTE GENERAL TREATMENT

- Confinement to a stall or small pen; minimize movement by use of sedation
- Use antiinflammatory drugs judiciously to maintain low activity level.
- Blood transfusion if laceration has resulted in signs of hypovolemia and hypoxia.
- Broad-spectrum antibiotics
- Surgical stabilization of rib fragments in cases of fragments near the heart

CHRONIC TREATMENT

Four to 6 weeks of confinement is recommended to allow for healing of the fracture

POSSIBLE COMPLICATIONS

- Myocardial, vascular, or pulmonary laceration
- Diaphragmatic hernia
- Hemothorax
- Pneumothorax
- Death

RECOMMENDED MONITORING

Serial ultrasound evaluations to determine healing of fracture

PROGNOSIS AND OUTCOME

Rib fractures with clinical complications have a guarded prognosis. Healed rib fractures are not known to result in long-term complications.

PEARLS & CONSIDERATIONS

Careful palpation of the ribcage during routine well foal examinations will allow for detection of rib fractures.

SUGGESTED READING

EDITORS: **ELIZABETH M. SANTSCHI** and **PHOEBE A. SMITH**

ElibeVet.com

Fractures: Small Splint Bones

BASIC INFORMATION

DEFINITION

Fractures and proliferative periostitis of the second and fourth metacarpal/metatarsal bones (MC/MT-II and MC/MT-IV).

SYNONYM(S)

- "Splint bone" fractures
- A proliferative periostitis lesion is commonly known as a *splint*.

EPIDEMIOLOGY

SPECIES, AGE, SEX Proliferative periostitis affecting MC-II (and less frequently MC-IV) is commonly seen in young horses in early training.

RISK FACTORS

- Poor conformation, particularly at the carpus and tarsus, is a risk factor for proliferative periostitis of MC/MT-II and MC/MT-IV.
- Carpus or tarsus valgus or varus, and "offset knees" or "bench knees" exacerbate strains on these bones. Base narrow, toe-out conformation of the forelimbs may exacerbate the tendency for interference, specifically trauma to the contralateral MC-II.

ASSOCIATED CONDITIONS AND DISORDERS Concurrent suspensory desmitis is often seen in horses with fractures of the distal aspect of the small metacarpal/metatarsal bones.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Splint bone fractures are divided into three types based on location: Proximal, midshaft, and distal (Figures 1 to 3).

HISTORY, CHIEF COMPLAINT

- Horses with proliferative periostitis have a history of either gradual (insidious) or acute onset of lameness. Lameness may be unilateral or bilateral and is usually mild to moderate. Lameness improves with rest and antiinflammatory treatment and recurs with resumption of exercise. Sometimes a cosmetic blemish (focal hard swelling) is the first sign noted by the owner or trainer.
- Horses with splint bone fractures often have a history of external trauma (eg, a kick). Lameness in these cases is invariably acute and typically moderate to severe. Horses with fractures of the distal aspect that are associated with internal trauma (repetitive strain) and possibly a concurrent suspensory branch desmitis have a more variable history with onset being either acute or gradual and ranging from mild-to-moderate (rarely severe). Some distal splint fractures are discovered as incidental findings.

PHYSICAL EXAM FINDINGS

- A "splint" is recognized as a focal swelling along the shaft of the affected bone that is smooth and firm to hard on palpation. In some cases, the swelling is located axially, and the lesion can only be detected by palpation (most effectively with the limb held in flexion). Single lesions are most common, but multiple lesions affecting the same bone are sometimes present. Multiple lesions are most common on MC-II in young horses associated with early training. In this group, splints are also commonly bilateral. Horses exhibit variable degrees of pain on palpation of the splint. Pain is most severe in the acute stages and does not always correlate well with the degree of swelling or exostosis. Chronic splints, or those that have healed clinically, are typically not sensitive to palpation.
- Horses with distal splint bone fractures generally have very mild to moderate local soft tissue inflammation. The degree varies with the chronicity of the injury. Fractures that are more than 1 or 2 weeks old may have minimal residual associated swelling. Suspensory enlargement, most commonly of the associated branch, may also be present. Focal pain is common on firm palpation of the fracture site. If the

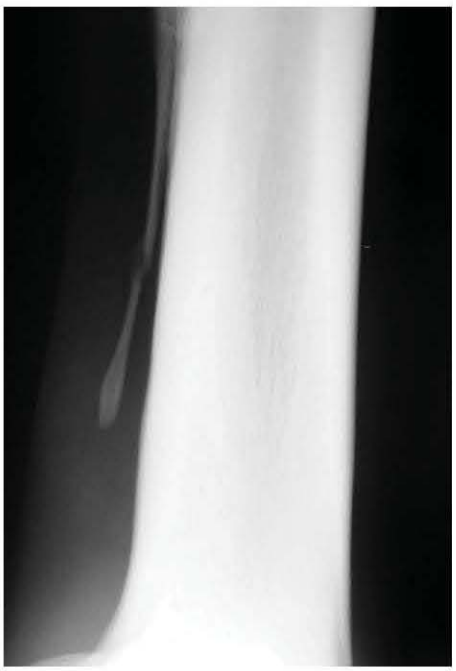

FIGURE 1 Dorsomedial-to-palmarolateral oblique radiograph of the left metacarpus of a horse with a typical fracture of the distal aspect of MC-II.

FIGURE 2 Dorsolateral-to-palmarolateral oblique radiograph of the left metatarsus of a horse with an acute fracture of the midshaft of MT-IV.

ElibeVet.com

FIGURE 3 Dorsolateral-to-palmarolateral oblique radiograph of the right metacarpus of a horse with a displaced fracture of the proximal aspect of MC-II. This fracture is best treated with internal fixation using a small plate.

FIGURE 4 Dorsolateral-to-plantaromedial oblique radiograph of the right metatarsus of a horse with a chronic fracture of the mid-shaft of MT-IV. Note the extensive periosteal callus and persistent fracture gap typical of a delayed union or nonunion in this non-surgically managed fracture.

fracture is chronic, a callus can often be palpated along with instability if the distal tip or "button" is pressed axially.
- Variable degrees of soft tissue swelling and pain on palpation of the fracture site are the hallmarks of fractures of the more proximal portions of the splint bones. Open wounds or abrasions may be present if the fracture is the result of external trauma. Signs of soft tissue infection are common with chronic fractures associated with open wounds.

ETIOLOGY AND PATHOPHYSIOLOGY

- Splints
  - Caused by internal (most common) or external (less common) trauma
  - Internal trauma is the result of cyclic strains during exercise.
  - Initiated by tearing and inflammation of the interosseous ligament and underlying periosteum of the cannon and splint bones.
  - Focal desmitis and periostitis develop.
  - Swelling is initially a combination of soft tissue edema and fibrosis.
  - Progresses to periosteal new bone or exostosis.
  - Eventually, a synostosis often develops between the splint and cannon bone.
  - In contrast, splints caused by external trauma begin as a primary focal periostitis or osteitis of the affected bone.
  - In either case, if the exostosis becomes exuberant and projects axially, a secondary, focal suspensory desmitis may develop.
- Splint bone fractures
  - Distal fractures: Cyclic axial compressive forces during loading and tensile strains imparted by the suspensory ligament
  - Middle and proximal fractures: Blunt external trauma
  - Some oblique fractures of the head of MC-II may be avulsion fractures or the result of internal torsional forces.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Splints and closed splint bone fractures are differentials for each other.

INITIAL DATABASE

- Physical examination
- Lameness examination, including diagnostic analgesia in selected cases
- Radiographs confirm the diagnosis.

ADVANCED OR CONFIRMATORY TESTING

- Nuclear scintigraphy may be helpful in selected cases.
- Ultrasound examination of the suspensory ligament in selected cases
- Synoviocentesis is indicated to rule in or rule out joint involvement in open fractures of the proximal aspect of the bone.

TREATMENT

THERAPEUTIC GOALS

- Splints: Reduce or eliminate the inciting cause, reduce inflammation, minimize the size of the exostosis, and allow the lesion to become quiescent or "set up."
- Fractures
  - Distal fractures: Eliminate the source of chronic irritation or inflammation.
  - Mid-shaft fractures: Minimize the convalescent time and prevent formation of exuberant callus or exostosis.
- Proximal fractures: Promote primary bone healing, preserve the stability of the proximal portion, and minimize the potential for degenerative joint disease.

ACUTE GENERAL TREATMENT

- Splints
  - Local and systemic antiinflammatory therapy (cold hosing or icing, bandaging, nonsteroidal antiinflammatory drugs)
  - Stall rest when lameness is unusually severe (ie, apparent at a walk)
  - Controlled exercise: Handwalking 2 to 6 weeks in most cases; handwalking and paddock turnout for 1 to 4 months in more severe or chronic or recurrent cases
  - Local corticosteroid injection

ElibVet.com

- Fractures
  - Stall rest and antiinflammatory therapy (as above) pending decisions on definitive treatment
  - Wound care and antimicrobial therapy in cases with open wounds or established infection

CHRONIC TREATMENT

- Splints
  - Corrective trimming and shoeing to reduce strains on the bone and minimize the tendency for interfering
  - Boots and protective bandages to offer protection from interference
  - Surgery (partial ostectomy) is reserved for refractory cases with chronic or recurrent lameness and those with exuberant exostoses.
- Fractures
  - Nonsurgical management may be effective in selected cases.
  - Surgery decreases the convalescent time and minimizes the potential for delayed or nonunion and exuberant callus formation (Figure 4).
  - Distal and mid-shaft fractures are generally best treated surgically by partial ostectomy.
  - Segmental ostectomy is an option for some mid-shaft fractures.
  - Simple debridement of comminuted fragments in open fractures is an option in some cases.
  - Proximal fractures are treated with internal fixation when feasible to preserve joint integrity.
  - Complete ostectomy of MT-IV is a viable option in selected cases.

POSSIBLE COMPLICATIONS

- Secondary suspensory desmitis is a concern in cases of splints or fractures with exuberant callus or exostosis formation.
- Septic arthritis is a potential complication with open fractures involving the carpometacarpal or tarsometatarsal joints.

RECOMMENDED MONITORING

Follow-up radiography to monitor fracture healing (non-ostectomy cases)

PROGNOSIS AND OUTCOME

- The prognosis for proliferative periostitis (splints) is very good to excellent in the majority of cases.
- The prognosis for splint bone fractures is also typically good to excellent if diagnosed early and properly treated.
- Exceptions: Cases with concurrent suspensory desmitis; cases of proximal fractures with resultant osteoarthritis (chronic displacement or septic arthritis)

PEARLS & CONSIDERATIONS

Occasionally, a horse with a fractured splint bone resulting from blunt trauma will also have a hairline fracture of the cannon bone. Radiographs should be carefully scrutinized in these cases, particularly before general anesthesia.

Frostbite

BASIC INFORMATION

DEFINITION

Destruction of the skin, and often deeper tissues, by freezing temperatures

SYNONYM(S)

Cryopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX Frostbite may affect any horse with prolonged exposure to below-freezing temperatures, particularly in conjunction with high humidity, low wind chill factors, and a wet haircoat or blanket. Debilitated animals and neonates are at particular risk.

RISK FACTORS Low ambient temperatures

ASSOCIATED CONDITIONS AND DISORDERS Hypothermia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to cold climates
- Horses may not present with clinical signs until tissue sloughing is noted.

PHYSICAL EXAM FINDINGS

- Clinical signs include erythema and bulla formation superficially.
- Hemorrhagic blisters, ulceration, gangrene, anesthesia, or hyperesthesia may occur in the deeper subcutaneous tissues.
- There may be color change to the tissue beneath the hair from white to deep purple.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cold temperatures induce vasoconstriction, infarction, and endothelial damage.
- Crystallization of water into ice in the tissue and capillaries leads to further tissue damage and ischemic necrosis.
- Further mechanical effects include free radical generation, production of prostaglandins and thromboxane A2, release of proteolytic enzymes, and generalized inflammation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Any blistering disease

INITIAL DATABASE

- None required
- Specific tests may be dictated by the concurrent illness or injury that led to frostbite.

ADVANCED OR CONFIRMATORY TESTING

Doppler ultrasonography may provide a view of vascular flow to the affected region.

ElibEVet.com

TREATMENT

THERAPEUTIC GOAL(S)

- Rewarm the affected region slowly.
- Treat the secondary effects of the cold-induced damage (tissue necrosis, infection).

ACUTE GENERAL TREATMENT

- Because rewarming followed by refreezing can be more harmful to the extremity than a delay in rewarming, protect the involved extremity and avoid rewarming until correct procedures can be performed.
  - In human patients, the affected tissue is warmed by placing it in water with 10% povidone-iodine at 40° C for about 20 minutes and elevating the region immediately afterward.
  - In horses, the tissue can be rewarmed with warm, damp towels (without rubbing, which can injure frozen cells), circulating warm water heating pads, warm water bottles, or forced warm air blankets and moving the animal to a warm environment out of the wind.
- Nonsteroidal antiinflammatory drugs (flunixin meglumine, 1.1 mg/kg q12h IV) should be used to control pain and decrease inflammation.
- Pentoxifylline (8.4 mg/kg q12h PO) can be used to improve microvascular circulation and prevent erythrocyte clumping.
- Aspirin (acetylsalicylic acid, 17 mg/kg, q12h PO) and low-molecular-weight heparin (50–80 U/kg, q24h SC) can be used to prevent microvascular thrombosis.
- Acepromazine can also be used for vasodilation.
- Antibiotics should be started if the patient is debilitated or young or if necrosis is anticipated.

CHRONIC TREATMENT

- Local tissue care is important to care for the skin.
  - Topical aloe vera gel should be applied to the skin three or four times daily.
  - Topical nitroglycerin may also help improve circulation to the affected tissue.

POSSIBLE COMPLICATIONS

- Skin and hoof sloughing may occur depending on the severity of the injury.
- Local infection may occur and may progress to sepsis if severe.

PROGNOSIS AND OUTCOME

Persistent edema and failure to rewarm are poor prognostic indicators for the affected tissues.

PEARLS & CONSIDERATIONS

Avoid exposure of debilitated animals to low ambient temperatures.

Fumonisin Toxicosis

BASIC INFORMATION

DEFINITION

Fumonisins are mycotoxins produced by field infections of primarily *Fusarium verticillioides* and *Fusarium proliferatum* in corn that cause leukoencephalomalacia, hepatotoxicity, and cardiovascular dysfunction in horses.

SYNONYM(S)

- Equine leukoencephalomalacia (ELEM)
- Moldy corn disease

EPIDEMIOLOGY

SPECIES, AGE, SEX Any horse of any gender or age is susceptible to the adverse effects of fumonisins.

RISK FACTORS

- Feeding corn screenings or broken corn kernels increases the risk of fumonisin toxicosis.
- Three main fumonisins in corn are responsible for toxicity:
  - Fumonisin B1 (FB1) and fumonisin B2 (FB2) are approximately equal in toxicity but naturally occur in a ratio of about 3:1 for FB1/FB2.
  - Fumonisin B3 (FB3) is much less toxic.
- The development of clinical signs depends on the dose. Horses fed high fumonisin concentrations can develop leukoencephalomalacia in 5 to 8 days, but it may require several months for clinical signs to appear at low fumonisin concentrations.
- The Food and Drug Administration's Center for Veterinary Medicine guidelines recommend maximum levels of total fumonisins (FB1 + FB2) in corn used for equine feed of 5 mg/kg (ppm) and in the final equine ration of 1 mg/kg (ppm).

GEOGRAPHY AND SEASONALITY Fumonisins occur worldwide, primarily in corn. Insect damage and adverse weather conditions, particularly drought during the corn-growing season followed by cool and moist conditions during pollination and kernel formation, favor fumonisin production.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The clinical signs from fumonisin contamination of equine rations are probably related to the dose, duration of exposure, and tolerance of the individual horse. Although not truly distinct, two forms may appear in a herd outbreak or in an individual animal:
  - Equine leukoencephalomalacia or classic neurotoxic syndrome
  - Hepatic syndrome

HISTORY, CHIEF COMPLAINT

- The initial clinical signs may include a lack of appetite and neurologic signs, including aimless wandering, depression, hyperexcitability, or sudden death.
- The cardiovascular dysfunction includes decreases in heart rate and

ElibeVet.com

cardiac output, which may contribute to signs of dyspnea and edema.
- Horses with liver damage may show icterus, hemorrhage, and depression.
- The time from the onset of clinical signs to death may be 24 hours to 7 days. Typically, if only liver damage occurs and the fumonisin exposure stops, the liver lesions may be reversible.

PHYSICAL EXAM FINDINGS
- Horses with hepatic disease may display:
  - Icterus
  - Petechiae of mucous membranes
  - Hemorrhage
  - Depression
  - Swelling of the lips or muzzle
- Horses with ELEM may develop:
  - Aimless circling
  - Head pressing
  - Standing motionless for a period or displaying continuous repetitive movements until death
  - Paresis
  - Ataxia
  - Apparent blindness
  - Hyperexcitability
  - Facial paralysis
  - Coma
  - Tonic-clonic seizures
  - Death

ETIOLOGY AND PATHOPHYSIOLOGY
- Fumonisins inhibit key enzymes in the synthesis of sphingolipid and disrupt sphingolipid metabolism, increasing sphinganine and sphingosine and decreasing complex sphingolipids. Sphingolipids are involved in cell growth, cell-to-cell communication, differentiation, and neoplastic transformation. Elevated sphinganine-to-sphingosine ratios are associated with fumonisin toxicosis.
- Sphingosine inhibits L-type calcium channels in myocardial cells, decreasing cardiac contractility.
- Fumonisin toxicity in horses and resulting increases in sphingosine concentrations are associated with development of vasogenic cerebral edema as a direct result of increased blood-brain barrier permeability. It is hypothesized that increased sphingosine concentrations inhibit the calcium channels in cerebral arterioles, leading to altered cerebral blood pressure and vasogenic cerebral edema. Elevations in protein, albumin, and immunoglobulin G (IgG) concentrations have been identified in the cerebrospinal fluid (CSF) of horses with ELEM.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Brain trauma, abscesses, and edema
- Cerebrospinal nematodiasis
- Hyperammonemia
- Acute lead toxicosis
- Poisonous plants causing pyrrolizidine alkaloid toxicosis
- Aflatoxicosis

INITIAL DATABASE
- Serum biochemical changes are related to the hepatotoxicity and include elevated liver enzymes, including aspartate aminotransferase, gamma-glutamyl transpeptidase, and alkaline phosphatase.
- CSF changes in horses with ELEM include increased concentrations in protein, albumin, and IgG.

ADVANCED OR CONFIRMATORY TESTING
- Hepatic lesions include a swollen, brownish liver with irregular nodules. Histologic changes include hepatocyte vacuolation, loss of hepatic architecture, periacinar necrosis, bile stasis, portal fibrosis, and bile ductule proliferation.
- ELEM lesions appear as softening and necrosis of subcortical cerebral white matter, with lesions ranging from very small to large cavitations and inward collapse of cortical gray matter. Hemorrhages may be evident. Lesions are generally not symmetrical or bilateral and can involve the thalamus, cerebellum, brainstem, and medulla oblongata.
- Suspect feed should be analyzed for fumonisins (FB1 and FB2). Typically, the analysis is by high-performance liquid chromatography or enzyme-linked immunosorbent assay.
- An increased sphingosine-to-sphinganine ratio in serum or urine is a sensitive early indicator of fumonisin toxicosis; however, this analysis is not common in diagnostic laboratories.

TREATMENT

THERAPEUTIC GOAL(S)
There is no antidote for fumonisins. Typically, the clinical onset is acute and progressive until death occurs.

ACUTE GENERAL TREATMENT
- The important action is to identify the source and stop exposure to fumonisins in the ration.
- Because of the delay in onset of clinical signs after the start of exposure, decontamination is generally of limited to no value.
- Horses with hepatic damage should be provided appropriate supportive care.

PROGNOSIS AND OUTCOME

The appearance of clinical signs from fumonisin exposure indicates a grave prognosis. The majority of horses with ELEM die. If an affected animal survives, significant neurologic damage may be a sequela.

PEARLS & CONSIDERATIONS

COMMENTS
- Corn and corn products in equine rations should be periodically analyzed for fumonisin concentrations.
- Distillers' grains are often contaminated with fumonisins at a concentration of concern for horses; therefore, feeding distillers' grains to horses is not recommended.

CLIENT EDUCATION
Emphasize to clients that corn screenings or broken corn kernels may contain toxic concentrations of fumonisins and produce fatal ELEM in horses.

EDITOR: **CYNTHIA L. GASKILL**

ElibVet.com

Gasterophilus

BASIC INFORMATION

DEFINITION

The most common, although rarely clinically significant, gastric endoparasite in adult horses and foals

SYNONYM(S)

- "Bots," the bot fly larvae, are the stage found in the equine stomach.
- *Gasterophilus intestinalis* and *Gasterophilus nasalis* are most commonly found in horses; other less frequently identified species include *Gasterophilus haemorrhoidalis* and *Gasterophilus pecorum.*

EPIDEMIOLOGY

GEOGRAPHY AND SEASONALITY

- Found worldwide.
- Adult bot flies are present during the summer months and lay their eggs on the hairs of the horse's face and legs in the fall. The larvae overwinter in the equine stomach, are passed in the feces in the spring, and then pupate and mature into adult bot flies.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Associated clinical signs are rare but may include signs similar to gastric ulceration (see "Gastric Ulceration" in this section) if large numbers are present in the stomach or signs consistent with gastric outflow obstruction (see "Gastric Impaction" in this section) if large numbers obstruct the duodenum.

PHYSICAL EXAM FINDINGS

- Usually within normal limits.
- In the fall, small, yellow bot fly eggs may be visible stuck to the hairs of the face and forelimbs.

ETIOLOGY AND PATHOPHYSIOLOGY

Direct life cycle:

- The adult bot fly lays eggs on the horse's hair coat (legs or head) during warm months. The eggs hatch on the hair coat, releasing first-stage larvae, which then enter the oral cavity by crawling there or are ingested by the horse during grooming behavior.
- First- and second-stage larvae develop in the oral cavity in the gingival tissue (*G. nasalis*) or tongue (*G. intestinalis*).
- Late second-stage larvae are swallowed and mature to third-stage larvae in the stomach. The third-stage larvae then attach to the gastric (*G. intestinalis*) or proximal duodenal (*G. nasalis*) mucosa, where they overwinter.
- Third-stage larvae detach from the gastric mucosa in the spring and are passed in the feces and pupate. Adult bot flies emerge during the summer and repeat the cycle.
- In general, *Gasterophilus* organisms are nonpathogenic, and related clinical disease is uncommon unless large numbers of larvae are present in the stomach, resulting in gastric mucosal pain or inflammation or in the duodenum, resulting in gastric outflow obstruction.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Gastric ulceration

INITIAL DATABASE

Complete blood count and serum biochemical profile: Usually within reference intervals

ADVANCED OR CONFIRMATORY TESTING

Gastroscopy:

- The larvae, which are usually yellow or tan, are seen attached to the gastric mucosa as solitary organisms or occasionally in clusters.
- The presence of bot fly larvae is often an incidental finding.

TREATMENT

THERAPEUTIC GOAL(S)

Eliminate the larval stage.

ACUTE GENERAL TREATMENT

- Ivermectin: 200 µg/kg PO once
  - *Gasterophilus* larvae are very susceptible to avermectins but are not eliminated by other classes of anthelmintics.
- Remove bot eggs from the hair coat in the fall using a bot knife.

PROGNOSIS AND OUTCOME

Good; rarely associated with clinical disease and easy to eliminate with ivermectin

PEARLS & CONSIDERATIONS

COMMENTS

Concurrent gastric ulceration is rarely present. If gastric ulceration is present in a horse with gastric *Gasterophilus* larvae, other inciting causes for ulcers should be suspected and investigated (see "Gastric Ulceration" in this section).

PREVENTION

Routine deworming should include administration of ivermectin in the winter months to eliminate *Gasterophilus* larval infestation.

Gastric Dilation

BASIC INFORMATION

DEFINITION

Distension of the stomach with fluid or gas

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Colic (often acute onset and severe)
- ± History of consumption of large volume of fermentable feed such as grain, grass clippings, or apples

PHYSICAL EXAM FINDINGS

- Tachycardia, tachypnea.
- Decreased to absent gastrointestinal borborygmi.
- Variable gross abdominal distension ranging from absent to dramatic.

ElibeVet.com

- Depression, fever, dehydration, and hyperemic or injected mucous membranes are often seen if the underlying cause is inflammatory small intestinal disease (proximal duodenitis or jejunitis).

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary gastric dilation: Occurs when large volumes of gas are rapidly produced after consumption of a large amount of highly fermentable material (grain, grass clippings, apples)
- Secondary gastric dilation: Caused by reflux of small intestinal fluid contents retrograde into the stomach because of small intestinal obstructive lesions or caused by excessive small intestinal fluid secretion and small intestinal dysmotility with proximal duodenitis or jejunitis, postoperative ileus, or equine grass sickness
- Emesis or spontaneous regurgitation of gastric contents into the esophagus is usually prevented in the horse with severe gastric dilation because of mechanical distortion of the cardia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Gastric impaction

INITIAL DATABASE

Passage of a nasogastric tube yields a large volume of fluid (often 10–20 L) or gas and usually results in at least temporary resolution of the colic episode. This confirms the diagnosis of gastric dilation but does not help to differentiate primary from secondary gastric dilation.

ADVANCED OR CONFIRMATORY TESTING

- Should be undertaken to determine the underlying cause of gastric dilation and may include the following:
  - Complete blood count: Often within reference intervals, although leukopenia and significant hemoconcentration suggest small intestinal inflammatory disease as the underlying cause
  - Serum biochemistry profile: Hypochloremia, hyponatremia, and other electrolyte derangements are frequently observed.
  - Rectal examination: May be normal with primary gastric dilation, although caudal displacement of the spleen because of the marked gastric distension is occasionally appreciated. Small intestinal distension or thickening is often noted in secondary gastric dilation.
  - Transabdominal ultrasonography: Caudal displacement of the gastric contour, beyond the 15th intercostal space, is often present. Small intestinal distension, hypomotility, and increased mural thickness (>5 mm) are often seen in secondary gastric dilation
  - Peritoneal fluid analysis: Usually within reference intervals in primary gastric dilation. Variable in secondary gastric dilation, depending on the inciting cause.
- Exploratory celiotomy is often indicated if colic persists or recurs after gastric decompression or if a primary small intestinal obstructive lesion is suspected.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove excess gastric fluid or gas to prevent gastric rupture.
- Eliminate the underlying cause.

ACUTE GENERAL TREATMENT

- Gastric decompression via a nasogastric tube
  - If it is difficult to pass the tube through the cardia, instillation of 20 to 40 mL of 2% lidocaine down the nasogastric tube may promote sufficient cardiac relaxation to permit passage of the tube.
  - Maintenance of an indwelling nasogastric tube is often necessary to maintain gastric decompression. The tube may be capped and the horse monitored for reaccumulation of gastric fluid every 1 to 3 hours, or the tube may be left uncapped to allow gas and fluid to spontaneously escape.
  - A finger from a latex glove with a small opening cut in the end may be secured over the end of an uncapped nasogastric tube to allow gas or fluid efflux but prevent unwanted influx of air into the stomach.
- Gastric lavage (see "Gastric Impaction" and "Grain Overload" in this section) is indicated in primary gastric dilation to remove ingested fermentable feed if possible.
- The underlying cause of secondary gastric dilation should be investigated and treated appropriately.
- The horse should be kept NPO (nothing by mouth) until the inciting cause has resolved and continuous or intermittent gastric decompression is no longer necessary.

POSSIBLE COMPLICATIONS

Gastric rupture

PROGNOSIS AND OUTCOME

- Primary gastric dilation: The prognosis is good to excellent if gastric decompression is accomplished early and maintained.
- Secondary gastric dilation: The prognosis is variable and depends on the underlying inciting cause.

PEARLS & CONSIDERATIONS

- Passage of a nasogastric tube should be performed in any horse with signs of colic or unexplained tachycardia. If small intestinal distension is noted on rectal examination, enteral fluids or laxatives should not be administered (even if no significant reflux is obtained on initial examination), and the horse should be serially monitored for development of gastric reflux until the small intestinal distension is resolved.
- If transfer to a referral hospital is necessary in a horse with gastric dilation, it is imperative that the horse be shipped with a well-secured, uncapped indwelling nasogastric tube in place.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

ElibeVet.com

Gastric Impaction

BASIC INFORMATION

DEFINITION

Distension of the stomach with feed or a phytobezoar or trichobezoar

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals may be predisposed to indiscriminate hair ingestion, resulting in trichobezoar formation

RISK FACTORS

- Feeding poor-quality roughage or certain feed stuffs such as beet pulp and wheat bran, which may not be adequately hydrated by saliva and gastric fluid contents
- Poor dentition resulting in inadequate mastication
- Concurrent gastrointestinal (GI) disease, resulting in generalized decreased GI motility
- Pyloric outflow obstruction (see "Gastric Outflow Obstruction" in this section)

ASSOCIATED CONDITIONS AND DISORDERS Horses with acute or chronic hepatic disease have an increased incidence of gastric impaction, although the direct relationship between the two conditions is poorly understood.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Inappetence or anorexia
- Colic (variable severity)

PHYSICAL EXAM FINDINGS

- Variable; may be within normal limits.
- Mild to moderate tachycardia and tachypnea and evidence of mild to moderate dehydration (prolonged skin tent, tacky mucous membranes, and prolonged capillary refill time) are frequently observed.
- Gross abdominal distension is uncommon unless a concurrent distal intestinal obstruction is present.
- Rectal examination
  - Often within normal limits in primary gastric impaction, although caudal displacement of the spleen may be appreciated.
  - Small intestinal or large colonic distension may be noted if an accompanying distal intestinal obstruction has predisposed to the gastric impaction.

ETIOLOGY AND PATHOPHYSIOLOGY

- Feed material accumulates within the stomach with:
  - Consumption of large amounts of poor-quality roughage or dry feed stuffs
  - Dehydration or limited water intake
  - Impaired gastric emptying caused by pyloric outflow obstruction or more distal intestinal obstruction
- Bezoar formation
  - Persimmon seed or hair ingestion may result in formation of a phytobezoar or trichobezoar, respectively.
  - A large bezoar may obstruct the pylorus, or a small bezoar may obstruct the duodenum, resulting in impaired gastric outflow.
- Idiopathic gastric impaction infrequently occurs as a primary cause of colic in the absence of a specific predisposing or concurrent cause.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Gastric dilation

INITIAL DATABASE

- Passage of a nasogastric tube
  - It is typically difficult to impossible to pass the tube through the cardia, and the horse may show signs of pain when this is attempted.
  - Significant gastric reflux is usually not present because the impacted material is usually dry and fibrous.
  - Gastric contents may have a stale, foul, fermentative odor.
- Complete blood count and serum biochemical profile
  - Usually within reference intervals or consistent with mild dehydration
  - Increased serum liver enzyme activity and bile acid concentration are present if the gastric impaction is secondary to hepatic disease.

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis is difficult and is often made during exploratory laparotomy because of protracted and unrelenting abdominal pain.

- Transabdominal ultrasonography: Caudal displacement of the gastric contour beyond the left fifteenth intercostal space may be seen. However, the sonographic location of the gastric contour can vary dramatically and occasionally extends to this location in the absence of a gastric impaction.
- Gastroscopy
  - Useful for visualization of a phytobezoar or trichobezoar
  - Identification of feed material at the level of the cardia in a fasted horse is consistent with gastric impaction
  - However, accurate determination of gastric size is not possible with gastroscopic examination.
  - An apparently large amount of feed material is often visualized in the stomach of nonfasted horses and may appear endoscopically identical to a true gastric impaction.
  - Thus, one-time gastroscopy may be misleading. The persistence of a large amount of feed material on serial examinations over 12 to 36 hours in a fasted horse is needed for a presumptive gastroscopic diagnosis of gastric impaction.

TREATMENT

THERAPEUTIC GOAL(S)

- Prevent further gastric distension or gastric rupture.
- Promote hydration of gastric contents to allow gastric emptying.
- Resolve inciting, concurrent intestinal obstruction, if present.

ACUTE GENERAL TREATMENT

- It is vital to withhold all feed, water, and oral medications because of the substantial risk of gastric rupture.
- Medical therapy: Promote hydration of gastric contents and breakdown of the impaction.
- Administer IV balanced polyionic fluids at 100 to 200 mL/kg/day.
- Intragastric administration of isotonic fluids and laxatives can be helpful but should be done in small volumes via gravity flow with great caution because gastric rupture is a potential consequence:
  - 8% dioctyl sodium sulfosuccinate (DSS): 100 to 200 mL once
  - ~1 L of isotonic fluids q4–8h
  - 1 L of mineral oil may be alternated with magnesium sulfate salts (8 oz/1 L water) q6–12h
- Administration should be ceased and administered fluids siphoned out if the horse shows any signs of discomfort during or after administration.
- Administration of 0.5 to 1 L of carbonated soda (eg, Coca-Cola) via nasogastric tube q12–24h can aid the breakdown of impacted material in both feed impactions and persimmon phytobezoars.
- Gastric lavage via a large-bore nasogastric tube
  - Perform gently q6–12h with instillation of small volumes of fluid (<1 L) via gravity flow at a time.

ElibEVet.com

- If an equivalent or greater volume of fluid and gastric contents is not siphoned out on each attempt, gastric lavage should be discontinued to avoid further distension of the stomach.
- Analgesic therapy
  - Flunixin meglumine (0.5–1.1 mg/kg IV q12h) as needed to control pain
  - Sedation with α_2 adrenergic agonists or opioids should be minimized if possible to avoid potential decreased GI motility.
  - Prokinetic therapy is not recommended unless a pyloric or more distal intestinal obstruction has been ruled out.
- Surgical therapy
  - Exploratory celiotomy is indicated in horses with increasing or persistent abdominal pain or in those in which medical management over 2 to 4 days is ineffective.
  - If gastric impaction is diagnosed or confirmed at surgery, direct instillation of isotonic fluids and gastric massage can be performed to help soften the impaction.
  - Surgical resolution of a gastric impaction or removal of a gastric bezoar via gastrotomy is extremely challenging in adult horses because of limited surgical exposure and inability to exteriorize the stomach, resulting in the substantial risk for abdominal contamination at surgery.

CHRONIC TREATMENT

Horses with hepatic disease or pyloric outflow obstruction that are at risk for recurrent gastric impactions can be managed conservatively with low-bulk diets consisting of short clipped-pasture, complete pelleted feed, or both.

POSSIBLE COMPLICATIONS

Gastric rupture

RECOMMENDED MONITORING

Serial gastroscopy every 24 hours until resolution of the impaction: Before refeeding, endoscopic evaluation of the pylorus and proximal duodenum is recommended to ensure a mechanical obstruction is not present.

PROGNOSIS AND OUTCOME

- Feed impactions
  - Guarded to fair with prompt medical therapy in primary gastric impactions
  - High likelihood of recurrence if occurs secondary to pyloric outflow obstruction
- Phytobezoars or trichobezoars: Guarded to poor because of difficulty resolving without surgery
- Poor if gastrotomy is required.

PEARLS & CONSIDERATIONS

COMMENTS

- Gastric impaction should not be overlooked as a primary or secondary cause of colic, especially in horses in which difficulty passing a nasogastric tube through the cardia is noted.
- Definitive diagnosis can require exploratory laparotomy, but surgical resolution via gastrotomy carries substantial risk and should only be attempted if medical management is unsuccessful.

PREVENTION

- Ensure good-quality roughage, access to water, and appropriate dental care.
- Limit or prevent access to persimmon trees and persimmon fruit.

SUGGESTED READING

Murray MJ: Diseases of the stomach. In Mair T, Divers T, Ducharme N, editors: *Manual of equine gastroenterology*, London, 2002, Saunders Elsevier, pp 241–248.

AUTHOR: **KELSEY A. HART**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Gastric Rupture

BASIC INFORMATION

DEFINITION

Full-thickness disruption of the gastric wall

EPIDEMIOLOGY

RISK FACTORS Gastric distension from any cause

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Colic: Signs may improve or resolve temporarily immediately after gastric rupture occurs
- Inappetence
- Profuse sweating
- Tachypnea (often marked)

PHYSICAL EXAM FINDINGS

- Depressed mentation progressing to obtundation or recumbency
- Rectal temperature is variable, ranging from hypothermia caused by circulatory collapse and shock to pyrexia caused by endotoxemia.
- Marked tachycardia and tachypnea are usually noted.
- Mucous membranes are injected, muddy, purple to grey, and tacky or dry, with a prolonged capillary refill time.
- Decreased to absent gastrointestinal borborygmi
- ± Gross abdominal distension
- Rectal examination
  - Serosal surfaces often feel "gritty," and definition of the abdominal structures is often dramatically improved because of pneumoperitoneum.
  - Small intestinal distension may be present if gastric distension was secondary to a more distal intestinal obstruction.
  - May be normal

ETIOLOGY AND PATHOPHYSIOLOGY

- Any mechanical or functional lesion resulting in gastric outflow obstruction and gastric distension can ultimately culminate in gastric rupture (see "Gastric Dilation," "Gastric Impaction," "Gastric Outflow Obstruction," and "Grain Overload" in this section).
- Severe gastric ulceration causing perforation (uncommon; see "Gastric Ulceration in Adult Horses" and "Gastric Ulceration in Foals" in this section).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rupture of another gastrointestinal viscus
- Rarely, severe compromise to bowel with severe enterocolitis or protracted strangulating intestinal lesions can present similarly

INITIAL DATABASE

- Complete blood count
  - Significant polycythemia caused by hemoconcentration

ElibEVet.com

- Variable leukogram; often leukopenic
- Lactate: Often marked hyperlactatemia (>5 mmol/L) caused by circulatory collapse
- Serum biochemical profile
  - Variable electrolyte derangements
  - Often marked hyperglycemia
  - Marked metabolic acidosis is common
  - Variable azotemia (prerenal)
- Abdominal ultrasonography
  - Evaluation of the dorsal abdomen may be obscured by pneumoperitoneum.
  - Increased free peritoneal fluid of variable echogenicity may be present.
  - Small intestinal distension or increased mural thickening may be noted if primary small intestinal disease is present.
  - Occasionally normal (in acute rupture).

ADVANCED OR CONFIRMATORY TESTING

- Abdominocentesis
  - Gross evaluation
    - Green/brown or hemorrhagic discolored fluid
    - Feed material may be grossly visible.
    - Often foul smelling
  - Cytological evaluation
    - Feed material present
    - Intra- and extracellular mixed bacterial population, usually in large numbers
    - The leukocyte count and total protein concentration may be markedly increased.
- Exploratory celiotomy: Necessary for antemortem confirmation of gastric rupture, although rapid systemic decompensation and welfare implications normally preclude this procedure

TREATMENT

THERAPEUTIC GOAL(S)

Treatment is not indicated because of the grave prognosis.

ACUTE GENERAL TREATMENT

Humane euthanasia

PROGNOSIS AND OUTCOME

Grave

PEARLS & CONSIDERATIONS

- The potential fatal consequences of marked gastric distension highlight the importance of passage of a nasogastric tube and maintenance of gastric decompression in horses with signs of colic or unexplained tachycardia.
- The administration of oral or intragastric fluids or laxatives to horses that are producing gastric reflux or have small intestinal distension should be avoided.

AUTHOR: **KELSEY A. HART**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Gastric Ulceration in Adult Horses

BASIC INFORMATION

DEFINITION

Disruption of the gastric mucosa, potentially extending into the lamina propria

EPIDEMIOLOGY

SPECIES, AGE, SEX Most common in race horses (estimated >90% prevalence) and performance horses in active training

RISK FACTORS

- High-concentrate diet
- Stress: Shipping, showing, racing, heavy training
- Gastrointestinal (GI) disease or other illness
- Anorexia or withholding of feed
- Nonsteroidal antiinflammatory drug (NSAID) and corticosteroid therapy

ASSOCIATED CONDITIONS AND DISORDERS

- Inflammatory bowel disease (IBD; idiopathic or autoimmune)
- Gastric outflow obstruction

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Inappetence
- Colic: Usually mild and often associated with feeding
- Bruxism or hypersalivation
- Mild depression
- Weight loss may be noted if chronic or severe
- Behavior or performance issues are often presumptively or anecdotally associated but are not consistent findings. These may include:
  - Discomfort when girthing or mounting, reluctance to move forward, hypersensitivity to leg aids
  - Sudden or gradual decrease in performance
- Many adult horses have no clinical signs even with severe gastric ulceration.

PHYSICAL EXAM FINDINGS

- Usually within normal limits unless the patient has a concurrent predisposing disease.
- Moderately poor body condition and rough hair coat are sometimes present in severe cases. Marked weight loss in a horse that is diagnosed with gastric ulceration suggests concurrent predisposing disease such as IBD and warrants further diagnostic investigation for such a cause.
- Rectal examination: Usually normal unless ulceration is secondary to other GI disease such as IBD, a chronic or recurrent colonic displacement, or other partial intestinal obstruction.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hydrochloric acid is continuously secreted by the parietal cells in the gastric glandular epithelium.
- The gastric mucosa is typically protected from the extremely acidic gastric contents by several mechanisms, including:
  - A mucus-bicarbonate barrier
  - Gastric mucosal blood flow, which is supported by prostaglandins such as prostaglandin E_2 (PGE_2)
  - Eating, which increases gastric pH by stimulating secretion of alkaline saliva and by absorption of gastric secretions by ingested roughage to prevent their contact with the gastric mucosa

ElibeVet.com

- Anything that disrupts these innate protective mechanisms may result in gastric ulceration
  - High-concentrate diets, infrequent feeding and withholding of feed, and anorexia result in prolonged periods of low gastric pH, resulting in lesions in the poorly protected squamous mucosa.
  - NSAID and corticosteroid therapy (by decreased production of protective prostaglandins), intense exercise, and other systemic illness may result in alterations in mucosal blood flow, resulting in both squamous and glandular lesions.
- Bacterial causes of gastric ulceration (eg, *Helicobacter pylori*) have not been documented in horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Gastric neoplasia
- Infectious (bacterial or fungal) gastritis (rare)

INITIAL DATABASE

- Complete blood count
  - Usually within reference intervals.
  - Mild anemia may be present with severe ulceration, but severe hemorrhage associated with gastric ulceration is uncommon in horses.
- Serum biochemical profile
  - Usually within reference intervals.
  - The presence of a hypochloremic metabolic alkalosis in conjunction with gastric ulceration should warrant investigation for a primary gastric outflow obstruction.
  - Severe hypoproteinemia or hypoalbuminemia may suggest more diffuse intestinal protein loss, as with malabsorptive diseases such as IBD or intestinal neoplasia, and warrants further investigation for these conditions.
- Fecal occult blood test: Neither sensitive nor specific for gastric ulceration and thus not recommended for diagnosis
- Transabdominal ultrasonography
  - A portion of the gastric wall is visualized in the left cranial flank, in the region of the ninth to fourteenth intercostal spaces, but it is not possible to image the entire gastric contour in horses, so gastric ulceration may be easily missed by transabdominal ultrasonography.
  - Focal or diffusely increased gastric mural thickness (>1 cm) or focal disruptions in the contour of the gastric wall may indicate gastric ulceration but can be difficult to differentiate from normal gastric rugal folds.

ADVANCED OR CONFIRMATORY TESTING

Gastroscopy:

- A 2- to 3-m flexible endoscope is necessary to fully evaluate the stomach in adult horses and most ponies.
- Twelve to 24 hours of fasting is required before gastroscopy to ensure sufficient visualization for complete evaluation.
- The most common location for gastric ulceration is in the squamous mucosa, just above the margo plicatus, although ulceration may occur anywhere in the squamous or glandular mucosa, including the pyloric region or cardia.
- Ulceration in the cardia and distal esophagus is often associated with gastroesophageal reflux and pyloric outflow obstructions.
- Gastric ulcers are graded on a scale of 0 to 3
  - 0 = Normal, no ulceration
  - 1 = Mild ulceration with single or multifocal hyperemic areas or small superficial ulcers
  - 2 = Moderate ulceration with moderately sized single or multifocal ulcers
  - 3 = Severe ulceration with large, multifocal, coalescing or diffuse, deep, often hemorrhagic ulcers
- Hyperkeratosis of the squamous mucosa in the absence of active ulceration is consistent with previous gastric ulceration.

TREATMENT

THERAPEUTIC GOALS

- Eliminate predisposing disease, stress, or dietary causes.
- Increase gastric pH to limit further mucosal damage.
- Promote mucosal blood flow and support healing.

ACUTE GENERAL TREATMENT

- Decrease or discontinue NSAID therapy if at all possible.
- Decrease or eliminate dietary concentrate and permit access to pasture if possible.
- Gastric acid suppression
  - Proton pump inhibitors
    - Omeprazole: 4 mg/kg PO q24h
      - Requires up to 72 hours to effectively increase gastric pH
      - A lower dose (2 mg/kg PO q24h) may be effective in treating gastric ulceration
      - Very effective, with a success rate greater than 95%
      - The parenteral form (Losec, 0.5 mg/kg IV q24h) may be useful in hospitalized patients in which gastric reflux prevents oral administration (not available in the United States).
    - Pantoprazole (1.5 mg/kg IV q24h) is available for patients in which oral omeprazole cannot be used, but pantoprazole may be cost prohibitive.
  - Histamine H2-receptor antagonists
    - Cimetidine: 16 to 25 mg/kg PO or 6.6 mg/kg IV q6–8h
      - Inhibit hepatic cytochrome p450 oxidase, thus altering metabolism of other drugs; use with caution in patients on concurrent medications
    - Ranitidine: 6.6 mg/kg PO or 1.5 mg/kg IV q8h
    - Famotidine: 2.8 to 4.0 mg/kg PO or 0.23 to 0.5 mg/kg IV q8–12h
    - Because of the need for more frequent administration, these agents are most useful to rapidly increase gastric pH during the initial 72 hours of proton pump inhibitor therapy but may also be effective when used alone.
  - Antacids (magnesium hydroxide, aluminum hydroxide): Require frequent administration (q2–4h) to have any effect on increasing gastric pH; thus not recommended
- Mucosal protectants
  - Sucralfate: 20 mg/kg PO q6–8h
    - Adheres to ulcerated mucosa, providing protection from gastric acid, and stimulates local production of protective prostaglandins and cytokines to promote mucosal healing
    - Useful in improving comfort during initial therapy (3–7 days) in horses with severe gastric ulceration
  - Misoprostol: 2.5 to 5.0 µg/kg
    - A PGE_2 analogue that inhibits acid secretion, promotes mucosal blood flow, and enhances bicarbonate and mucus production
    - Useful in NSAID-induced gastric ulceration
    - Side effects may include abdominal pain and diarrhea.
    - Should not be used in pregnant mares or handled by women who are or may become pregnant

CHRONIC TREATMENT

Acid suppression therapy should be continued for 3 to 4 weeks to ensure complete mucosal healing.

DRUG INTERACTIONS

Sucralfate can prevent the absorption of other drugs and should not be given within 1 to 2 hours of other medications, particularly orally administered H2-receptor antagonists.

ElibVet.com

POSSIBLE COMPLICATIONS

Perforation of a gastric ulcer may occur but is very rare in adult horses.

RECOMMENDED MONITORING

- Improvement in clinical signs is often adequate for determining response to therapy.
- In asymptomatic horses or those with severe ulceration, gastroscopy should be repeated in 4 to 6 weeks to ensure complete resolution.
- Repeat gastroscopy is imperative in horses whose clinical signs do not improve with or recur after medical therapy. Biopsy of gastric lesions is warranted in these cases and can be performed transendoscopically.

PROGNOSIS AND OUTCOME

- Primary gastric ulceration carries a good prognosis with medical therapy of sufficient duration and appropriate diet and management changes.
- Recurrence is common in performance horses. Some horses may require intermittent or prolonged prophylactic therapy (see below).

PEARLS & CONSIDERATIONS

COMMENTS

Gastric ulceration in a pasture or pleasure horse or persistent or recurrent gastric ulceration despite appropriate medical therapy and dietary and management changes should prompt an extensive diagnostic search for an underlying and predisposing problem (eg, IBD, recurrent intestinal obstruction).

PREVENTION

- Dietary and routine management
  - Limit or eliminate concentrates or grain.
  - Feed small meals often and provide access to pasture or free-choice hay to prevent large fluctuations in or prolonged periods of low gastric pH.
  - Elimination of shipping and training stress is impossible in racehorses and performance horses, but provision of maximal turnout time and maintenance of a consistent routine are helpful and should be attempted.
  - Avoid long-term NSAID or corticosteroid therapy if possible.
- Medical ulcer prophylaxis
  - Omeprazole: 1 to 2 mg/kg PO q24h
  - Has been shown to effectively prevent gastric ulceration in race horses in some studies but may not be necessary with above diet and routine changes
  - Efficacy at preventing NSAID-induced gastric ulceration is unknown
- Corn oil (45 mL PO qd on feed) has been shown to decrease gastric acid output and increase PGE2 synthesis in horses and thus may have some gastroprotective effects. However, it was ineffective in preventing experimentally induced gastric ulceration in one study.

Gastric Ulceration in Foals

BASIC INFORMATION

DEFINITION

Disruption of the gastric mucosa, potentially extending into the lamina propria

SYNONYM(S)

Gastroduodenal ulcer disease (GDUD)

EPIDEMIOLOGY

SPECIES, AGE, SEX Most common in foals ages 1 to 6 months but is also occasionally seen in younger foals

RISK FACTORS

- Gastrointestinal (GI) disease, especially diarrhea
- Nonsteroidal antiinflammatory drug (NSAID) therapy
- Anorexia or withholding of enteral nutrition

ASSOCIATED CONDITIONS AND DISORDERS Neonatal encephalopathy (neonatal maladjustment syndrome) and sepsis in young foals

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Colic
  - Variable severity but usually more severe than in adult horses with gastric ulceration.
  - May be manifest as increased periods of recumbency.
  - Young foals with gastric ulcers are often observed to roll onto their backs or lie in dorsal recumbency, but this may also be observed in foals with colic due to other causes.
- Bruxism
- Hypersalivation
- Inappetence
- Diarrhea is commonly associated with GDUD in foals in contrast to the case in adult horses.
- Poor condition if the case is chronic and severe.
- In contrast to adult horses, foals with GDUD almost always show related clinical signs.

PHYSICAL EXAM FINDINGS

- Tachycardia and tachypnea are common during colic episodes
- ± Fever
- ± Evidence of diarrhea
- Poor body condition and rough hair coat may be present in severe cases

ETIOLOGY AND PATHOPHYSIOLOGY

- Similar to adult horses, in which an imbalance between innate gastroprotective factors and injurious factors such as hydrochloric acid and proteolytic enzymes (pepsin) occurs
  - Innate gastroprotective factors include the mucus-bicarbonate barrier; adequate gastric mucosal blood flow; and nursing or eating, which rapidly increases gastric pH.
  - These protective mechanisms are easily disrupted in foals, with rapid decreases in gastric pH seen in healthy foals with more than 20 minutes of not nursing. This may result in lesions in the glandular mucosa.

ElibeVet.com

- The gastric squamous mucosa undergoes rapid thickening and then desquamation in neonatal foals, which may also predispose them to squamous mucosal lesions.
- Concurrent disease in foals, such as neonatal encephalopathy or sepsis, may significantly disrupt gastric mucosal blood flow and may result in or worsen both glandular and squamous gastric ulceration.

- Duodenal ulceration is uncommon in adult horses but occurs frequently in foals. This may be a direct result of impaired duodenal mucosal defenses and subsequent injury from exposure to gastric acid, or it may be related to more diffuse intestinal disease (bacterial enterocolitis).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious enterocolitis
- Pyloric stenosis (congenital)
- Small intestinal obstructive lesions

INITIAL DATABASE

- Complete blood count
  - Usually within reference intervals with primary GDUD.
  - Mild anemia may be present with severe ulceration, but severe hemorrhage is uncommon.
  - Abnormalities in the leukogram, such as leukopenia or leukocytosis, may be present in severe cases of GDUD or may reflect concurrent infectious enterocolitis, sepsis, or other illness.
- Serum biochemical profile
  - Usually within reference intervals.
  - The presence of a hypochloremic metabolic alkalosis should warrant investigation for a concurrent pyloric outflow obstruction.
- Fecal occult blood test: Neither sensitive nor specific for gastric ulceration and thus not useful for diagnosis.
- Transabdominal ultrasonography
  - A portion of the gastric wall is visualized in the left cranial flank in the region of the ninth to fourteenth intercostal spaces, but it is not possible to image the entire gastric contour, so gastric ulceration may be easily missed.
  - Focal or diffusely increased gastric mural thickness (>8–10 mm) or focal disruptions in the contour of the gastric wall may indicate gastric ulceration but can be difficult to differentiate from normal gastric rugal folds.

ADVANCED OR CONFIRMATORY TESTING

- Gastroduodenoscopy
  - A 2- to 3-m flexible endoscope is necessary to fully evaluate the stomach and duodenum in most foals.
  - Feed should be withheld and nursing prevented for approximately 1 hour before gastroduodenoscopy in very young foals and for 2 to 6 hours in older foals on solid feed.
  - Ulceration may occur anywhere in the squamous or glandular mucosa, pyloric region, or cardia. Glandular and pyloric mucosal lesions and duodenal ulcers are more common in foals than adults.
  - Ulceration in the cardia and distal esophagus is often associated with gastroesophageal reflux and pyloric outflow obstructions. Pyloric sphincter function should be evaluated carefully and further evaluation or treatment for gastric outflow obstructions pursued if indicated (see "Pyloric Stenosis" in this section).
  - A specific grading system has not been established for foals, but a similar grading system as for adult horses (see "Gastric Ulceration in Adult Horses" in this section) is often used.

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate predisposing causes and treat the underlying disease.
- Increase gastric pH to limit further mucosal damage.
- Promote mucosal blood flow and support healing.

ACUTE GENERAL TREATMENT

- Discontinue and avoid NSAID therapy.
- Promote frequent nursing or feed (roughage) intake in older foals to help increase gastric pH.
- Supportive care with IV fluids is indicated in dehydrated or anorectic foals.
- Acid suppression
  - Proton pump inhibitors
    - Omeprazole: 4 mg/kg PO q24h
      - Appears to increase gastric pH more rapidly (with one dose) in foals compared with adult horses (with approximately three doses).
      - The parenteral form (Losec, 0.5 mg/kg IV q24h) is useful in foals in which gastric reflux prevents PO administration (not available in the United States).
    - Pantoprazole: 1.5 mg/kg IV q24h
      - Has been shown to effectively increase gastric pH in foals
      - Available in the United States
  - Histamine H2-receptor antagonists
    - Cimetidine: 16 to 25 mg/kg PO or 6.6 mg/kg IV q6–8h
      - Inhibits hepatic cytochrome p450 oxidase and thus alters metabolism of other drugs; use with caution in patients on concurrent medications
    - Ranitidine: 6.6 mg/kg PO or 1.5 mg/kg IV q8h
    - Famotidine: 2.8 to 4.0 mg/kg PO or 0.23 to 0.5 mg/kg IV q8–12h
  - Antacids (magnesium hydroxide, aluminum hydroxide): Less effective than the above; not recommended
- Mucosal protectants
  - Sucralfate: 20 mg/kg PO q6–8h
    - Adheres to ulcerated mucosa, providing protection from gastric acid, and stimulates local production of protective prostaglandins and cytokines to promote mucosal healing
    - Appears to effectively improve comfort in foals with severe lesions
  - Misoprostol: 2.5 to 5.0 µg/kg PO q12–24h
    - A prostaglandin E2 (PGE2) analogue that inhibits acid secretion, promotes mucosal blood flow, and enhances bicarbonate and mucus production
    - Useful in NSAID-induced gastric ulceration
    - Side effects may include abdominal pain and diarrhea
    - Should not be handled by women who are or may become pregnant
- Analgesic therapy
  - Avoid NSAIDS!
  - Sedation with diazepam, α_2 adrenergic agonists, or opioids (butorphanol) may be beneficial in foals with severe colic.
  - Intragastric administration of 2% lidocaine may provide transient pain relief in severe cases (10–20 mL diluted to 60 mL with saline for an average foal; be careful not to exceed a total dose of ~7–8 mg/kg). IV lidocaine (1.5 mg/kg IV slow bolus; then 0.05 mg/kg/min IV continuous rate infusion) may also be beneficial for analgesic and prokinetic effects, but lidocaine safety and pharmacokinetics have not been determined in foals.
- Antimicrobial therapy
  - Not indicated in foals with uncomplicated primary GDUD
  - Broad-spectrum antimicrobial prophylaxis should be considered in

ElibeVet.com

foals with severe GDUD with fever or concurrent diarrhea because a significant proportion of foals with diarrhea have bacteremia.

CHRONIC TREATMENT

Medical therapy should be continued for 3 to 4 weeks to ensure complete mucosal healing.

DRUG INTERACTIONS

Sucralfate can prevent the absorption of other drugs and should not be given within 1 to 2 hours of other oral medications, particularly orally administered H2-receptor antagonists.

POSSIBLE COMPLICATIONS

- Gastric or duodenal ulcer perforation
- Pyloric or duodenal stricture resulting in pyloric outflow obstruction

RECOMMENDED MONITORING

Gastroscopy should be repeated in approximately 4 weeks to ensure complete resolution and assess for development of pyloric or duodenal stricture formation.

PROGNOSIS AND OUTCOME

- Prognosis is good if foal shows a good clinical response within 3 to 5 days of initiating early and aggressive medical therapy.
- Prognosis is guarded to poor if pyloric outflow obstruction develops.

PEARLS & CONSIDERATIONS

COMMENTS

- Gastric acid provides an important protective mechanism in preventing GI bacterial invasion; thus increasing the gastric pH with acid suppression therapy is not innocuous.
  - Critically ill, recumbent neonatal foals do not appear to have extremely acidic gastric pH and may not need acid suppression therapy.
  - Sucralfate may provide adequate gastric ulcer prophylaxis in foals that are at risk for but do not have active gastric ulceration.
- However, foals may be at greater risk for NSAID-induced gastric ulceration than adult horses.
  - Avoid NSAIDs in foals if possible.
  - If prolonged NSAID use is unavoidable, concurrent administration of sucralfate or omeprazole may be considered for ulcer prophylaxis, although the efficacy of omeprazole in preventing NSAID-induced ulceration has not been established experimentally.

Glanders

BASIC INFORMATION

DEFINITION

A disease of horses caused by infection with the bacteria *Burkholderia mallei* that may affect the skin, nasal passages, or lungs

SYNONYM(S)

Farcy (cutaneous form)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Horses, donkeys, and mules are affected.
- Occasional cases are seen in cats, dogs, goats, sheep, and camels.
- Carnivores may be infected from ingestion of contaminated meat.

RISK FACTORS Poor sanitation, crowding, immunosuppression

CONTAGION AND ZOONOSIS

- Rare but serious zoonotic disease
- Enters via cutaneous exposure
- Cutaneous and systemic infections occur with mortality that may approach 95% in untreated humans

GEOGRAPHY AND SEASONALITY

- Restricted to Eastern Europe, Asia, Africa, the Middle East, Central America, and South America
- Endemic in some countries, including Iraq, Turkey, Pakistan, India, Mongolia, and China
- Eradicated from Europe, Australia, and North America

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cutaneous form
- Nasal form
- Acute pulmonary form

HISTORY, CHIEF COMPLAINT

- Cutaneous swellings, erosions, ulcerations with exudate
- Lymphatic cording
- Depression, inappetence
- Dyspnea, nasal discharge, increased respiratory rate

PHYSICAL EXAM FINDINGS

- Cutaneous form ("farcy"): Nodules with subsequent development of ulcers and exudation. Swollen lymphatic vessels with cording and development of "farcy buds" that enlarge, ulcerate, and drain.
- Nasal form: Nodules on nasal septum develop into stellate scars with purulent nasal discharge. These may obstruct the nasopharynx with severe dyspnea.
- Acute pulmonary form: High fever, bronchopneumonia

ETIOLOGY AND PATHOPHYSIOLOGY

- Short, gram-negative, aerobic, facultative intracellular, nonmotile, non–spore-forming bacterial rods
- Host-adapted pathogen that does not persist long in the environment
- Probably enters horses through the mucous membranes with common feed and water the most likely sources of infection
- Subclinical infection in horses may contribute to spread in a group of horses
- Disease may be more severe in donkeys and mules

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cutaneous form ("farcy"): Ulcerative lymphangitis (*Corynebacterium pseudotuberculosis*), sporotrichosis (*Sporothrix schenckii*), epizootic lymphangitis (*Histoplasma farciminosum*), melioidoses (*Burkholderia pseudomallei*)
- Nasal form: Strangles, neoplasia, upper respiratory tract infection
- Acute pulmonary form: Bacterial bronchopneumonia, African horse sickness, acute interstitial pneumonia

ElibeVet.com

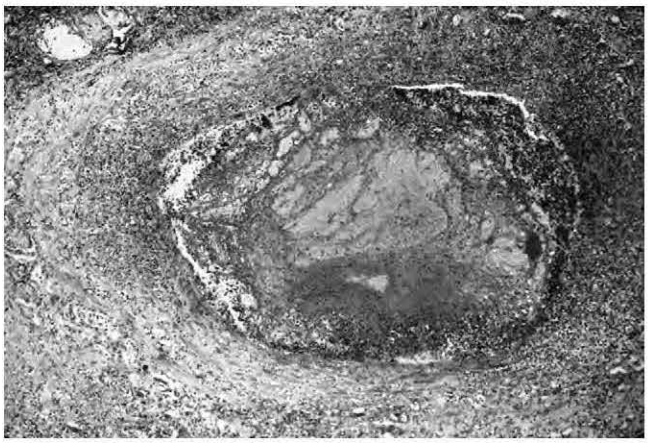

FIGURE 4 Photomicrograph of a typical nodule from a horse with glanders. (From Sellon DC, Long MT: *Equine infectious diseases.* St Louis, 2007, Saunders Elsevier.)

INITIAL DATABASE

Laboratory tests are consistent with acute or chronic infection.

ADVANCED OR CONFIRMATORY TESTING

- Mallein test: Intradermal injection of bacterial extract in the neck or eyelid with subsequent observation for hypersensitivity reaction. Reactions include fever higher than 104° F, local swelling of 35 mm in diameter after 48 to 72 hours, and lacrimation. False-negative and -positive reactions may occur.
- Serologic tests: Complement fixation, agglutination, enzyme-linked immunosorbent assay, and counter immunoelectrophoresis. Many false-positive and -negative results may occur.
- Culture or immunohistochemical staining to detect organism in tissues or exudates.

TREATMENT

THERAPEUTIC GOAL(S)

Eradication of the disease

ACUTE GENERAL TREATMENT

- The organism may be susceptible to enrofloxacin, ticarcillin-clavulanate, imipenem, chloramphenicol, doxycycline, rifampicin, and erythromycin.
- Treatment is rarely attempted.
- There has been a recent report of cure with 3-week treatment using combination treatment with IV enrofloxacin and trimethoprim-sulfadiazine.

PROGNOSIS AND OUTCOME

- Euthanasia or slaughter of infected Equids is strongly recommended and is mandatory in many countries, including the United States.
- No vaccine is available.

PEARLS & CONSIDERATIONS

There have been no naturally occurring cases of glanders in North America in more than 60 years.

EDITORS: **MAUREEN T. LONG** and **DEBRA C. SELLON**

Glaucoma

BASIC INFORMATION

DEFINITION

Pathologic disease state associated with elevated intraocular pressure (IOP)

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Horses prone to developing recurrent uveitis are at risk for developing glaucoma.

RISK FACTORS

- Any type of ocular trauma
- Chronic or recurrent uveitis

ASSOCIATED CONDITIONS AND DISORDERS Chronic or recurrent uveitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary glaucoma: No underlying or preceding ocular disease

ElibeVet.com

- Secondary glaucoma: Any ocular abnormality, such as uveitis or neoplasia, that results in elevated IOP and glaucoma

HISTORY, CHIEF COMPLAINT

- The most common cause of glaucoma in horses is chronic or recurrent uveitis (a type of secondary glaucoma). Historically, these horses have multiple episodes of intraocular inflammation followed by a severe, unrelenting bout of ocular cloudiness and discomfort (as a result of the development of glaucoma) that does not respond to traditional uveitis therapy.
- Horses with primary glaucoma most commonly present with partial or diffuse corneal edema. These eyes may or may not be painful.

PHYSICAL EXAM FINDINGS

- Horses with secondary glaucoma associated with chronic uveitis have high IOP (40–80 mm Hg); diffusely edematous corneas; and signs of chronic intraocular inflammation, such as posterior synechia (adhesions), a miotic pupil, and cataract formation. These eyes may appear enlarged or normal sized (Figure 1).
- Horses with primary glaucoma most commonly present with partial or diffuse corneal edema. These eyes may or may not be painful. Early in the disease process, vision and pupil size may be normal. IOP may range from 35 to 80 mm Hg.
- With chronic primary glaucoma, vision decreases, the cornea becomes diffusely edematous, and other signs of chronic glaucoma may become evident (eg, diffuse corneal edema, corneal striae, retinal and optic nerve degeneration). In general, however, the horse tends to lose vision much later in the disease process compared with dogs and humans. An increased size of the eye (>40–45 mm anterior to posterior) and lens subluxation may also occur late in the disease.

ETIOLOGY AND PATHOPHYSIOLOGY

Aqueous humor, which acts to supply metabolic needs of intraocular structures, is produced constantly by the ciliary body of the equine eye. The fluid must also drain constantly from the eye through the iridocorneal and uveoscleral outflow pathways. Obstruction of this outflow of fluid may be the result of an abnormally developed drain (ie, primary glaucoma) or through damage to the drain from scarring, vascularization, or accumulation of debris (ie, secondary glaucoma). The result of this obstruction is retention of aqueous humor and a subsequent increase in the pressure within the eye. The pathologic disease state associated with elevated IOP is called glaucoma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of corneal edema should be ruled out:

- Corneal ulcers
- Immune-mediated keratitis (IMMK), especially the endothelial form of IMMK
- Uveitis
- Primary endothelial disease
- Anterior lens luxation

INITIAL DATABASE

- A tonometer is essential for the diagnosis of equine glaucoma. Applanation tonometers must be used. The most practical and portable applanation tonometers are the Tonopen, Tonometer, and TonoVet Tonometer. For accurate tonometry, auriculopalpebral nerve blocks should be performed because tension on the eyelids may artificially elevate the IOP. In addition, tranquilization may artificially lower the IOP. The pressure measurement should be taken from the most normal, least edematous location of the cornea if possible.
- A thorough and complete ophthalmic examination should also be done to help differentiate the cause of the glaucoma and to rule out other causes of corneal edema, such as keratitis. With glaucoma, the cornea is edematous, but rarely, yellow or creamy cellular infiltrate, epithelial loss (ie, corneal ulceration), or diffuse vascularization is present. These findings are more common with primary corneal disease. The complete ophthalmic examination will also determine if the glaucoma is primary or secondary. Glaucoma secondary to intraocular disease other than uveitis is rare but is possible with intraocular tumors and luxation of the lens.

ADVANCED OR CONFIRMATORY TESTING

Tonometry is needed for confirmation of glaucoma.

TREATMENT

THERAPEUTIC GOAL(S)

Lower the IOP

ACUTE GENERAL TREATMENT

Treatment options reported in the horse include:

- Topical timolol 0.5% (1 drop or 0.2 mL) BID
- If there is poor control with this therapy (after 7–10 days), the next choice is a combination of timolol 0.5% and dorzolamide HCl (1 drop or 0.2 mL q8h).
- Another option is brinzolamide HCl (1 drop or 0.2 mL q8h).
- Systemic nonsteroidal antiinflammatory drugs also seem to lower the IOP by an unknown mechanism.

CHRONIC TREATMENT

If there continues to be poor IOP control and there is potential for vision, then laser cycloablation (laser destruction of the ciliary body) is indicated.

POSSIBLE COMPLICATIONS

Vision loss is common because the disease is progressive. Both eyes are at risk and should be monitored.

RECOMMENDED MONITORING

Examine weekly until pressures are controlled and then every 3 months.

PROGNOSIS AND OUTCOME

Prognosis is guarded for saving the eye.

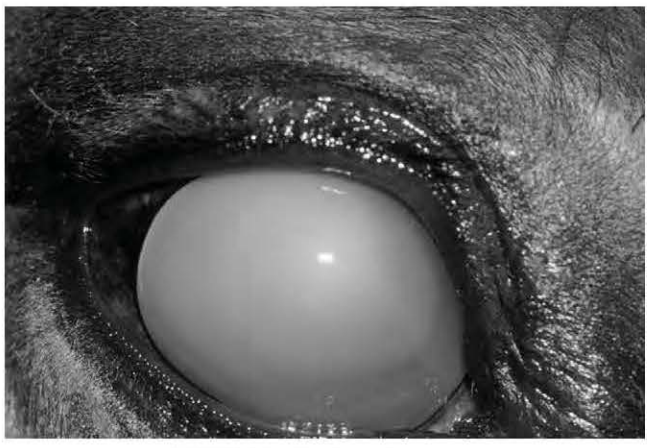

FIGURE 1 Equine glaucoma.

ElibeVet.com

PEARLS & CONSIDERATIONS

COMMENTS

Both eyes are at risk and should be monitored.

PREVENTION

- Minimizing ocular and corneal trauma may help prevent the development of glaucoma.
- Use of a quality fly mask is recommended.
- Feeding hay on the ground is recommended to minimize ocular trauma.

CLIENT EDUCATION

Client communication is essential so it is understood that treatment is aimed at controlling, not curing, this condition. Persistent treatment is required to maintain vision.

AUTHOR & EDITOR: **BRIAN C. GILGER**

Glomerulonephritis

BASIC INFORMATION

DEFINITION

Glomerulonephritis is a renal disease in which immune-mediated glomerular damage is the initiating factor. The hallmark of glomerulonephritis is increased permeability of the glomerular barrier. Proliferative glomerulonephritis is characterized by proliferation of the mesangial cells with an influx of inflammatory cells. Membranous glomerulonephritis is characterized by accumulation of matrix and thickening of the glomerular basement membrane (GBM) and capillary wall.

SYNONYM(S)

Glomerulonephropathy, proliferative glomerulonephritis, membranous glomerulonephritis

EPIDEMIOLOGY

RISK FACTORS Glomerulonephritis has been reported with several underlying disease processes, including equine infectious anemia (75% of cases have histologic evidence of glomerulonephritis), *Streptococcus equi* subsp. *equi* and *Streptococcus equi* subsp. *zooepidemicus* infection, purpura hemorrhagica, and leptospirosis. Any chronic infection or neoplasia can be a predisposing cause of glomerulonephritis.

CONTAGION AND ZOONOSIS *S. equi* subsp. *equi* and *S. equi* subsp. *zooepidemicus* may cause poststreptococcal glomerulonephritis in humans.

ASSOCIATED CONDITIONS AND DISORDERS Hypercoagulability and thrombosis are common complications of glomerulonephritis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Proliferative or membranous glomerulonephritis
- Glomerulonephritis may cause subclinical or clinical disease.

HISTORY, CHIEF COMPLAINT

- Weight loss
- Polyuria
- Polydipsia
- ± Ventral edema
- ± Decreased appetite
- ± Lethargy

PHYSICAL EXAM FINDINGS

- Poor body condition
- ± Ventral edema

ETIOLOGY AND PATHOPHYSIOLOGY

- Circulating immune complexes are deposited along the glomerular capillaries or form in situ along the GBM.
- Rarely, glomerulonephritis results from true immune-mediated disease caused by antibodies against the GBM.
- Inflammatory cells infiltrate the glomerulus, releasing proteolytic enzymes and reactive oxygen species that further damage the glomerulus and increase glomerular permeability.
- Complement is activated by immune complexes (type III hypersensitivity), leading to platelet activation, thrombosis, and further glomerular damage.
- Mesangial cells proliferate, excess matrix is produced, and fibrosis occurs.
- The glomerular barrier may also be damaged as a result of ischemia, toxic insult, or infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Protein-losing enteropathy
- Protein-losing nephropathy (glomerulonephritis or acute tubular necrosis)
- Hepatic disease

INITIAL DATABASE

- Complete blood count and fibrinogen concentration
- Serum chemistries: Decreased total protein and albumin; may also have elevated blood urea nitrogen, creatinine, and triglyceride concentrations
- Urinalysis: Proteinuria; may also have hematuria and lipiduria
- Rectal examination: The left kidney may feel small if the patient has advanced renal disease.
- Renal ultrasonography: Loss of corticomedullary contrast with advanced renal disease

ADVANCED OR CONFIRMATORY TESTING

- Glucose or D-xylose absorption test: To rule out protein-losing enteropathy
- Urine protein:creatinine ratio: A value greater than 2:1 indicates glomerular protein loss
- Antithrombin III: Decreased in plasma and increased in urine
- Systemic complement concentration: Decreased
- Systemic blood pressure: May be increased
- Streptococcal M-protein titer: May be increased if *S. equi* infection is the underlying cause
- Coggins test: Positive result if equine infectious anemia is the underlying cause
- Renal biopsy: To confirm lesion and help determine prognosis
- Light microscopy, immunohistochemistry, or electron microscopy: To confirm lesion
- Immunofluorescence: To determine the underlying etiology. Granular, irregular staining indicates immune complex deposition, whereas linear staining indicates anti-GBM antibodies.

TREATMENT

THERAPEUTIC GOAL(S)

- Address underlying disease, if present
- Provide immune modulation
- Reduce hypercoagulability
- Reduce hypertension
- Decrease dietary protein intake

ElibeVet.com

ACUTE/CHRONIC GENERAL TREATMENT

- Immunosuppressive therapy: Only if indicated for underlying disease. Corticosteroids are known to increase GFR, stimulate glomerular hypertrophy, and enhance matrix production in humans. They can also increase the risk of infection, thrombosis, and azotemia.
- Immune modulation: Supplement dietary omega-3 fatty acids, such as linseed oil (2–6 oz/d), canola oil, or commercial diets high in omega-3 fatty acids.
- Hypercoagulability: Low-dose aspirin therapy (4–12 mg/kg PO q24–48h).
- Hypertension: Angiotensin-converting enzyme (ACE) inhibitors, such as enalapril (0.5–1 mg/kg PO q12–24h), may be effective, if not cost prohibitive. Acepromazine (0.02 mg/kg PO q8–12h) is inferior to the ACE inhibitors but may be useful.
- Reduce dietary protein: 1.3 g of crude protein/kg/d is the lower end of protein requirement for horses. This can be accomplished by feeding 6.4 kg of grass hay and 2 kg of 12% protein senior-type feed per day.

POSSIBLE COMPLICATIONS

Long-term immunosuppressive treatment may increase the risk of concurrent disease and laminitis (if large doses of corticosteroids are administered).

RECOMMENDED MONITORING

Monitor the degree of proteinuria and azotemia as well as the horse's clinical condition.

PROGNOSIS AND OUTCOME

- The prognosis for long-term survival is poor, even with treatment.
- Horses with chronic low-grade azotemia may still be used for breeding and light riding.

PEARLS & CONSIDERATIONS

COMMENTS

- Renal changes caused by glomerulonephritis are common in horses, but clinical disease is rare.
- Glomerulonephritis is the most common cause of chronic renal failure in horses.
- Horses are the only domestic species in which anti-GBM complexes have been found in naturally occurring cases of disease.
- Horses are the only species to have focal glomerulosclerosis.

PREVENTION

Appropriate routine care and quarantine protocols may reduce the risk of infectious diseases that have been associated with glomerulonephritis.

Grain Overload

BASIC INFORMATION

DEFINITION

Ingestion (almost always accidental) of a large quantity of grain

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Recent consumption of a large amount of grain
- Well-educated horse owners may request evaluation and treatment immediately after discovering excessive grain ingestion before the development of clinical signs.
- Signs typically occur within 1 to 48 hours, depending on the amount and type of grain consumed, and usually include colic, profuse sweating, and trembling.
- Lameness caused by acute laminitis may also be observed.
- Diarrhea is sometimes reported but is less common.

PHYSICAL EXAM FINDINGS

- Early on, the physical examination results may be within normal limits.
- If clinical signs are present, they include some or all of the following:
  - Marked tachycardia and tachypnea
  - Variable rectal temperature, ranging from hypothermia because of poor perfusion or shock to pyrexia associated with endotoxemia
  - Hyperemic to purple mucous membranes, prolonged capillary refill time, cold extremities, poor jugular refill, prolonged skin tent
  - Severe gross abdominal distension, absent gastrointestinal borborygmi, or hypermotile or "fluidy" gastrointestinal sounds
  - Signs of laminitis: Bounding digital pulses, weight shifting, lameness, reluctance to move or pick up the feet, sensitivity to hoof testers over the toe
- Rectal examination
  - May be within normal limits early on.
  - Colonic gas distension with taut colonic bands is usually present by the time clinical signs have developed.

ETIOLOGY AND PATHOPHYSIOLOGY Rapid consumption of an excessive amount of soluble carbohydrates has several consequences.

- Early on, especially if a very large volume of grain has been consumed, overdistension of the stomach and primary gastric dilatation caused by fermentation occurs (see "Gastric Dilation" in this section) and may result in gastric rupture in severe cases.
- As the ingested grain material enters the small intestine, the enteric carbohydrate digestive capacity is overwhelmed. Fermentation of this excess carbohydrate thus occurs in the cecum and large colon, resulting in rapid overgrowth of fermenting hindgut bacteria and death of normal fiber-digesting bacterial flora.
- This damages the colonic mucosal barrier, permitting bacterial byproducts, such as lactic acid, endotoxin, and exotoxins, to enter the systemic circulation and culminating in a massive systemic inflammatory response.
- The horse may succumb to the severe cardiovascular consequences of septic or endotoxic and hypovolemic shock or may develop laminar vascular disruption and inflammation culminating in laminitis.

ElibeVet.com

DIAGNOSIS

INITIAL DATABASE

- Passage of a nasogastric tube: May yield significant volumes of fluid or gas if gastric dilatation is severe. An indwelling nasogastric tube should be left in place for at least 12 to 24 hours to maintain gastric decompression (see "Gastric Dilation" in this section).
- Complete blood count: Severe polycythemia and leukopenia characterized by neutropenia with a left shift and toxic changes in neutrophils is evident in symptomatic horses.
- Serum biochemistry profile and blood gas analysis
  - Moderate to severe lactic acidosis
  - Variable electrolyte derangements
  - Azotemia is frequently observed because of prerenal, renal, or combined factors.

ADVANCED OR CONFIRMATORY TESTING

- Transabdominal ultrasonography may reveal gastric, small intestinal, or large colonic distension or increased mural thickness.
- Peritoneal fluid analysis is usually within reference intervals, but if colonic damage is severe, evidence of intraperitoneal inflammation or ischemia (increased white blood cell count and total protein concentration, sanguinous appearance) may be apparent.

TREATMENT

THERAPEUTIC GOAL(S)

- In acute ingestion, relieve gastric distension and remove grain from the stomach if possible.
- Prevent or limit colonic absorption of bacterial toxins.
- Provide supportive care for septic, endotoxic, and hypovolemic shock.
- Provide laminitis prophylaxis.

ACUTE GENERAL TREATMENT

- Asymptomatic horses
  - Gastric lavage (see "Gastric Impaction" in this section) is indicated if the horse is evaluated in the first 4 to 6 hours after grain ingestion or if a significant amount of feed remains in the stomach on initial evaluation.
  - If gastric reflux is absent, substances to bind bacterial toxins and promote colonic emptying should be administered via nasogastric tube and may include:
    - Activated charcoal: 0.5 lb in 1 L warm water once
    - Bio-Sponge powder: 1 to 2 lb in 1 L water q24h for 1 to 3 days
    - Mineral oil: 2 to 3 L q24h for 1 to 3 days
  - Antiinflammatory and analgesic therapy: Flunixin meglumine (1.1 mg/kg IV once and then 0.25–0.3 mg/kg IV or PO q6-8h for 48–72 hours).
  - Remove all feed for 24 hours (permit free access to water) and then gradually reintroduce the horse to feed with small amounts of grass hay or short periods of pasture grazing over 24 to 48 hours.
- Symptomatic horses
  - Gastric lavage and bacterial toxin binders or laxative therapy as above
  - If cecal or colonic distension is severe, cecal trocharization may be necessary to relieve distension (see "Cecal Trocharization" in Section II).
  - Antiinflammatory and analgesic therapy
    - Flunixin meglumine: 1.1 mg/kg IV q12h initially for colic; then decreased to 0.25 mg/kg IV q6–8h for antiinflammatory effects when signs of colic resolve
    - Lidocaine: 1.3 mg/kg IV as a slow bolus and then 0.05 mg/kg/min IV continuous-rate infusion (promotes intestinal motility in addition to providing analgesic therapy)
    - ± Pentoxifylline: 8 mg/kg PO q8–12h (may decrease inflammatory cytokine production and promote laminar blood flow via rheologic and antiplatelet effects)
    - ± Dimethylsulfoxide (90% solution): 0.5 to 1.0 g/kg diluted to less than 10% solution in IV fluids q12h for 1 to 3 days (may scavenge free radicals and limit oxidative injury)
  - Antiendotoxic therapy
    - Equine plasma (2–4 L IV; may be regular equine plasma or hyperimmune plasma with antiendotoxin antibodies) or hyperimmune antiendotoxin serum (Endoserum, 1–2 mL/kg diluted in 3–5 L isotonic fluids IV)
    - Polymyxin-B: 2000 to 6000 IU/kg (diluted in 500–1000 mL 0.9% saline) IV q12h for 1 to 3 days after the patient is hydrated if renal function is adequate
  - Laminitis prophylaxis
    - Placement of frog supports, deep bedding, and maintenance in ice boots for 1 to 2 days should be initiated immediately even if no signs of laminitis are present.
    - If signs of laminitis occur, treatment should be rapid and aggressive (see "Laminitis, Acute" in this section).
  - IV fluid therapy
    - Initial fluid resuscitation may include isotonic crystalloids (25–50 mL/kg IV bolus), hypertonic saline (2–4 mL/kg IV once), or Hetastarch (5–10 mL/kg IV bolus once).
    - Resuscitation fluids should be followed by balanced polyionic crystalloid IV fluids at 100 to 200 mL/kg/d until rehydration is established and then at 50 to 100 mL/kg/d for maintenance as needed.
  - Feed should be withheld until signs of colic, gastric distension, and gastric reflux have ceased and then should be reintroduced as for asymptomatic horses as above.
  - Antimicrobial therapy should be avoided because it may slow reestablishment of normal colonic bacterial flora.

POSSIBLE COMPLICATIONS

- Laminitis
- Gastric rupture
- Colonic rupture
- Death from cardiovascular collapse in endotoxic shock

PROGNOSIS AND OUTCOME

- Asymptomatic horses: Prognosis is good if early, aggressive treatment is initiated.
- Symptomatic horses: Prognosis is guarded to poor.
- Severe, persistent signs of colic and early development of laminitis are associated with a grave prognosis even with aggressive medical therapy.

PEARLS & CONSIDERATIONS

The absence of clinical signs on initial evaluation in a horse with grain overload does not imply that severe disease will not develop. Early and aggressive treatment is indicated in any horse that consumes a moderate to large amount of grain and can be very successful at preventing the potentially devastating sequelae associated with grain overload.

ElibeVet.com

Granulosa Cell Tumor

BASIC INFORMATION

DEFINITION

A granulosa cell tumor (GCT) is a sex-cord stromal tumor of the ovary. It is by far the most common tumor of the equine ovary. When the tumor is composed primarily of granulosa cells, the term GCT is used; when both granulosa and theca cells are present, the term granulosa-theca cell tumor (GTCT) is used.

EPIDEMIOLOGY

SPECIES, AGE, SEX Intact equine females of any age. The mean age is 10.6 years with a range of 2 to 20 years. Juvenile cases have also been reported.

ASSOCIATED CONDITIONS AND DISORDERS Behavioral problems, infertility

CLINICAL PRESENTATION

DISEASE FORMS, SUBTYPES

- GCT
- GTCT

HISTORY, CHIEF COMPLAINT

- Behavioral abnormalities
  - Prolonged anestrus
  - Aggressive or stallion-like behavior
  - Persistent estrus
- Infertility

PHYSICAL EXAM FINDINGS The affected ovary is enlarged and firm, and the ovulation fossa is usually not palpable. The contralateral ovary is almost always small and inactive. Rarely, bilateral tumors have been reported.

ETIOLOGY AND PATHOPHYSIOLOGY

- GCT is a neoplasm of the sex cord stroma.
- It is the only ovarian abnormality in mares associated with inactivity of the contralateral ovary.
- Inactivity of the contralateral ovary is presumed to occur by suppression of pituitary follicle-stimulating hormone as a result of inhibin secretion from the neoplastic ovary.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of ovarian enlargement (hematoma; pregnancy; or other ovarian neoplasm, including cystadenoma, teratoma, or dysgerminoma). Some forms of ovarian enlargement (as during pregnancy or with an ovarian hematoma) resolve with time, but GCT/GTCT does not. Most importantly, GCT/CTCT is the only cause of ovarian enlargement that is associated with inactivity of the contralateral ovary. In rare cases when the mare continues to cycle on the contralateral ovary, the tumors are thought to be in the early stages of development.
- Other causes of prolonged anestrus: Season, old or young age, chromosomal abnormality, persistent luteal tissue, pregnancy, progestin administration, anabolic steroid administration, gonadotropin-releasing hormone vaccination, or persistent endometrial cups
- Other causes of stallion-like behavior: Anabolic steroid administration, disorder of sexual differentiation (eg, male pseudohermaphroditism)

INITIAL DATABASE

- Ultrasonography of the affected ovary reveals a multicystic, honeycombed structure, but the tumor may also present as a solid mass or as a single large cyst. The contralateral ovary is small and inactive, but mares with GCT on one ovary and a functional contralateral ovary have been reported.
- Serum inhibin is elevated in 90% of cases. Serum testosterone is elevated in 50% to 60% of cases. Serum progesterone is baseline (<1.0 ng/mL) because normal follicular development, ovulation, and corpus luteum formation do not occur. Measurements of inhibin above 0.7 ng/mL, testosterone above 50 to 100 pg/mL, and progesterone below 1.0 ng/mL in a nonpregnant mare are suggestive of a GCT.

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis is by histopathology, but a presumptive diagnosis can be made based on clinical examination and suggestive serum inhibin, testosterone, and progesterone concentrations.

TREATMENT

THERAPEUTIC GOALS

Surgical removal is recommended. The tumor will continue to grow and may eventually cause colic or other problems.

ACUTE GENERAL TREATMENT

Surgical removal of the affected ovary results in resolution of clinical signs. Surgical approaches include colpotomy, flank or ventral midline laparotomy, and laparoscopy. Follicular activity resumes in the unaffected ovary during the breeding season after surgery. Mares are suitable broodmares after normal cyclicity resumes.

POSSIBLE COMPLICATIONS

- Although uncommon, metastasis has been reported.
- Large GCT/GTCTs may cause colic or other gastrointestinal problems.
- Rupture of GCT/GTCTs has been reported, with intraabdominal hemorrhage.
- Adhesions of GCTs to abdominal viscera have been reported.
- Torsion of the ovary containing a GTCT has been described.

PROGNOSIS AND OUTCOME

- Prognosis for fertility is excellent after surgical removal and resumption of follicular activity.
- Prognosis for survival is excellent after surgical removal.

PEARLS & CONSIDERATIONS

GCT/GTCT is the only ovarian abnormality in mares associated with inactivity of the contralateral ovary.

Grass Sickness

BASIC INFORMATION

DEFINITION

Neurologic disease primarily associated with the degeneration of neurons in the autonomic nervous system, particularly the enteric nervous system

SYNONYM(S)

Equine dysautonomia

EPIDEMIOLOGY

SPECIES, AGE, SEX Grass sickness most commonly affects horses between 2 and 7 years of age. Older horses rarely develop the disease, possibly because of the development of immunity or tolerance to the causative agent. The disease is very rare in foals and weanlings.

GENETICS AND BREED PREDISPOSITION All Equids appear to be susceptible to grass sickness, with the disease having been reported in horses, ponies, donkeys, and captive exotic Equidae. There is no breed predisposition.

RISK FACTORS

Numerous risk factors have been identified, including:

- Cool weather temperatures (7°–11° C) and dry weather with irregular ground frosts in the preceding 2 weeks
- Horses in good or fat body condition
- Higher numbers of horses and the presence of young horses on the premises
- Sandy soils and loam soils
- Increased levels of soil nitrogen
- Previous occurrence of grass sickness on the premises
- Grazing grass: The disease is extremely rare in horses with no access to grass. Co-grazing with ruminants gives some protection from the disease.
- Dietary change
- Movement or recent stress, especially movement to a new pasture in the preceding 2 to 4 weeks
- Pasture disturbance (eg, construction or mole activity)
- High-frequency use of anthelmintics and specific use of ivermectin for ultimate and penultimate treatments
- Mechanical removal of feces from the pasture
- Pasture cutting

GEOGRAPHY AND SEASONALITY

- The northeast region of Scotland has the highest incidence of grass sickness, but the disease is also recognized throughout the United Kingdom as well as in many other Northern European countries, including Norway, Sweden, Denmark, France, Switzerland, and Germany. The disease does not occur in Australasia, Asia, Africa, North America, or Ireland. A clinically and pathologically identical disease known as mel seco (dry sickness) occurs in South America.
- Cases of equine grass sickness may occur throughout the year, but there is a significant peak in incidence in the northern hemisphere in the spring and early summer.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Grass sickness can be divided into three subdivisions—acute, subacute, and chronic—which are characterized clinically by varying degrees of gastrointestinal immotility and dysphagia, although it should be emphasized that there is a continuum. The acute and subacute forms of the disease are invariably fatal; however, a proportion of mildly affected horses with the chronic form may survive.

HISTORY, CHIEF COMPLAINT

- Acute form
  - The onset and progression of clinical signs is rapid, with death occurring in less than 48 hours.
  - Animals usually present with depression or somnolence, inappetence, and rapid progression to varying degrees of abdominal pain in many cases.
  - The degree of colic may, however, be relatively mild and inconsistent with the profound elevation in pulse rate.
- Subacute form
  - Clinical signs are generally similar to but less severe than those of acute cases. Their duration is longer, and the outline of the abdomen quickly develops a marked "tucked-up" appearance.
  - This finding does not appear to be entirely attributable to loss of body condition, although significant weight loss does become apparent.
- Chronic form
  - Clinical signs in the chronic form are more insidious in onset.
  - The most obvious signs include severe weight loss with the development of a distinct "tucked-up" abdomen. Affected horses often have a very base narrow stance, thus adopting the characteristic "elephant on a tub" posture.
  - Some horses show apparent weakness, and a reduced anterior phase to the stride results in occasional toe dragging.

PHYSICAL EXAM FINDINGS

- Acute form
  - Dehydration is usually present, which can be demonstrated by prolonged tenting of the skin. A generalized, marked reduction in intestinal motility is evident during abdominal auscultation.
  - Bilateral ptosis may or may not be present.
  - Muscle fasciculations of the triceps and quadriceps muscle groups may be observed, and sweating may be generalized or localized to the flanks, neck, and shoulder regions.
  - Dysphagia is almost invariably present but may be difficult to appreciate because of coexisting inappetence. It may be apparent, however, when observing the animal attempting to drink, when many affected horses flick their muzzles through the water or "paw" at the water bucket, presumably because of frustration.
  - Excessive dribbling of saliva is often present and probably results from a combination of excessive saliva production and a reduced ability to swallow.
  - Some horses show spontaneous gastric reflux with foul-smelling green or brown fluid exiting from both nostrils. As the disease progresses, abdominal distension becomes apparent in most cases.
- Subacute form
  - Affected animals are almost invariably dysphagic.
  - Persistent tachycardia is present with or without any evidence of abdominal pain.
  - Patchy sweating, usually around the flanks, neck, and shoulder, and muscle tremors of the triceps and quadriceps muscle groups are often present.
  - As the disease progresses, many subacute cases will exhibit worsening episodes of colic.
- Chronic form
  - Bilateral ptosis is often present resulting in a sleepy, depressed expression.
  - Persistent tachycardia is present; however, the heart rate is lower than in acute and subacute cases, rarely exceeding 60 beats/min.
  - Varying degrees of muscle tremor, patchy sweating, and abdominal pain are present.
  - Signs of colic are usually mild and transient.

ElibeVet.com

- Varying degrees of dysphagia are common, but the associated reduction in appetite may make this difficult to appreciate.
- Frequently, affected horses accumulate chewed food between the cheeks and molar teeth, often resulting in a fetid odor to the breath.
- Many chronic cases will have severe rhinitis with the accumulation of dry hemorrhagic mucoid material on the nasal septum and nasal turbinates.
- Although this can be appreciated by close inspection of the rostral nasal septum using a pen torch (light), often the animal will make a distinctive "snuffling" sound during breathing that originates from the nasal cavity.

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of grass sickness is unknown. Numerous epidemiologic studies have found no evidence for a conventional infectious agent. Considerable evidence exists to suggest that a natural neurotoxin may be implicated, and the presence of a neurotoxic component in the plasma of acute cases has been demonstrated experimentally.
- Investigations into the possible role of toxic plants, viruses, fungal, chemical, and bacterial toxins have failed to identify the cause. The current leading hypothesis is that equine grass sickness results from a toxicoinfection with *Clostridium botulinum* types C and D, whereby toxin is produced locally within the horse's gastrointestinal tract by resident bacteria. Horses with equine grass sickness have lower serum concentrations of antibody against surface antigens of *C. botulinum* type C and one of its neurotoxins (BoNT/C) compared with co-grazing horses. Significantly higher levels of mucosal IgA antibodies against BoNT/C and BoNT/D (the neurotoxin produced by *C. botulinum* type D) have been identified in the small intestines of horses with acute grass sickness compared with control subject.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain are simple or nonstrangulating obstructions of the gastrointestinal tract such as sand impaction, enterolithiasis, large colon displacements, large intestinal intraluminal obstructions, tympany, small colon impactions, and ileal impactions.
- Other causes of large intestinal distension on examination per rectum include sand impaction, enterolithiasis, tympany, large colon displacements, and other intraluminal obstructions.
- Dehydration of feed within the large intestine may occur secondary to small intestinal obstruction.

INITIAL DATABASE

- Acute form
  - The pulse is usually weak and may exceed 100 beats/min in many cases. Pyrexia (≤40° C) may be present.
  - Passage of a nasogastric tube invariably results in the retrieval of many liters of malodorous reflux.
  - Rectal examination reveals a dry rectal mucosa, and some horses strain excessively during the rectal examination.
  - Frequently, distension of the small intestine can be appreciated; consequently, the rectal findings in many acute cases may appear similar to those encountered in some surgical colic cases with associated small intestinal obstruction.
  - In some cases, a hard secondary impaction of the large colon can be palpated in the caudal abdomen. The distinct corrugated nature of this structure often distinguishes it from the relatively smooth outline of a primary colonic or cecal impaction.
- Subacute form
  - Nasogastric reflux and small intestinal distension are usually absent early on in the course of the disease; however, they may develop in a small number of horses as the disease progresses.
- Chronic form
  - Colonic and cecal impaction is common and readily appreciated during rectal examination. Abdominal auscultation usually reveals a reduction in intestinal motility.
  - Small intestinal distension and colonic impaction are rare, so rectal examination usually reveals a lack of contents within the palpable regions of the colon and cecum.
  - No alterations in blood clinical chemistry or hematologic parameters are pathognomonic for grass sickness. Because one of the major differential diagnoses of grass sickness is colic, most of the comparisons of clinical chemistry parameters have been made between horses with grass sickness, normal control subjects, and horses with colic.
  - Plasma cortisol, catecholamine, and histamine concentrations are significantly higher in horses with acute and subacute grass sickness than in horses with colic and normal animals. The acute phase proteins haptoglobin and orosomucoid are increased in all three forms of grass sickness but not in the majority of colic cases. Also, the protein content of peritoneal fluid is higher in horses with grass sickness compared with horses with medical colic.

ADVANCED OR CONFIRMATORY TESTING

- There is no definitive noninvasive antemortem diagnostic test for equine grass sickness. In most cases, the diagnosis is based on the clinical signs and history. Repeated examinations may be necessary before a diagnosis can be made.
- Confirmation of a diagnosis of grass sickness can only be made by demonstrating the characteristic histopathologic lesions in the autonomic or enteric ganglia during postmortem examination or by ileal biopsy at laparotomy. This latter technique may be useful in the antemortem diagnosis of acute and subacute cases in which surgical colic is a major differential diagnosis. In chronic cases, however, where subsequent treatment is being considered, anesthesia and surgery are likely to adversely affect the outcome. Rectal biopsy is not yet a reliable technique in grass sickness because the enteric neurons in the rectum are only mildly affected, and only a small sample can be obtained.
- Esophageal endoscopy and barium swallow radiography may reveal defective esophageal motility. Reflux esophagitis may also be recognized by endoscopy.
- Topical application of phenylephrine eye drops (0.5%) to one eye with subsequent examination 30 minutes later often reveals reversal of ptosis in the ipsilateral eye, with an increase in angle between the corneal surface and the eyelash. It should be recognized that false-positive responses may occur with this test.

TREATMENT

THERAPEUTIC GOAL(S)

- Euthanasia may be required in many cases.
- Nursing treatment of selected horses with chronic grass sickness may be possible.

ACUTE GENERAL TREATMENT

- Acute form: The prognosis in acute cases is hopeless; therefore, euthana-

ElibEVet.com

sia is required after this diagnosis has been made.
- Subacute form: Although a small number of cases that present initially as subacute cases will gradually progress to the chronic stage, the vast majority will die or require euthanasia within 7 days of the onset of signs.

CHRONIC TREATMENT

- Some horses affected by chronic grass sickness may survive. However, strict selection of treatment candidates and adherence to good management protocols are important. The suggested criteria for selection of cases for treatment include:
  - A willingness to attempt to drink and swallow food
  - Retention of some ability to drink and swallow food
  - Absence of continuous moderate to severe signs of colic
- Treatment involves intensive nursing care.
- High-energy, high-protein feeds are ideal and can be mixed with molasses, biscuits, and succulents (eg, apples and carrots) to improve palatability. The preference of the horse for a particular feed will often change from day to day. The frequent provision of feed is indicated with a recommendation of four to five feeds per day. Soaking the feeds may facilitate swallowing in some cases; however, whether to dampen the feed or not again depends the individual animal's preference.
- The energy content of the feed may be improved by the addition of up to 500 mL of corn oil, but this should be done gradually. The consumption of concentrate feed to minimize excess weight loss is vital to the horse's survival.
- Nasogastric feeding has been attempted in some horses with extremely limited success, so the indication for such treatment remains questionable.
- The importance of nursing, frequent human contact, frequent grooming, and regular walking out and hand-grazing cannot be overemphasized. Occasionally, it may be necessary to handfeed some horses when their appetite is especially poor. In many cases, despite a moderate degree of food intake, the body weight will continue to decrease quite dramatically during the first 2 to 4 weeks. The prognosis, however, is considerably poorer if this decrease in body weight continues beyond 6 weeks' duration.
- Mild to moderate postprandial colic may occur, and this can be managed with phenylbutazone (2.2–4.4 mg/kg IV or PO q12h) or flunixin meglumine (0.5–1.1 mg/kg IV q12h) and omeprazole (4 mg/kg PO q24h).
- The use of gastrointestinal motility enhancers and appetite stimulants has been attempted in the past but with disappointing results.

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of pain and continued weight loss.

PROGNOSIS AND OUTCOME

Overall, the prognosis for equine grass sickness is extremely poor.

PEARLS & CONSIDERATIONS

COMMENTS

Only selected horses with chronic equine grass sickness can survive. Other horses should be euthanized on humane grounds.

PREVENTION

- Avoiding risk factors is a key to prevention.
- No vaccine is currently available, although work is currently being undertaken to evaluate the safety and immunogenicity of a recombinant protein-based vaccine against *C. botulinum* toxins.

CLIENT EDUCATION

Education of clients about risk factors may decrease the incidence of equine grass sickness.

Guttural Pouch Empyema

BASIC INFORMATION

DEFINITION

Accumulation of purulent material within one or both of the guttural pouches. In some cases, chondroids, or concretions of inspissated purulent material, may also be present.

SYNONYMS

- Catarrh of the guttural pouch
- Strangles (if caused by infection with *Streptococcus equi* subsp. *equi*)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Seen most commonly in young horses and older horses with possible immune compromise (eg, Cushing's disease)
- Horses of any age or breed or both sexes can be affected.

RISK FACTORS

- Prior upper respiratory tract infection (especially with *S. equi* subsp. *equi* or *Streptococcus equi* subsp. *zooepidemicus*)
- Retropharyngeal lymph node abscessation and rupture
- Fracture of the stylohyoid bone
- Infusion of irritant substances into the guttural pouch
- Pharyngeal orifice stenosis or adhesions
- Pharyngeal perforation due to passage of a nasogastric tube
- Immune compromise secondary to pituitary disease

CONTAGION AND ZOONOSIS

- Approximately 30% of horses with guttural pouch empyema are culture pos-

ElibeVet.com

itive for *S. equi* subsp. *equi*. This is the causative agent of strangles and is highly contagious.
- Horses with clinical signs of guttural pouch empyema should be handled with appropriate biosecurity precautions due to this risk until the results of bacterial culture and sensitivity or polymerase chain reaction (PCR) are obtained.

ASSOCIATED CONDITIONS AND DISORDERS
- Chondroids: Found in approximately 20% of horses with guttural pouch empyema
- Strangles
- Laryngeal hemiplegia
- Dysphagia
- Dyspnea

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Persistent mucopurulent nasal discharge (unilateral or bilateral) is the most common presenting complaint.

PHYSICAL EXAM FINDINGS
- Mucopurulent nasal discharge
- Retropharyngeal swelling that is painful on palpation
- Other clinical signs: Cough, fever, anorexia, depression, dyspnea, dysphagia, respiratory noise, extended head and neck carriage, enlarged retropharyngeal ± submandibular lymph nodes

ETIOLOGY AND PATHOPHYSIOLOGY
- Guttural pouch empyema is most commonly caused by infection with β-hemolytic streptococci. *S. equi* subsp. *equi* or *S. equi* subsp. *zooepidemicus* species are the most common species
- Other isolates include *Escherichia coli*, *Klebsiella* spp., *Corynebacterium* spp., *Bordetella* spp., and *Salmonella* spp.
- Horses can be asymptomatic carriers of *S. equi* subsp. *equi* in their guttural pouches after an infection for an extended period of time.
- Chondroids form as a result of chronic inflammation within the guttural pouch and consist of epithelial cells, inflammatory products, and necrotic tissue. Their presence complicates treatment and may necessitate surgical intervention.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Guttural pouch tympany
- Strangles
- Pharyngitis
- Upper or lower respiratory tract infection

INITIAL DATABASE
- Complete blood count: Normal or leukocytosis
- Fibrinogen: Increased
- Hematocrit: Normal
- Total protein: Normal or increased
- Upper airway endoscopy
  - Mucopurulent material ± chondroids in one or both guttural pouches
  - Retropharyngeal lymph node enlargement (seen on the floor of the guttural pouch; may cause dorsal pharyngeal collapse)
  - Mucosal hyperplasia, thickening, and discoloration of the pharyngeal ostium
  - Pharyngeal abnormalities: Lymphoid hyperplasia, narrowing, or edema
- Radiography (less sensitive than endoscopy)
  - Fluid line(s) within the affected pouch(es)
  - Chondroids
  - Retropharyngeal lymph node enlargement

ADVANCED OR CONFIRMATORY TESTING
- Bacterial culture and sensitivity testing of an aspirate from the guttural pouch or from a guttural pouch wash to determine the causative agent
- PCR testing for *S. equi* subsp. *equi* to rule out strangles

TREATMENT

THERAPEUTIC GOALS
- The hallmarks of treatment are guttural pouch drainage and lavage, systemic antimicrobial therapy, and systemic antiinflammatory treatment.
- Medical therapy alone is successful in the majority of cases; however, about 20% of cases require more extensive therapy, which may include surgical intervention.

ACUTE GENERAL TREATMENT
- Guttural pouch drainage and lavage
  - Transendoscopically or via devices placed into the guttural pouch (Chambers catheter, Foley catheter, male dog urinary catheter, polyethylene tubing, or commercially available guttural pouch catheters).
  - Horses should be heavily sedated to facilitate drainage and prevent aspiration pneumonia.
  - Lavage should be done daily for 5 to 10 days.
  - The lavage solution should be an isotonic electrolyte solution.
    - Noxious agents (iodine, hydrogen peroxide, antiseptics) are contraindicated because they may cause severe inflammation and harmful side effects, such as dysphagia.
    - Antimicrobials may be added to the solution, but studies have not shown this to be any more effective than electrolyte solutions alone.
    - There are successful reports of the use of acetylcysteine in the lavage solution to break the disulfide bonds in the mucoproteins; however, some authors advise against this because it can also cause inflammation.
- Systemic antimicrobial therapy
  - Should be used as an adjunct to drainage and lavage and not as a sole treatment.
  - Also used to prevent the development of aspiration pneumonia.
  - Should be based on results obtained from bacterial culture and sensitivity testing.
  - Until those results are available, empirical therapy should be initiated.
    - The drug of choice for the most common isolates β-hemolytic streptococci) is a penicillin or cephalosporin.
      - Potassium penicillin (22,000 IU/kg, IV q6h) is the treatment of choice but may be cost prohibitive.
      - Procaine penicillin G (22,000 IU/kg IM q12h) is a cheaper alternative.
      - Ceftiofur (2 mg/kg IV or IM q12h) can also be used.
      - Potentiated sulfonamides should not be used empirically because about 75% of isolates in one study were resistant.
- Systemic antiinflammatory treatment: Phenylbutazone (2.2 mg/kg IV or PO q12h or 4.4 mg/kg IV or PO q24h) or flunixin meglumine (1.1 mg/kg IV or PO q12–24h).
- Horses in severe respiratory distress may require an emergency tracheotomy.

CHRONIC TREATMENT
- When chondroids are present, they must be removed.
- Nonsurgical removal (via endoscopic snares or baskets)
  - Successful in about 40% of cases
  - Can be extremely time consuming and necessitate increased hospitalization time and cost
- Surgical removal
  - Helps expedite the process of removing the chondroids, decreasing hospitalization time and cost.
  - Traditional techniques (Viborg's triangle, hyovertebrotomy, White-

ElibeVet.com

house, and modified Whitehouse approaches) are performed under general anesthesia. Potential complications include iatrogenic nerve damage.
  - A modified Whitehouse approach in standing horses was recently reported. It provides good drainage and avoids general anesthesia.
  - Laser surgery: Creates a fistula in the pharyngeal opening to remove the chondroids. Avoids general anesthesia and decreases the risk of iatrogenic nerve damage.
- Horses with chronic dysphagia may require an esophagostomy to provide enteral nutrition until cranial nerve function returns.
- Horses with secondary aspiration pneumonia should be treated appropriately.

DRUG INTERACTIONS

For horses with chronic disease, creatinine values should be checked before treating the horse with nonsteroidal anti-inflammatory drugs or aminoglycoside antimicrobials.

POSSIBLE COMPLICATIONS

- Rupture of the guttural pouch has been reported as a complication of daily guttural pouch lavage.
- Nerve damage: Either from the inflammation caused by the empyema or from iatrogenic damage from lavage with noxious solutions or surgical intervention can be seen.
  - Cranial nerves VII, IX, X, XI, and XII, as well as the pharyngeal branch of the vagus nerve, the cranial cervical ganglion, the cranial laryngeal nerve, and the cervical sympathetic stump, may be affected.
  - Clinically, this may manifest as laryngeal hemiplegia, dysphagia, signs of facial nerve paralysis, persistent dorsal displacement of the soft palate, Horner's syndrome, and pharyngeal collapse.
  - These deficits may improve over time but may be permanent.
- Aspiration pneumonia

RECOMMENDED MONITORING

- Repeat endoscopic evaluation should be performed to evaluate the success of daily lavage.
- Repeat PCR testing for *S. equi* subsp. *equi* should be performed in horses with positive test results to determine when biosecurity measures can be discontinued.

PROGNOSIS AND OUTCOME

- About 80% of horses with guttural pouch empyema respond favorably to medical treatment, with an average duration of hospitalization of 5 to 10 days and a good prognosis for return to previous use.
- About 20% of horses experience complications or have chondroids that necessitate more intensive treatment or surgical intervention.
  - Horses with chondroids but without neurologic signs have a good prognosis, but treatment can be prolonged, and the associated costs are increased.
  - Horses with neurologic deficits have a fair to poor prognosis, depending on the duration of clinical signs and the specific neurologic deficit. Treatment duration and cost can be substantially increased in these horses.

PEARLS & CONSIDERATIONS

COMMENTS

- All horses with clinical signs of guttural pouch empyema should be cultured for strangles and treated with appropriate isolation and biosecurity protocols until the disease is ruled out.
- If medical management is not successful within 5 to 7 days or after chondroids are identified, surgical treatment is indicated and can decrease hospitalization time and cost if performed early on.

CLIENT EDUCATION

- Clients should be aware that any horse with persistent mucopurulent nasal discharge could be affected with guttural pouch empyema and possibly strangles.
- These horses should be kept isolated from other horses at the farm until they are examined by a veterinarian.

Guttural Pouch Mycosis

BASIC INFORMATION

DEFINITION

Fungal infection within the guttural pouch(es) that affects the neurovascular structures inside of the pouch, causing hemorrhage and neurologic deficits

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS Aspiration pneumonia, laryngeal hemiplegia, Horner syndrome

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute, severe epistaxis (unilateral or bilateral)
- Chronic neurologic deficits: Dysphagia, laryngeal or pharyngeal paralysis, esophageal obstruction, Horner's syndrome, facial nerve paralysis

HISTORY, CHIEF COMPLAINT

- The most common presenting complaint is moderate to severe epistaxis.
- Dysphagia is the second most common presenting complaint.

PHYSICAL EXAM FINDINGS

- Acute, moderate to severe epistaxis:
  - Unilateral is most common, but it can also be bilateral
  - Signs of hypovolemic or hemorrhagic shock
- Tachycardia, tachypnea, pale mucous membranes, weak peripheral pulses, anxious demeanor, weakness
- Neurologic deficits:
  - Dysphagia: Horses may present with esophageal obstruction, aspiration pneumonia, or tongue protrusion or have feed material in the nares.

ElibeVet.com

- Laryngeal or pharyngeal paralysis: A respiratory noise may be noted during exercise.
- Horner syndrome: Ptosis, meiosis, enophthalmos, patchy sweating, and nasal mucosa congestion on the affected side.
- Facial nerve paralysis: Ear droop, ptosis, lip droop, and inability to blink on the affected side.

- The inability to blink may lead to the development of corneal ulcers on the affected side.
- Other less common clinical signs: Nasal discharge, colic, blindness, unusual head carriage, parotid area pain, head shyness.

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common etiologic agents recovered from horses with guttural pouch mycosis are *Emericella nidulans* and *Aspergillus fumigatus*.
- These fungi are ubiquitous and thrive in warm, moist areas such as bedding material containing urine and water.
- These fungi act as opportunistic pathogens, entering the guttural pouch through the pharyngeal orifice, where they incite an inflammatory response.
- This leads to the formation of a diphtheritic membrane, composed of necrotic tissue, cell debris, bacteria, and fungal mycelia.
- The fungi can penetrate deeper tissues, causing thromboarteritis, aneurysm, and hemorrhage.
  - This typically occurs in the internal carotid artery (two thirds of cases).
  - The external carotid artery, its branches, or the maxillary artery are affected in the other third of cases.
- Damage may occur to any of the nerves within the guttural pouch because of the acute inflammatory response or because of chronic fibrosis.
  - Cranial nerves VII, IX, X, XI, and XII; the pharyngeal branch of the vagus nerve; the cranial cervical ganglion; the cranial laryngeal nerve; and the cervical sympathetic stump may be affected.
  - Neurologic deficits are generally seen in the more chronic stages of the disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Trauma to the nasal passages or sinuses
- Rupture of the ventral straight muscles of the head
- Masses of the nasal passages, sinuses, or guttural pouches
  - Progressive ethmoidal hematomas
  - Neoplasia: Squamous cell carcinoma, fibrosarcoma, melanoma, hemangiosarcoma
  - Paranasal sinus cysts
- Exercise-induced pulmonary hemorrhage
- Bacterial or fungal sinusitis

INITIAL DATABASE

- Complete blood count: Normal
- Hematocrit: Normal in the acute stages (<24 hours after hemorrhage); decreased later
- Total protein: Normal in the subacute stages (<4–6 hours after hemorrhage); decreased later
- Fibrinogen: Normal, decreased (if substantial hemorrhage), or increased (chronic inflammation or infection)
- Platelet count: Normal or decreased after substantial hemorrhage
- Serum chemistry: Normal or azotemia (prerenal) if hypovolemic shock is present
- Upper airway endoscopy
  - Blood clot at the pharyngeal orifice of the affected pouch
  - Diphtheritic membrane along the roof or wall of the affected pouch
    - Internal carotid artery: The medial compartment of the affected pouch
    - External carotid artery, maxillary artery: The lateral compartment of the affected pouch
    - May not be able to identify the affected artery or arteries if there is active hemorrhage; the affected pouch will be filled with blood and clot material that inhibits visualization.
  - In chronic cases with neurologic deficits, there may be pharyngeal collapse, laryngeal hemiplegia, dorsal displacement of the soft palate, and feed material on the pharyngeal walls.

TREATMENT

THERAPEUTIC GOAL(S)

- The first hemorrhagic episode is generally not fatal; however, after this occurs, prompt surgical intervention should be recommended because subsequent episodes of hemorrhage are often fatal and may occur within hours to days after the initial episode.
- Treatment should be aimed at stabilizing the horse hemodynamically to transport it to a referral center for surgery.
- Although medical therapy has been described, surgical occlusion of the affected artery or arteries is the treatment of choice and should be performed promptly after the first hemorrhagic episode.

ACUTE GENERAL TREATMENT

- Hemodynamic stabilization after an acute hemorrhagic episode
  - Crystalloid colloid fluid therapy until blood volume is restored
    - Fresh-frozen plasma (FFP) is the colloid of choice because it contains platelets and clotting factors and provides oncotic support.
    - Hetastarch should be avoided because of its potential for exacerbating coagulopathies and promoting hemorrhage.
    - Large-bore IV catheters can be placed in both jugular veins in cases of severe hemorrhage for large-volume resuscitation.
    - Normovolemia should be restored; fluid therapy should not be too aggressive because the resultant increase in blood pressure may dislodge a forming clot at the affected artery.
  - Blood transfusions
    - Do if packed cell volume is below 20% acutely or below 12% to 14% with chronic blood loss.
    - Perform cross-match if available.
      - In acute, severe bleeds, this may not be practical; a Quarter Horse or Standardbred gelding should be used as the donor.
      - 10 L can be collected safely from a 500-kg donor.
  - Treatments aimed at stopping hemorrhage
    - Aminocaproic acid (100 mg/kg IV) inhibits fibrinolysis
    - FFP (4–5 mL/kg IV): Monitor for transfusion reactions
- Broad-spectrum IV antimicrobial therapy to guard against secondary bacterial infections
- Antiinflammatory and analgesic therapy
- Phenylbutazone (2.2 mg/kg IV or PO q12h or 4.4 mg/kg IV or PO q24h) or flunixin meglumine (1.1 mg/kg IV or PO q12–24h)
- Medical therapy
  - Is not the treatment of choice; treatment is often prolonged, costly, and ineffective
  - If there is no surgical option, treatment consists of systemic and topical therapy.
    - Itraconazole: 3 mg/kg PO q12h for 4 to 5 months
    - Enilconazole: 60 mL of a 33.3-mg/mL solution flush q24h
- Surgical occlusion of the affected artery or arteries
  - Direct arterial ligation
    - Difficult to identify the proper artery or arteries to ligate if active hemorrhage obscures endoscopic visualization

ElibeVet.com

- Increased morbidity and mortality versus newer surgical techniques
- No specialized equipment required

- Balloon catheter occlusion
  - Decreased morbidity and mortality versus direct ligation
  - Difficult to identify the proper artery or arteries to ligate if active hemorrhage obscures endoscopic visualization
  - Does not stop hemorrhage from aberrant vasculature (if present)
- Transarterial coil embolization
  - Lowest morbidity and mortality rates
  - Minimally invasive
  - Can detect affected vessels if active hemorrhage is present; does not rely on endoscopy
  - Can detect and occlude aberrant vessels
  - Need specialized equipment (fluoroscopy, coils, and a special surgery table)
  - Steep learning curve

CHRONIC TREATMENT

- After surgical occlusion of the affected artery or arteries, secondary complications may need to be addressed.
  - Dysphagia may necessitate placement of an esophagostomy tube for long-term enteral nutrition.
  - Aspiration pneumonia: IV antimicrobials as directed by the results of a bacterial culture and sensitivity taken from a transtracheal wash.

POSSIBLE COMPLICATIONS

- Dysphagia may be seen preoperatively or may develop postoperatively.
  - Poor prognostic indicator
  - May take 6 to 18 months to resolve or may be permanent
- Laryngeal hemiplegia is often permanent.
- Facial nerve paralysis and Horner's syndrome typically resolve within months.
- Surgical site infections: More common with direct ligation or balloon catheterization.

RECOMMENDED MONITORING

Repeat endoscopic evaluation of the affected guttural pouch.

PROGNOSIS AND OUTCOME

- Up to 50% of horses with hemorrhage caused by guttural pouch mycosis die because of hemorrhagic shock without treatment. This risk is greatly reduced with surgical intervention.
- Medical therapy is costly, prolonged, and often ineffective, with an approximate 35% fatality rate because of severe hemorrhage.
- Surgical therapy results in improved success rates:
  - About 20% of horses that undergo direct arterial ligation experience postoperative hemorrhage versus 10% of those that undergo balloon catheter occlusion and 6% of those that undergo transarterial coil embolization.
  - Transarterial coil embolization techniques result in improved survival rates (84%), decreased morbidity, and decreased hospitalization time.
- Neurologic deficits may persist for months to years and may contribute to postoperative morbidity and mortality.
- Dysphagia is a poor prognostic indicator.

PEARLS & CONSIDERATIONS

COMMENTS

Any horse with guttural pouch mycosis should be considered a surgical candidate, even if there is no active hemorrhage present at the time of endoscopic evaluation.

CLIENT EDUCATION

- Surgical therapy is ultimately more effective and often less costly than medical therapy.
- Clients should be made aware of the risk of development of neurologic deficits, especially if the horse is intended to be athletic after surgery.

AUTHOR: **LIBERTY M. GETMAN**

EDITOR: **ERIC J. PARENTE**

Guttural Pouch Tympany

BASIC INFORMATION

DEFINITION

A congenital abnormality causing air accumulation in the guttural pouch secondary to an abnormality involving the plica salpingopharyngea

EPIDEMIOLOGY

SPECIES, AGE, SEX The most commonly affected age is 1 year or younger, with fillies being more commonly affected.

GENETICS AND BREED PREDISPOSITION Arabians are the most commonly affected breed. In addition to Arabians, other breeds, such as Thoroughbreds and Quarter Horses, can be affected.

ASSOCIATED CONDITIONS AND DISORDERS Air distension of the guttural pouch may result in respiratory noise, dyspnea, dysphagia, aspiration pneumonia, and secondary guttural pouch empyema.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT The most common historical finding associated with guttural pouch tympanites is a soft, fluctuant, nonpainful, and elastic swelling in the parotid region. Affected horses may also exhibit unilateral or bilateral mucopurulent nasal discharge secondary to guttural pouch empyema.

PHYSICAL EXAM FINDINGS Most horses with guttural pouch tympany without evidence of guttural pouch empyema have a normal rectal temperature and heart rate. Some horses with severe air distension of the guttural pouch may have tachypnea and dyspnea.

ETIOLOGY AND PATHOPHYSIOLOGY

- Tympany of the guttural pouch is the direct result of the entrapment of air within one or both guttural pouches.
- In normal horses, the guttural pouch openings open when the horse swallows, allowing passage of air in and out of the pouch.

ElibeVet.com

- In horses affected with guttural pouch tympany, air is allowed into the guttural pouch via the plica salpingopharyngea but is not allowed to exit the guttural pouch.
- The cause of guttural pouch tympany is most likely secondary to redundancy or abnormal function of the plica salpingopharyngea. The plica salpingopharyngea is a soft tissue structure that lies just beneath the cartilaginous opening of the guttural pouch.
- A redundant plica salpingopharyngea can be congenital or secondary to chronic guttural pouch inflammation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Guttural pouch empyema
- Bronchopneumonia

INITIAL DATABASE

- Complete blood count: Typically normal unless the horse has aspiration pneumonia or severe guttural pouch empyema
- The diagnosis is readily made based on clinical signs alone. The characteristic nonpainful, pliable swelling in the parotid region is difficult to confuse with any other condition.
- The most challenging diagnostic dilemma is determining whether the condition is unilateral or bilateral, since a unilateral disorder will often result in a mild external swelling on the contralateral side.
- Methods of determining whether the condition is bilateral include passage of an endoscope into one or both guttural pouches, aspiration of air from the pouch with the most distension, and obtaining a dorsoventral radiographic view of the skull.
- In unilateral guttural pouch tympany, passage of the endoscope into the affected guttural pouch results in complete decompression of the guttural pouch. If the side with endoscope decompresses but the contralateral side does not, then the condition is bilateral. If there is no change in the external appearance of either guttural pouch, then the condition is most likely unilateral on the contralateral side.
- The second method of determination is to pass a Chambers catheter into the most distended guttural pouch under endoscopic guidance. The findings as described above hold true for this technique.
- Some authors have mentioned external needle decompression of the guttural pouch, but we do not recommend it because of the chance for iatrogenic damage to the neurovascular structures within the guttural pouch.
- The final method of determination of unilateral or bilateral disease is a dorsoventral radiographic view of the skull. Whereas unilateral guttural pouch tympany causes displacement of the affected medial septum of the guttural pouch toward the contralateral side, bilateral guttural pouch tympany results in bilateral air distension of each guttural pouch.
- Endoscopic findings compatible with guttural pouch tympanites include collapse of the dorsal pharyngeal wall, and if concurrent guttural pouch empyema is present, purulent exudate can be visualized exiting the guttural pouch opening.

TREATMENT

THERAPEUTIC GOAL(S)

Relief of air distension from the affected guttural pouch

ACUTE GENERAL TREATMENT

- The surgical management of horses with guttural pouch tympany is the only viable technique to resolve the clinical signs. The most important surgical consideration is the determination of unilateral versus bilateral disease. The surgical techniques for guttural pouch tympanites have been well described.
- Acceptable surgical techniques for unilateral guttural pouch tympany include fenestration of the median septum of the guttural pouch (allowing communication between the abnormal and normal pouch) with laser or traditional surgery, traditional surgical resection of the plica salpingopharyngea on the affected side, and laser plica salpingopharyngea fistula.
- Bilateral guttural pouch tympany can be managed with a combination of medial septum fenestration with resection of the plica salpingopharyngea on one side with laser fenestration of the median septum and unilateral laser plica salpingopharyngea fistula or with bilateral laser plica salpingopharyngea fistula.
- Fenestration of the median septum between the normal and abnormal pouch allows air to escape through the normal guttural pouch opening.
- The principle behind resection of the plica salpingopharyngea is to enlarge the normal opening into the guttural pouch. Laser fistulation through the plica salpingopharyngea allows for continuous decompression of the guttural pouch.
- The most significant complication of any of these techniques is stricture of the newly created openings. To lessen the risk for stricture formation, the newly created openings can be stented with indwelling Foley catheters exiting one or both nasal passages.
- Frequent monitoring after surgery is very important to determine whether stricture is occurring.

POSSIBLE COMPLICATIONS

Stricture of laser fenestration of the median septum and plica salpingopharyngea may occur and may require repeat fenestration. Dysphagia after laser fenestration of the median septum may occur and may be persistent. Concurrent guttural pouch empyema may require specific medical therapy.

RECOMMENDED MONITORING

The recurrence of air accumulation within the guttural pouch should be monitored. Recurrence may be secondary to stricture of surgically created fenestrations.

PROGNOSIS AND OUTCOME

- The prognosis after surgical treatment of guttural pouch tympany is good, although in our experience, more than one surgical procedure may be required, especially if stricture develops.
- Foals affected by dysphagia or aspiration pneumonia in combination with guttural pouch tympany have a guarded to fair prognosis.

PEARLS & CONSIDERATIONS

- Guttural pouch tympany may be treated in a standing horse with laser surgical procedures.
- For unilateral cases, laser creation of a plica salpingopharyngeal fistula with a contact laser fiber is technically easier to perform than fenestration of the median septum and likely to have fewer complications.
- Horses with bilateral guttural pouch tympany are preferentially managed with laser fenestration of the median septum of the guttural pouch and creation of unilateral salpingopharyngea fistula.
- Horses treated with laser fenestration of the median septum or plica salpingopharyngea should be monitored at monthly intervals with endoscopy for postoperative stricture formation.

EDITOR: **ERIC J. PARENTE**

Head Injury

BASIC INFORMATION

DEFINITION

Injury to the head caused by a sudden (mechanical and usually external) force. This entry focuses on the consequences to the central nervous system (CNS).

SYNONYM(S)

Traumatic brain injury (TBI)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young animals are more prone to traumatic (training) accidents.
- Basilar bones fuse at around 5 years of age, so young animals may be more susceptible to basilar bone fractures.

GENETICS AND BREED PREDISPOSITION Thoroughbred breeds may be more prone to traumatic accidents because of their temperament and the young age at which race training commences.

RISK FACTORS

- Temperament or disposition
- Management: Training and pasture group composition

ASSOCIATED CONDITIONS AND DISORDERS

- Sudden death
- Fractures of the basilar bones (Figure 1)
- Cranial nerve disorders
- Vestibular disease
- Cerebellar disease
- Temporohyoid osteoarthropathy: A pathologic process in which fusion between the temporal and stylohyoid bones occurs that may result in skull fractures with secondary traumatic damage to the vestibular apparatus, cranial nerve VII, or both

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Closed head injury: Skull remains intact
- Open head injury: Penetrating wound that causes skull fracture and brain damage

HISTORY, CHIEF COMPLAINT

- Down or recumbent
- External damage to the head: Wounds, fractures, hemorrhage
- Blood or cerebrospinal fluid (CSF) from the ear canals
- Signs of neurologic disease: Unresponsiveness, ataxia, blindness

PHYSICAL EXAM FINDINGS

- Varies depending on the severity of the insult
- Wounds or fractures of the skull
- Hemorrhage or CSF from the nostril, mouth, or ear canals
- Signs range from inapparent to recumbency with unconsciousness to death.
- Severe damage: Down, unresponsiveness, obtundation, respiratory abnormalities, cardiovascular instability, depression, inability to get up
- Milder damage: Ataxia, circling, blindness and pupillary abnormalities (signs are typically asymmetrical)
- Cranial nerve deficits (eg, cranial nerve VII)
- Signs of vestibular or cerebellar disease
- Altered behavior

ETIOLOGY AND PATHOPHYSIOLOGY

- Although head injury in horses is quite common, subsequent brain injury occurs only in 25% to 50% of cases.
- Primary damage: Initial mechanical disruption of vasculature and components of the CNS, such as cell bodies (neurons, astrocytes, oligodendrocytes) and axons
- Secondary damage: A complex cascade of molecular, cellular, and biochemical events that may occur for days to months after the initial insult, resulting in delayed tissue damage
- Systemic alterations further contribute to the tissue damage: Hypoxia, ischemia, brain swelling, alterations in intracranial pressure (ICP), hydrocephalus, infection, breakdown of blood-brain barrier, impaired energy metabolism, altered ionic homeostasis, changes in gene expression, inflam-

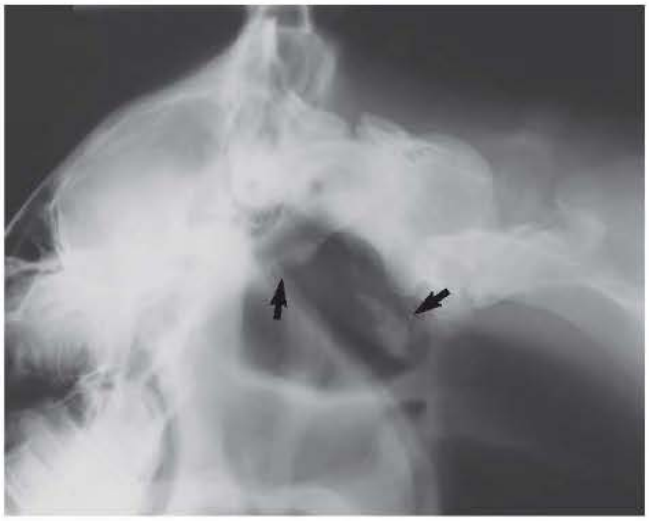

FIGURE 1 Lateral radiograph of the head showing an avulsion basilar skull fracture. *Arrows* point to the defect in the basisphenoid/basioccipital bone (*left*) and the avulsed fracture fragment (*right*).

ElibeVet.com

mation, and activation or release of autodestructive molecules occur and exacerbate the initial injury.
- Elevation of the ICP: Particularly a concern in closed head injury; an increase in ICP caused by, for example, a hematoma or edema will lead to a decreased cerebral perfusion pressure and subsequently decreased cerebral blood flow.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of sudden death
  - Lightning strike
  - Cardiac disease
- Other causes of CNS disease with a neuroanatomic localization rostral to foramen magnum
  - Equine herpesvirus-1 myelopathy
  - Equine protozoal myeloencephalitis
  - Leukoencephalomalacia
  - Meningitis
  - Neoplasia
  - Temporohyoid osteoarthropathy
  - Trauma
  - Viral encephalitides (Eastern equine encephalomyelitis, Western equine encephalomyelitis, Venezuelan equine encephalomyelitis, rabies, West Nile virus)

INITIAL DATABASE

- History
- Complete physical and neurologic examination

ADVANCED OR CONFIRMATORY TESTING

- Imaging of the head: Radiography, computed tomography for bony lesions, magnetic resonance imaging for brain pathology
- CSF analysis: Hemorrhage
- Rule out other (infectious) disease through complete blood count, serum titers, and CSF analysis.

TREATMENT

THERAPEUTIC GOAL(S)

- Prevent further neurologic damage.
- Save or salvage undamaged or reversibly damaged components.
- Enhance recovery or regeneration.

ACUTE GENERAL TREATMENT

- Optimize oxygen delivery.
  - Optimize cerebral blood flow.
  - Optimize mean arterial blood pressure and hemoglobin concentration.
    - Fluid therapy
    - Vasopressor or inotropic support (or both)
  - Ensure that ICP is not elevated.
    - Mannitol: 20%; 0.25 to 2.0 mg/kg IV
    - Hypertonic saline: 3%, 5%, 7.5%: 4 to 6 mL/kg IV; 23.4%; monitor serum sodium
- Prevent or reduce elevated temperature.
  - Antiinflammatory drugs
    - Corticosteroids: Dexamethasone (0.1–0.25 mg/kg IV q6–24h) or methylprednisolone sodium succinate (0.5–2.5 mg/kg IV q6h); the dose and interval depend on the severity of clinical signs
    - Flunixin meglumine: 1.1 mg/kg IV q12–24h
    - Dimethyl sulfoxide: 0.5 to 1.0 g/kg IV q12–24h; must be diluted to a 10% solution or less in an isotonic balanced electrolyte solution
- Prevent or contain seizure activity.
  - Diazepam (0.05–0.2 mg/kg IV), midazolam (0.1–0.4 mg/kg IV; as a continuous rate infusion in 50-kg foals: 1–3 mg/hr)
  - Phenobarbital: 4 to 10 mg/kg PO q12h
- Antibiotic treatment with antimicrobials that penetrate into the CNS, particularly in open head injury

CHRONIC TREATMENT

- Provide adequate nutritional support.
- Provide sling support in horses that are unable to stand or get up on their own.
- Provide physiotherapy rehabilitation. Exercise has been shown to be beneficial for recovery of function after CNS damage in multiple animal models.

POSSIBLE COMPLICATIONS

Deterioration because of development of cerebral edema

RECOMMENDED MONITORING

- Periodic repeat neurologic examinations to assess response to therapy and recovery of function
- Monitor appetite and hydration status. Monitor urine and creatinine concentration if treating with possible nephrotoxic drugs.

PROGNOSIS AND OUTCOME

- Depend on the severity of sustained brain damage and early treatment
- Gauged by response to treatment; recovery can be remarkable
- In general, horses with basilar skull fractures and brainstem injuries have a grave prognosis.
- Horses with recumbency, tetraparesis, and severe dementia have a grave prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Particularly animals with suspect closed head injury may need thorough repeated evaluation because the damage may not be immediately obvious.

PREVENTION

Prevent injuries by increasing safety around horses and when handling horses.

CLIENT EDUCATION

Clients should be knowledgeable on topics such as (multiple) horse management and safe handling and training.

Heart Murmur

BASIC INFORMATION

DEFINITION

- Murmurs are audible vibrations heard during a normally silent part of the cardiac cycle. Blood flow through the heart is generally laminar, but a number of circumstances may alter the normal laminar flow, causing turbulent flow to develop. This may cause vibration of cardiac structures, resulting in a murmur that can be heard with a stethoscope. Turbulence is most likely generated when blood viscosity is low, when the blood flow velocity is high, or when the diameter of the blood vessel is large. Three different types of murmurs exist, two of which are not associated with cardiac abnormalities.
  - Functional murmur (systolic flow murmur, systolic ejection murmur): These benign murmurs are common in horses, especially in racehorses, because the large stroke volume and large diameters of the great vessels induce turbulent blood flow in aortic and pulmonary artery roots in early systole.
  - Physiologic murmur: A number of conditions such as anemia and endotoxemia can lead to altered blood viscosity as well as increased cardiac output, which induces turbulent blood flow, leading to a benign systolic murmur. This is quite often heard in horses presented with substantial hemorrhage, high fever, or colic.
  - Pathologic murmur: Acquired or congenital cardiac malformations (eg, valvular regurgitations or ventricular septal defects [VSDs]) result in high-velocity blood flow, inducing a murmur.

SYNONYM(S)

- Cardiac murmur
- Murmur

EPIDEMIOLOGY

SPECIES, AGE, SEX Whereas degenerative valvular diseases are often seen in older horses, clinically significant congenital cardiac diseases are often discovered in young animals.

GENETICS AND BREED PREDISPOSITION

- A high proportion of both Thoroughbreds and Standardbreds have heart murmurs; these may be either functional murmurs or murmurs caused by acquired valvular regurgitation.

RISK FACTORS

- High stroke volume and large diameter of the vessel may lead to a benign functional murmur.
- Systemic conditions such as anemia and endotoxemia may result in a benign physiological heart murmur.
- Acquired or congenital cardiac diseases often result in heart murmurs.

ASSOCIATED CONDITIONS AND DISORDERS Variable, depending on the cause of the murmur and the severity of the situation inducing the murmur

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES As defined above, heart murmurs can be divided into three different types with functional and physiologic murmurs considered to be benign. Pathologic murmurs may or may not have a clinical effect on the horse. Therefore two fundamental questions should be answered: What is the source of the murmur, and what is its clinical significance?

HISTORY, CHIEF COMPLAINT

- Heart murmur may be detected on routine examinations (eg, prepurchase examination, auscultation before sedation, vaccination or a general clinical examination) in otherwise healthy animals.
- Heart murmur may be detected in systemically ill patients (eg,. anemia, colic, endotoxemia). In this situation, it is important to rule out cardiac disease and to assess whether it is a physiologic murmur that will disappear after the primary disease has resolved.
- Heart murmurs detected in horses presented with signs of cardiac disease (eg, ventral edema, tachycardia, arrhythmia, tachypnea or dyspnea, exercise intolerance, or collapse).

PHYSICAL EXAM FINDINGS

- Before auscultation of the left hemithorax, palpation of the apex beat with the flat of the left hand should be performed because the point of maximal intensity (PMI) of the mitral valve is usually located in this area (apical area). The apical area lies above the point of the elbow at the caudal edge of the triceps musculature. In this region, the first (S1) and second (S2) heart sounds are of equal loudness. From this location, the stethoscope is advanced in a dorsocranial direction until S2 becomes more accentuated relative to S1 and the aortic and pulmonic valve area is identified (basal area).
- On the right hemithorax, the apex beat is rarely palpable unless the horse is thin and narrow chested or has enlargement of the right ventricle or atrium. The auscultation area is more cranially located compared with the apical area on the left side of the horse. Often the right forelimb should be placed cranial to the left forelimb to allow better access. The only valve auscultated on the right hemithorax is the tricuspid valve, and because of the anatomical location of the heart toward the left side of the thorax, the tricuspid valve may be difficult to hear in some horses.
- Murmurs are classified according to a number of different criteria.
  - Intensity: The intensity of a murmur is usually graded on a 6-point scale.
    - Grade I/VI is a very quiet murmur that can only be heard in a focal area after careful examination in a quiet area.
    - Grade II/VI is also a quiet murmur but is heard immediately at its PMI.
    - Grade III/VI is a moderately loud murmur that is easily appreciated.
    - Grade IV/VI is a loud murmur (particularly relative to S1 and S2) that is heard over a widespread area but has no obvious palpable prechordial thrill.
    - Grade V/VI is a loud murmur with a palpable thrill.
    - Grade VI/VI is loud enough that it can be heard with the stethoscope just off the chest wall and has an obvious palpable thrill.
  - Timing and duration: Murmurs should be classified as systolic, diastolic, or continuous when occurring in both systole and diastole. Simultaneous palpation of the peripheral pulse can help to differentiate timing if it is unclear with auscultation alone. They should also be classified as early, mid, or late systolic or diastolic. If the murmur is heard throughout systole or diastole but the heart sounds are still distinct, a holosystolic or a holodiastolic murmur is heard. *Pansystolic* or *pandiastolic* refers to a holosystolic or holodiastolic murmur that additionally engulfs the first, second, or both heart sounds.
  - PMI: The PMI of the murmur is where the murmur is most intense and indicates the likely source of the murmur. Identification of the

ElibeVet.com

valve areas is therefore important, but in general, the heart is divided into the apical area (mitral and tricuspid valves) and the more dorsally located basal area (aortic and pulmonary valves).

- Shape: The shape of the murmur describes its change in intensity over time. It is often described as crescendo (increasing in intensity); decrescendo (decreasing in intensity); or band shaped (plateau), which stays a constant intensity throughout the murmur. The shape can sometimes help to determine the cause of the murmur.
- Quality: The quality of the murmur is related to the characteristic of the sound and can be described as soft, coarse or harsh, or musical. A musical murmur is harmonic and is often caused by a vibrating structure (fenestrated valve leaflet or ruptured chordae tendineae).

ETIOLOGY AND PATHOPHYSIOLOGY

- Functional and physiologic murmurs are generated by turbulence induced by noncardiac disease.
- Pathologic murmurs can be acquired or congenital. The most common congenital condition is a VSD. However, the majority of pathologic murmurs are caused by valvular regurgitation.
- It is important to note that valvular stenosis is extremely rare in horses and is therefore rarely considered as a differential diagnosis in adult horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- With some practice, auscultation is almost as accurate as echocardiography for identifying the source of the murmur. After the clinician has determined that the murmur is pathologic, the intensity of the murmur, performance ability, and other clinical signs are useful indicators for determining the significance of the condition. However, an exact diagnosis and quantification of the severity of the condition requires an echocardiographic examination.
- Situations in which physiologic murmurs may be present are typically those in which noncardiac explanations for the murmur exist (eg, anemia, colic, fever). In these situations, the horse should be reassessed after resolution of the primary condition.

INITIAL DATABASE

- Auscultation
- Complete blood count and serum chemistry, especially packed cell volume and inflammatory markers for systemic illness
- Echocardiography if indicated

TREATMENT

THERAPEUTIC GOAL(S)

There is no treatment for heart murmurs. The primary goals are to provide an accurate prognosis for both the life and performance to the owner and to monitor the horse regularly if indicated based on the cardiac diagnosis.

RECOMMENDED MONITORING

- Most murmurs associated with mild or moderate regurgitation that is not progressive do not require specific monitoring.
- However, the owner should always be aware of the horse's attitude, heart rate, and exercise tolerance. Any changes should prompt a veterinary examination.
- The characteristics of the murmur (eg, intensity, duration, quality), regardless of the cause, should be monitored on an annual basis by the regular veterinarian. Any changes, particularly if accompanied by changes in clinical parameters, should prompt an echocardiographic examination.
- Annual echocardiograms should be performed in horses that have murmurs associated with pathology that has more potential to progress.

PROGNOSIS AND OUTCOME

- The prognosis is highly variable depending on the disorder causing the disease and its severity.
- Most valvular regurgitation has no clinical significance. Mild to moderate valvular regurgitation that does not progress is unlikely to impact either lifespan or most performance activity.
- In general, loud murmurs with palpable thrills are more likely to be clinically important than quiet ejection murmurs. However, the intensity of the murmur does not always correlate with the severity of the disease, and there are exceptions to this rule (eg, a loud murmur caused by a restrictive VSD may not be clinically significant, but a quiet murmur associated with a large VSD may indicate a large defect with low-velocity flow through the defect and a poor prognosis for life).

PEARLS & CONSIDERATIONS

Most horses with murmurs do not have clinically significant cardiac disease. However, if a murmur is associated with exercise intolerance, lethargy, respiratory signs, collapse, fever, or weight loss, veterinary attention should be sought immediately.

Hematuria

BASIC INFORMATION

DEFINITION

Blood in the urine. Hematuria can be microscopic or macroscopic.

EPIDEMIOLOGY

SPECIES, AGE, SEX The age and sex of the affected horse may rule out some possible causes of hematuria. Urethral rents as a cause of hematuria are reported only in geldings. Male horses are more commonly affected with cystic urolithiasis. Hematuria caused by a hematoma within the bladder and urachus has been reported in foals.

GENETICS AND BREED PREDISPOSITION Idiopathic hematuria is reported primarily in Arabian horses.

RISK FACTORS Horses fed alfalfa hay are at risk of developing hematuria caused by ingestion of blister beetles.

ASSOCIATED CONDITIONS AND DISORDERS

- Urolithiasis
- Blister beetle toxicosis (equine cantharidiasis)
- Urinary tract neoplasia

ElibeVet.com

- Pyelonephritis
- Cystitis
- Urethral rents
- Vascular anomalies

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The history and chief complaints vary with the cause of hematuria.
  - Urethral rents: Hemorrhage occurs immediately after urination.
  - Cystic calculi/urolith: Hematuria is likely to be more pronounced near the end of urination. Hematuria observed after exercise is the most common clinical sign displayed by horses affected with a cystic calculus and is virtually pathognomonic for the condition.
- Renal *Halicephalobus gingivalis* infections: Hematuria plus concomitant neurologic disease and osteomyelitis
- Cantharidin toxicosis: Hematuria plus signs of abdominal pain and a recent history of ingesting alfalfa.
- Miscellaneous: Dehydrated horses treated inappropriately with nonsteroidal antiinflammatory drugs (NSAIDs) may develop hematuria. Hematuria is observed occasionally in exercising horses, especially if the bladder has been emptied immediately before exercise.

PHYSICAL EXAM FINDINGS The hindlimbs are often stained with urine or blood. The presence of a cystic calculus can usually be confirmed by palpation of the bladder per rectum.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hemorrhage into the urethral lumen through a urethral rent occurs when pressure in the corpus spongiosum penis (CSP) increases with contraction of the bulbospongiosus muscle to expel urine remaining in the urethra after urination.
- Exfoliated epithelial cells may act as a nidus for formation of cystic calculi in horses because some horses with urinary calculi have infection of the upper urinary tract.
- A severe, often fatal, idiopathic hematuria is reported to occur in primarily Arabian horses. Some clinicians believe that this condition is caused by pyelonephritis, which is a suppurative bacterial infection of the renal pelvis and parenchyma.
- Hematuria in horses may be caused by renal infection with *H. gingivalis* (previously known as *Micronema deletrix*), a saprophytic nematode.
- Renal and vesicular neoplasia. Adenocarcinoma (renal cell carcinoma) and lymphosarcoma are the most common tumors affecting the kidney, but adenocarcinoma is more likely than lymphosarcoma to cause hematuria. Squamous cell and transitional cell carcinomas of the bladder are also reported to cause hematuria in horses.
- Cantharidin, the toxic principle of blister beetles, is irritating to the digestive and urinary tracts. Irritation of the urinary tract may cause pollakiuria and hemorrhage of the urinary mucosa.
- Trauma to the umbilicus during the periparturient period with damage to the umbilical blood vessels may result in retrograde bleeding into the urachus and bladder and subsequent hematuria.
- Bacterial toxins or immune complexes may cause endothelial damage in glomerular capillary loops and small arterioles (glomerulonephritis), leading to renal failure, intravascular hemolysis, and renal hemorrhage.
- Chronic or excessive administration of NSAIDs causes decreased renal medullary blood flow that may result in medullary necrosis, leading to renal hemorrhage.
- Vascular anomalies, either congenital or acquired, are a rare cause of hematuria in horses.
- Repeated concussion of the bladder during exercise can be sufficient to cause mucosal damage and hemorrhage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hematuria may be confused with hemoglobinuria, myoglobinuria, pigmenturia caused by ingestion of some plants (eg, red and white clover), drug-derived (rifampin, phenothiazine, nitazoxanide, and doxycycline) urinary pigments, and oxidizing agents (pyrocatechin) normally found in urine.
- Urolithiasis
- Blister beetle toxicosis (equine cantharidiasis)
- Urinary tract neoplasia
- Pyelonephritis
- Cystitis
- Urethral rents
- Vascular anomalies
- Glomerulonephritis
- NSAID toxicosis
- Exercise-induced hematuria
- Idiopathic hematuria

INITIAL DATABASE

- Complete blood cell count (CBC) and serum biochemistries, urinalysis, culture of urine collected by catheterization (failure to find bacteria or increased numbers of white blood cells during light microscopy does not rule out bacterial infection of the urinary tract), and palpation of the bladder and pelvic urethra per rectum
- The reproductive system of mares should be examined.
- Whereas an abundance of red blood cells (RBCs) found during microscopic examination of discolored urine suggests hematuria, an absence of RBCs suggests pigmenturia. RBCs may rupture if examination of urine, especially if it is dilute, is delayed (for as little as 1 to 2 hours), resulting in false hemoglobinuria. In this case, RBC ghosts may be seen during microscopic examination of sediment.
- Clinical signs of myopathy and markedly increased serum creatine kinase (CK) activity indicate myoglobinuria as a cause of urine discoloration. Activity of CK is increased to at least several thousand units per liter when significant muscle injury has occurred. Serum is clear if pigmenturia is caused by myoglobinuria.
- In contrast to hematuria and myoglobinuria, intravascular hemolysis causes discolored serum and urine.

ADVANCED OR CONFIRMATORY TESTING

- Endoscopy aids in the diagnosis of a cystic calculus, primary bacterial cystitis, and blood emanating from a ureteral opening (Figure 1).
- Endoscopic examination of a male urethra may identify a 5- to 10-mm linear defect on the convex surface of the urethra distal to the openings of the bulbourethral glands near the level of the ischial arch (Figure 2).
- Ultrasonography of the kidneys and bladder is indicated for cystic urolithiasis if blood is observed emanating from a ureteral orifice during cystoscopy or if no cause of hematuria is apparent.
- Endoscopic catheterization of the ureters for collection of urine if blood is thought to originate from a kidney

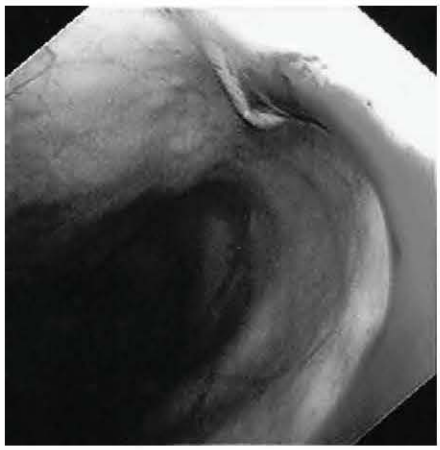

FIGURE 1 Cystoscopy showing blood from the right ureter in a horse with unilateral pyelonephritis.

ElibEVet.com

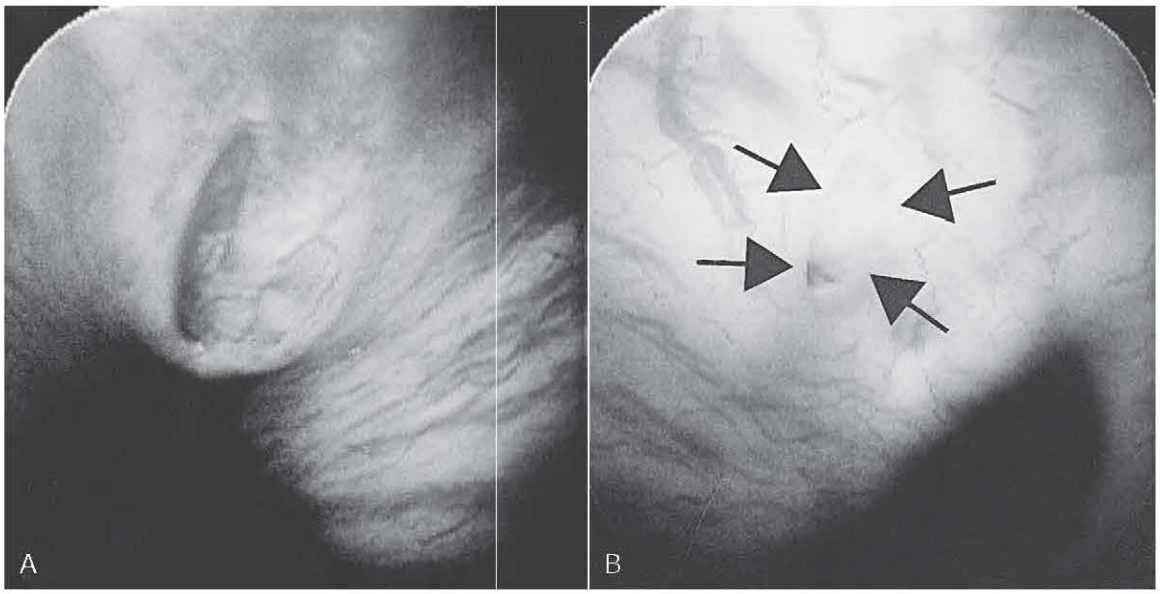

FIGURE 2 Endoscopic images of urethral defects or tears at the level of the ischial arch. **A,** A more acute lesion (hematuria of 2 weeks' duration) is surrounded by a raised rim of tissue. **B,** A chronic lesion (hematuria of 6 months' duration) is flat to recessed (between *arrows*). Evidence of inflammation around both lesions is minimal. (From Reed SM, Bayly WM, Sellon DC, editors: *Equine internal medicine*, ed 3. St Louis, 2010, Saunders Elsevier.)

- Kidney biopsy may be indicated if renal disease is the suspected cause of hematuria.
- If blister beetle toxicosis is suspected as the cause of hematuria, at least 500 mL of urine or 200 g of stomach contents should be submitted to a toxicology laboratory in a refrigerated container for identification of cantharidin. Samples should be collected early in the course of the condition. Suspect hay should also be inspected for possible blister beetles.

TREATMENT

THERAPEUTIC GOAL(S)

- The only treatment for cystic urolithiasis is surgical removal of the urolith.
- Nephrectomy is the treatment for horses with neoplasia of the kidney, but renal adenocarcinomas are usually inoperable because the neoplasm is often not diagnosed until the tumor has metastasized. Function of the contralateral kidney must be normal to perform a nephrectomy.
- Horses with hematuria associated with anuric or oliguric renal failure and intravascular hemolysis usually die, but treatment can be attempted with IV polyionic fluids, vasopressor agents, and diuretics to induce polyuria.

ACUTE GENERAL TREATMENT

- Urethral rents often heal without treatment, but surgical treatment may speed recovery. Affected geldings can be treated by temporary ischial urethrotomy or by an ischial incision that extends into the CSP but does not enter the lumen of the urethra.
- For horses with idiopathic hematuria, long-term antibiotic therapy may be appropriate. If renal hemorrhage is unilateral, then removal of the affected kidney may resolve the signs, but the remaining kidney may also begin to bleed.
- Horses suspected of having a renal infection of *H. gingivalis* should be treated with antiinflammatory drugs and a larvicidal anthelmintic agent.
- Treatment of horses with blister beetle toxicosis includes repeated administration of mineral oil by nasogastric tube because cantharidin is lipid soluble. Diuresis is indicated for affected horses with IV balanced polyionic fluids (with calcium added if the horse is hypocalcemic). Furosemide may be beneficial because cantharidin is excreted via the kidneys.
- Foals with cystic hematomas can be treated surgically by removing the cystic hematoma along with the umbilical remnants and bladder apex. Most affected foals respond to medical treatment with routine antimicrobial prophylaxis and IV fluids to promote diuresis.
- Some horses with severe renal hemorrhage and anemia may require blood transfusion.

CHRONIC TREATMENT

For horses with pyelonephritis, treatment for at least 3 weeks to several months with an appropriate antibiotic is indicated.

RECOMMENDED MONITORING

- Assessment of erythrocyte mass via periodic measurement of packed cell volume and urinalysis
- Horses with suspected pyelonephritis should have periodic CBCs and fibrinogen determinations, urinalyses, and a negative urine culture results before discontinuing antibiotics.
- Horses that have a kidney removed should have regular measurement of serum blood urea nitrogen and creatinine concentrations to monitor function of the remaining kidney.

PROGNOSIS AND OUTCOME

- The prognosis and outcome depend on the cause of hematuria.
- The generally favorable prognosis for horses with cystic urolithiasis has been questioned because of the high rate of recurrence in one large study and the finding that some of these horses may have concomitant pyelonephritis.
- Geldings with urethral rents respond favorably to an ischial incision that extends into the CSP.
- Horses with idiopathic hematuria or pyelonephritis often have recurrence of hematuria; affected horses may experience severe hematuria requiring blood transfusion for survival.
- Horses with hematuria caused by *H. gingivalis* usually die despite treatment.

ElibVet.com

- Horses with renal or vesicular neoplasia usually die or are euthanized, but removal of the affected portion of the bladder wall may result in survival of horses with vesicular neoplasia.

PEARLS & CONSIDERATIONS

The most common causes of hematuria in male horses are urolithiasis and urethral rents. Renal vascular anomalies, anuric or oliguric renal failure, and inappropriate administration of NSAIDs are rare causes of hematuria.

SUGGESTED READING

Schumacher J: Hematuria and pigmenturia of horses. *Vet Clin Equine* 23:655, 2007.

AUTHOR: **JOHN SCHUMACHER**

EDITOR: **BRYAN M. WALDRIDGE**

Hemoperitoneum

BASIC INFORMATION

DEFINITION

Hemorrhage into the peritoneal cavity

SYNONYM(S)

Hemoabdomen

EPIDEMIOLOGY

SPECIES, AGE, SEX Uterine or ovarian artery rupture occurs more often in aged multiparous broodmares than young or primiparous mares.

RISK FACTORS

- Late-term pregnancy or parturition
- Blunt abdominal trauma
- Recent abdominal surgery or percutaneous biopsy of abdominal organs (eg, liver, kidney, spleen)
- Coagulopathy

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Colic (often severe)
- Sweating
- Trembling or muscle fasciculations
- ± Historical evidence of the above risk factors

PHYSICAL EXAM FINDINGS

- Clinical signs related to hypovolemia and hemorrhagic shock, including:
  - Tachycardia (often marked)
  - Tachypnea
  - Weak peripheral pulses, cool extremities, and poor jugular refill
  - Pale mucous membranes, prolonged capillary refill time
  - Weakness
  - ± Altered mentation (depression is typical, but violent behavior or severe colic may also be seen)
- Moderate to severe gross abdominal distension is often noted, especially in the later stages.
- A mesenteric or broad ligament hematoma may be palpated on rectal examination, although the rectal examination is often within normal limits in horses with hemoperitoneum.

ETIOLOGY AND PATHOPHYSIOLOGY

- Rupture of an intraabdominal vessel or organ may occur with any of the following conditions:
  - Uterine or ovarian artery rupture with late-term pregnancy or parturition
  - Blunt external trauma, resulting in rupture of mesenteric vessels or the liver, spleen, or kidney. Rarely, displaced pelvic fractures may lacerate the iliac or pelvic arteries and result in hemoperitoneum.
  - Intraabdominal rupture of the umbilical vessels in neonatal foals
  - Iatrogenic hemorrhage after abdominal surgery (especially after enterotomy or intestinal resection and anastomosis) or biopsy of intraabdominal organs (liver, spleen, or kidney)
  - Intraabdominal neoplasia if invasion of intraabdominal blood vessels or spontaneous hemorrhage from highly vascular tumors occurs
  - Coagulopathy occasionally results in spontaneous hemoabdomen.
  - Rupture of an aortic or other vascular aneurysm is rare but has been described.
- Idiopathic hemoperitoneum also occurs with some frequency in adult horses with no historical risk factors or identifiable cause or source of hemorrhage.
- Rarely, hemorrhage may be confined to the mesentery; intestinal or uterine wall; or within the hepatic, splenic, or renal capsule. In these cases, horses may present with clinical and clinicopathologic findings consistent with acute intraabdominal hemorrhage, but the ultrasonographic findings and peritoneal fluid analysis may not demonstrate frank hemorrhage in the peritoneal cavity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Strangulating intestinal obstruction (in horses with signs of severe abdominal pain)

INITIAL DATABASE

- Packed cell volume (PCV) and total solids (TS)
  - May be normal in acute stages. A disproportionate decrease in TS concentration is often noted before the PCV decreases significantly.
  - Within 6 to 24 hours of initial hemorrhage, decreased PCV and TS concentration are typically observed.
- Complete blood count
  - Variable hematocrit, as for PCV above.
  - Leukogram is usually normal or consistent with a stress response.
  - The platelet count is usually within reference intervals unless a concurrent coagulopathy (disseminated intravascular coagulation, immune-mediated thrombocytopenia) is present.
- Serum biochemistry profile and blood gas analysis
  - Hypocalcemia is frequently present because of loss of albumin-bound calcium. Ionized calcium may be normal or low.
  - Hypoproteinemia or hypoalbuminemia is usually present.
  - Variable azotemia (prerenal or renal) is often present and is reflective of poor renal perfusion because of hypovolemia.
  - Hyperlactatemia (>2 mmol/L) or low venous oxygen (PvO_2 <30 mm Hg or SvO_2 <50%) in an anaerobically collected sample indicates significantly decreased oxygen-carrying capacity.
- The coagulation profile should be performed to rule out an underlying coagulopathy.

ElibeVet.com

- Transabdominal ultrasonography
  - A moderate to significant volume of homogeneously echogenic, swirling, free peritoneal fluid is usually visible in the ventral abdomen by the time clinical signs are present.
  - Ultrasonographic evidence of intra-abdominal neoplasia; mesenteric hematoma; or hepatic, splenic, or renal rupture may be apparent.
- Peritoneal fluid analysis: The peritoneal fluid is usually grossly hemorrhagic in appearance, with a PCV and TS concentration similar to the peripheral blood.
  - A very low PCV may indicate mild and resolving hemoperitoneum or intestinal compromise with a strangulating intestinal obstruction.
  - A PCV that is significantly higher than the peripheral blood is more consistent with splenocentesis than hemoperitoneum. Ultrasonographic visualization of the spleen at the site of the abdominocentesis is supportive of splenocentesis.
  - Cytologic evaluation of the peritoneal fluid may reveal platelets in acute or ongoing hemorrhage or hemosiderophages or erythrophagocytosis with previous or chronic hemorrhage (>6–12 hours' duration).

ADVANCED OR CONFIRMATORY TESTING

- Exploratory celiotomy
  - Because of the size and depth of the equine abdomen, surgical localization and ligation of the bleeding vessel or vessels is difficult to impossible in many cases. Thus medical management is usually preferable in most cases of hemoperitoneum.
  - Rarely, exploratory surgery may be indicated in horses exhibiting severe abdominal pain to confirm hemoperitoneum and rule out a concurrent intestinal lesion.

TREATMENT

THERAPEUTIC GOAL(S)

- Support hemostasis
- Replace intravascular volume and oxygen-carrying capacity
- Provide pain relief
- Provide supportive care

ACUTE GENERAL TREATMENT

- Hemostatic support: Keep the patient quiet with strict stall confinement and a quiet atmosphere.
- Sedation should be avoided if possible unless the horse is violent because of alterations in blood pressure caused by commonly used sedatives.
- Aminocaproic acid (10–40 mg/kg IV slowly in 1 L of 0.9% saline q6h *or* 70 mg/kg in 1 L of 0.9% saline IV over 20–30 minutes; then IV continuous rate infusion [CRI] at 15 mg/kg/h) to inhibit fibrinolysis.
- Fresh or fresh-frozen plasma should be administered to provide clotting factors and platelets if a primary coagulopathy is present.
  - Drainage of the blood from the peritoneal cavity is rarely, if ever, indicated because the increasing abdominal pressure actually supports hemostasis. In addition, erythrocytes and plasma proteins may be reabsorbed from the peritoneal cavity as hemorrhage ceases.
- Fluid therapy and blood transfusion
  - Aggressive fluid resuscitation with hypertonic saline, hydroxyethyl starch, or bolus administration of isotonic crystalloids should be avoided because a rapid increase in blood pressure may perpetuate hemorrhage. However, reestablishment of normovolemia is vital, and conservative fluid therapy with isotonic crystalloids at 50 to 100 mL/kg/d is indicated in most cases. The decrease in PCV that will occur with crystalloid therapy is not concerning because peripheral perfusion and tissue oxygenation improve with the resultant volume expansion. Fluid therapy rates should be sufficient to maintain mean arterial pressure above 70 mm Hg and ensure normal urine production.
  - Whole-blood transfusion or administration of synthetic bovine hemoglobin (Oxyglobin) is indicated in horses exhibiting clinical signs of hypovolemia or hemorrhagic shock or clinicopathologic evidence of decreased oxygen-carrying capacity as above, regardless of the PCV.
- Analgesic therapy and supportive care
  - Flunixin meglumine: 0.5 to 1.1 mg/kg IV q12h
  - Lidocaine (1.3 mg/kg IV slow; then 0.05 mg/kg/min IV CRI) for refractory pain
  - Naloxone (0.01–0.03 mg/kg IV) is an opioid antagonist that may be beneficial in hemorrhagic shock. It should not be used in conjunction with butorphanol.
- Prophylactic broad-spectrum antimicrobial therapy with ceftiofur (2.2 mg/kg IV q12h) or with potassium penicillin (22,000 IU/kg IV q6h) and gentamicin (6.6 mg/kg IV q24h) or enrofloxacin (5 mg/kg IV q24h) should be initiated because intraperitoneal blood is an optimal medium for bacterial growth.

POSSIBLE COMPLICATIONS

- Acute renal failure may occur because of hypoxic injury to the kidneys.
- Laminitis is also a possible complication if hemorrhagic shock or hypoperfusion is severe.

RECOMMENDED MONITORING

- PCV and TS, venous lactate concentration, and venous oxygen saturation should be monitored to determine if transfusion(s) is necessary.
- Urine output and renal function should also be monitored carefully during initial therapy.

PROGNOSIS AND OUTCOME

- The prognosis is variable and depends on the location of bleeding, inciting cause, and response to initial therapy.
  - If hemorrhage is confined to the mesentery or broad ligament, the prognosis for recovery is generally good, although hemorrhage may recur in subsequent pregnancies in broodmares.
  - If hemostasis is established early on and good clinical response to aggressive medical therapy is noted, prognosis is generally good even if the source of bleeding is never identified (eg, in idiopathic hemoabdomen).
  - The prognosis with splenic or hepatic rupture or rupture of a large uterine or mesenteric artery or aortic aneurysm is usually guarded to poor because hemorrhage can occur at such a rapid rate that even early and aggressive medical therapy is futile.

PEARLS & CONSIDERATIONS

In horses with acute hemoperitoneum, the peripheral PCV and TS are often normal. Thus, transabdominal ultrasonography and serial monitoring of the PCV and TS are vital for making an early and accurate diagnosis of hemoperitoneum.

ElibeVet.com

Hemorrhage

BASIC INFORMATION

DEFINITION

Loss of blood from the vascular space

SYNONYM(S)

- Extravascular blood loss
- Bleeding

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses of any age are susceptible to blood loss because of a number of causes; however, vessel rupture and urolithiasis are more common in older horses, and idiopathic hematuria is limited to males.

GENETICS AND BREED PREDISPOSITION Genetic platelet disorders and coagulation factor dysfunction have been identified in horses, as well as a genetic predisposition to granulomatous gastrointestinal proliferation and urolithiasis.

RISK FACTORS

- Horses in race training are at risk for developing exercise-induced pulmonary hemorrhage.
- Horses taking nonsteroidal antiinflammatory drugs (NSAIDs; eg, phenylbutazone) are at risk for right dorsal colon ulceration and hemorrhage.

CONTAGION AND ZOONOSIS

- Certain infectious and parasitic causes of hematuria may be transferred between horses
  - Strongylus vulgaris
  - Streptococcus equi

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Hemorrhage can be classified by location (internal or external), duration (acute or chronic loss), vessel size (capillary and venuole or arteriole versus larger vessel), and cause (coagulation disorder versus traumatic vessel disruption)

HISTORY, CHIEF COMPLAINT

- Chief complaints are variable and depend on the amount of blood lost and how acute the loss is.
  - External signs of blood loss may be apparent (Figure 1).
  - Significant blood loss may cause pallor, colic, sweating, and depression.
  - Less significant blood loss or chronic loss of blood may be noted as lethargy and exercise intolerance.

PHYSICAL EXAM FINDINGS

- Hypothermia, cool extremities, sweating
- Tachypnea
- Tachycardia with extreme blood loss
- Pale mucous membranes

FIGURE 1 Fatal guttural pouch mycosis. Complete exsanguination occurred within 10 minutes after rupture of the internal carotid.

- Poor pulse quality
- Decreased gastrointestinal sounds, colic
- Petechia, ecchymosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Traumatic vascular disruption occurs because of an injury that mechanically opens a vessel or vessels (caused by injury, disease, infection, or neoplasia) with a normal coagulation system that is unable or slow to repair the defect because of vessel size and blood pressure, repeated trauma, or systemic inflammation.
- Hemostatic bleeding disorders may occur by one of two pathways:
  - Primary hemostatic defects involve either a genetic failure of the platelets to functionally occlude a vascular leak or thrombocytopenia, which reduces effective platelet numbers. Both result in capillary and small vessel hemorrhage (petechia, ecchymosis).
  - Secondary hemostatic issues are related to coagulopathies caused by congenital defects, vitamin K deficiencies, hepatic disease, drug toxicity, envenomation, poisons, or consumption of coagulation factors (ie, disseminated intravascular coagulation). This results in overt hemorrhage into body cavities or externally.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Degenerative disorders
  - Vessel rupture
    - Aorta
    - Middle uterine artery
- Anomalies
  - Idiopathic hematuria in geldings and stallions
  - Coagulation abnormalities
    - Genetic platelet function disorders
    - Coagulation factor disorders (von Willibrand disease)
- Neoplastic conditions
  - Paranasal sinus and skull neoplasia
  - Urogenital (renal, ureteral, bladder, uterine, perineal) neoplasia
  - Abdominal organ neoplasia
- Inflammatory
  - Infectious
    - Guttural pouch mycosis (*Aspergillus* spp.)
    - Pneumonia
    - Pleuritis
    - Paranasal sinus infection
    - Pyelonephritis
    - Cystitis
    - Urolithiasis
    - Abdominal abscess (*Streptococcus equi*)
  - Parasitic
    - Verminous arteritis
    - Gastrointestinal and ectoparasites
  - Noninfectious
    - Gastrointestinal ulceration
    - Hepatic failure (lack of coagulation factors)
    - Envenomation
    - Systemic inflammatory response syndrome
- Immune disorder: Granulomatous enteritis
- Trauma
  - Exercise-induced pulmonary hemorrhage
  - Head trauma, skull fracture
  - Ventral straight muscle (longus capitus and rectus capitus ventralis muscle) rupture: Poll trauma

ElibeVet.com

- Thoracic trauma
- Rib fracture
- Abdominal trauma
  - Splenic rupture
  - Hepatic fracture
  - Mesenteric vessel rupture
- Iatrogenic trauma
  - Surgery
  - Nasogastric intubation
  - Percutaneous biopsy
- Wounds
- Foreign bodies

- Toxicity
  - NSAID (right dorsal colitis)
  - Rodenticides
  - Heparin overdose
  - High-dose colloid administration (hetastarch or dextran)

INITIAL DATABASE

- Physical examination: Determine the site or sites of hemorrhage.
- Packed cell volume (PCV) and total protein (may not reflect acute blood loss of <8 hours)
- Platelet count
- Arterial blood pressure (effective in identifying acute hemorrhage)
- Blood gas (pH, venous oxygen, base deficit)
- Central venous pressure

ADVANCED OR CONFIRMATORY TESTING

- Coagulation testing
  - Activated clotting time
  - Activated partial thromboplastin time
  - Prothrombin time
  - Thrombin clotting time
  - Protein C
  - D-dimers and fibrinogen
  - Thromboelastography

TREATMENT

THERAPEUTIC GOAL(S)

- Stop active bleeding
- Provide adequate tissue perfusion
- Increase the oxygen-carrying capacity of the blood

ACUTE GENERAL TREATMENT

- Hemostasis
  - Apply pressure to vessels (bandaging).
  - Seal vessels with cautery, ligation, or thrombin sealants.
  - Antifibrinolytic medications may assist inaccessible bleeding.
    - Aminocaproic acid: 3.5 mg/kg/min IV over 15 minutes; then continuous rate infusion of 0.25 mg/kg/min for up to 6 hours
    - Formalin (10%): 37 mL diluted to 1 L in 0.9% saline; bolus slowly
- Fluid resuscitation
  - Controlled hemorrhage: Shock dose fluid administration (see "Shock Dose Fluid Administration" in Section II)
    - Hypertonic saline, crystalloids, and colloids early
    - The goals of resuscitation is normalization of vital parameters to ensure microcirculation.
      - pH = 7.4
      - Lactate <2 mmol/L
      - Venous oxygen tension near 30 mm Hg
      - Urine production
      - Normal mentation
  - Uncontrolled hemorrhage: Hypotensive resuscitation
    - Administer fluid therapy (crystalloids only) to maintain a mean arterial pressure of 60 mm Hg.
      - Provides adequate tissue perfusion without disrupting the fibrin seal, promoting reactive vasoconstriction, or diluting clotting factors.
      - The goal of hypotensive resuscitation is to ensure minimal perfusion of the microcirculation.
        - pH >7.25
        - Lactate <4 mmol/L
        - Urine production
        - Normal mentation
- Normalization of hemostatic components
  - Indications for transfusion are lactate concentrations above 4 mmol/L, PCV below 12%, loss of 30% of the blood volume or uncontrolled hemorrhage, and persistent hypotension despite fluid resuscitation.
  - Goals of hemostatic transfusions are a PCV above 15% and platelets above 50,000/µL.
    - Plasma administration provides coagulation factors, albumin, and platelets.
    - Whole blood provides hemoglobin, coagulation factors, albumin, and platelets.
    - 2.2 mL/kg of whole blood increases PCV by approximately 1%.
    - Packed red blood cells provide hemoglobin only (for normotensive patients).

CHRONIC TREATMENT

Depends on the cause of hemorrhage

POSSIBLE COMPLICATIONS

Administration of colloids (hetastarch, dextrans) at high doses may inhibit coagulation through interference with von Willebrand factor and factor 8, as well as through further dilution of clotting factors.

RECOMMENDED MONITORING

- Depends on the cause of hemorrhage
- Monitor parameters of perfusion for severe hemorrhage (lactate, blood pressure, urination, mentation, pH).
- Monitor PCV.
- Monitor platelet count and coagulation profile.

PROGNOSIS AND OUTCOME

Related to the ability to stop acute hemorrhage, the horse's response to fluid resuscitation, and the ability to provide definitive therapy for the cause of bleeding

PEARLS & CONSIDERATIONS

Hypovolemic shock may not alter physical examination findings if it is compensated, so additional tests (lactate, pH, venous oxygen saturation) may be required to identify tissue oxygen debt.

ElibeVet.com

Hemorrhage, Postpartum

BASIC INFORMATION

DEFINITION

- Rupture of the middle uterine (most common), utero-ovarian, external iliac, vaginal, or adrenal artery near parturition
- Hemorrhage may be contained within the broad ligament or uterine wall, forming a hematoma, or may occur into the peritoneal cavity or uterine lumen.

SYNONYM(S)

Broad ligament hematoma, rupture of the uterine artery

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Intact mares during the immediate postpartum period; may also occur prepartum
- More common in multiparous mares older than 10 years of age
- Postpartum hemorrhage affects 2% to 3% of broodmares and accounts for 40% of deaths in peripartum mares.

RISK FACTORS

- Aging
- Multiple pregnancies
- Uterine prolapse
- Uterine torsion

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of recent parturition
- Abdominal pain
- Cardiovascular shock
- Hemorrhagic vulvar discharge
- Weakness, depression
- Cold sweat
- Ataxia

PHYSICAL EXAM FINDINGS

- Tachycardia
- Tachypnea
- Sweating
- Muscle fasciculation
- Pale mucous membranes. Mucous membrane color may be pink during the acute phase.
- Delayed capillary refill time
- Weak pulse

ETIOLOGY AND PATHOPHYSIOLOGY

- Aged-related degenerative changes in the elastic and collagen fibers of the arterial walls may predispose to rupture, especially during stretching of the broad ligament and arteries during late gestation.
- Low serum copper concentrations in aged mares may result in vessel fragility.
- Displacement of the uterus to the left by the cecum may increase tension on the right vessels and account for the predisposition for right-side ruptures.
- Uterine prolapse or torsion may result in rupture of the middle uterine artery.
- Bleeding may occur into the peritoneal cavity or uterine lumen, often resulting in exsanguination. Hemorrhage may also dissect into the broad ligament or between the myometrium and perimetrium, resulting in hematoma without exsanguination, unless the broad ligament or perimetrium tear.
- Necrosis, thrombosis, and rupture of the external iliac artery may result from damage to the intima and media by parasites.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Postpartum abdominal pain or depression
  - Toxic metritis
  - Uterine rupture
  - Intussusception of the uterine horn
  - Intestinal or mesenteric rupture or trauma
  - Colon torsion
  - Ileus
  - Diaphragmatic rupture
  - Bladder rupture
- Postpartum vulvar discharge
  - Soft tissue trauma of the birth canal
  - Normal lochia
  - Metritis

INITIAL DATABASE

- Complete blood count (CBC): Anemia and hypoproteinemia, hyperfibrinogenemia or hypofibrinogenemia. Clinicopathologic changes may not be present during the acute phase because of vascular compensation, splenic contraction, and relative loss of red blood cells and plasma.
- Transrectal palpation: Enlarged uterus or large, firm swelling within the broad ligament. Transrectal palpation may elicit pain.
- Vaginal speculum examination: Accumulation of blood in the cranial vagina
- Transrectal ultrasonography: Hematoma within the broad ligament or uterine wall
- Transabdominal ultrasonography: Swirling hyperechoic particles within the hypoechoic fluid consistent with hemoperitoneum

ADVANCED OR CONFIRMATORY TESTING

Abdominocentesis: Pink or red peritoneal fluid, increased total protein concentration and red blood cell count, phagocytized red blood cells consistent with hemoperitoneum

TREATMENT

THERAPEUTIC GOAL(S)

- Restore cardiovascular volume.
- Aid in hemostasis.
- Provide analgesia and sedation.
- Provide antimicrobial prophylaxis.

ACUTE GENERAL TREATMENT

- Restoration of cardiovascular volume
  - Resuscitation with hypertonic saline (7.5% NaCl solution): 2 to 4 mL/kg IV followed by 10 to 20 L of lactated Ringer's solution (LRS) over 2 to 4 hours.
  - Whole-blood transfusion from a cross-matched blood donor: 6 to 8 L at 30 mL/kg/h if estimated loss is 25% of blood volume or there is rapid uncontrollable hemorrhage
- Improvement of oxygen perfusion
- Intranasal oxygen insufflation: 5 to 10 L/min
- Pentoxifylline: 7.5 mg/kg PO q12h
- Hemostasis
  - Aminocaproic acid: Loading dose of 20 g diluted in 1 L of LRS IV given over 20 min followed by 10 g q12h for 36 to 48 hours
  - 10% formalin: 30 mL diluted in 1 L of isotonic fluids, IV q12–24h. The effect of formalin on coagulation parameters and bleeding times in horses is controversial.
  - Yunnan baiyao: 8 mg/kg PO q4h for 3 to 4 days
- Analgesia and sedation
  - Flunixin meglumine: 1.1 mg/kg q12h IV
  - Butorphanol tartrate: 0.02 to 0.04 mg/kg IV
  - Xylazine: 0.5 to 1.1 mg/kg IV q6–12h
  - Detomidine: 0.01 to 0.02 mg/kg IV or IM q6–12h
- Antimicrobial prophylaxis
  - Potassium penicillin: 22,000 IU/kg IV q6h and gentamicin 6.6 mg/kg IV q24h
  - Ceftiofur: 2.2 mg/kg IV q12h
  - Trimethoprim/sulfamethoxazole: 15 to 30 mg/kg PO q12h
- Maintain the mare in a dark, quiet environment to prevent increases in

ElibVet.com

blood pressure and disruption of the blood clot.
- Protect the foal from the mare's colic episodes. Do not separate the mare and foal to prevent agitation and further bleeding.

CHRONIC TREATMENT

Maintain strict stall confinement for 3 to 4 weeks.

POSSIBLE COMPLICATIONS

- Death
- Abscessation
- Peritonitis
- Endotoxemia secondary to abscessation
- Cardiac arrhythmias

RECOMMENDED MONITORING

- Monitor the CBC.
- Monitor hematoma for abscessation.
- Monitor for signs of colic or ileus that may result from release of inflammatory mediators that alter gastrointestinal activity or intestinal blood flow. Monitor fecal output and consistency and administer mineral oil (0.5–1 gallon) or bran mash if necessary.

PROGNOSIS AND OUTCOME

- Prognosis for survival is good for hemorrhage contained within the broad ligament because hemorrhage is usually self-limited, resulting in formation of a hematoma. Bleeding into the peritoneal cavity or uterine lumen carries a poor prognosis, and hemorrhage is often fatal.
- Reported survival rate is 84% with early diagnosis and aggressive medical therapy.
- A total of 49% of mares were reported to deliver one foal in subsequent pregnancies without further hemorrhage.

PEARLS & CONSIDERATIONS

COMMENTS

Blood volume replacement and therapeutic or diagnostic procedures may elevate blood pressure and may result in further bleeding.

CLIENT EDUCATION

- Postpartum hemorrhage may be life threatening.
- The veterinarian must be contacted immediately if a postpartum mare develops colic, weakness, or depression.

SUGGESTED READING

Arnold CE, Payne M, Thompson JA, et al: Periparturient hemorrhage in mares: 73 cases (1998–2005). *J Am Vet Med Assoc* 232:1345–1351, 2008.

AUTHOR: **MARIA S. FERRER**

EDITOR: **JUAN C. SAMPER**

Hemospermia

BASIC INFORMATION

DEFINITION

- The presence of blood (erythrocytes) in the ejaculate, either macroscopic (as evident on gross examination of red-tinged semen) or microscopic (occult hemospermia)
- Causes infertility by an unknown mechanism of the red blood cells on semen

SYNONYM(S)

Hematospermia

EPIDEMIOLOGY

SPECIES, AGE, SEX Occurs in stallions of any breed or age

RISK FACTORS Stallions that are bred frequently may be at increased risk.

ASSOCIATED CONDITIONS AND DISORDERS
- Urethritis
- Seminal vesiculitis
- Other diseases of the urogenital tract
- Hematuria

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT
- Red-tinged semen (if collected), or red fluid discharge from the mare's vulva or stallion's prepuce (if bred by natural cover)
- Bloody discharge from the penis after breeding (Figure 1)
- Blood on the collection dummy or phantom (Figure 2)
- Potentially slow or painful ejaculation when the stallion is bred or collected
- Potential observation of penile or preputial lesions

PHYSICAL EXAM FINDINGS
- Blood traces on the hind legs
- Presence of erythrocytes in semen (may not be grossly discolored if microscopic hemospermia is present [Figure 3])
- Stallions are usually clinically healthy with no systemic signs of illness.

ETIOLOGY AND PATHOPHYSIOLOGY
- Blood from lesions on the surface of the penis: Habronemiasis and squamous cell carcinoma are the most common.
- Blood from an inflammatory process in the urethra or seminal vesicles
- A urethral defect (urethral rent) results in hemospermia because of the increase in pressure in the corpus spongiosum penis during erection and ejaculation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bacterial or viral urethritis: Ulcerated urethral epithelium may slough
- Lesions of the glans penis or urethral process
  - Lacerations
    - Trauma
    - From the mare's tail hairs during breeding
  - Squamous cell carcinoma or other neoplasms
  - Cutaneous habronemiasis
- Improperly used stallion rings
- Urethral defects or rents
- Inflammation or infection of accessory sex glands (especially the seminal vesicles)

INITIAL DATABASE

- Complete examination of the stallion's penis should be performed.
- Inspect the glans, urethral process, and prepuce for lacerations or lesions
- Examination of the urethra and accessory sex glands via videoendoscopy (1-m endoscope)
  - Commonly, a linear urethral rent 5 to 10 mm long is present caudodorsally on the convex surface

ElibeVet.com

FIGURE 1 Bloody discharge from the urethral process of a stallion after semen collection.

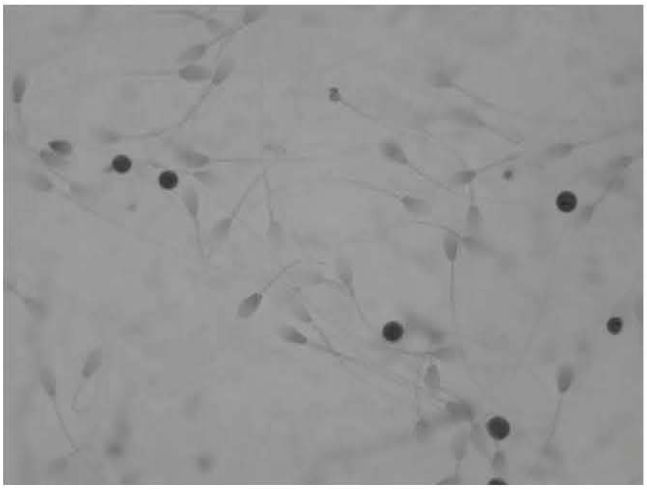

FIGURE 3 Microscopic (occult) hemospermia.

FIGURE 2 Bloody discharge on the collection dummy or phantom after collection.

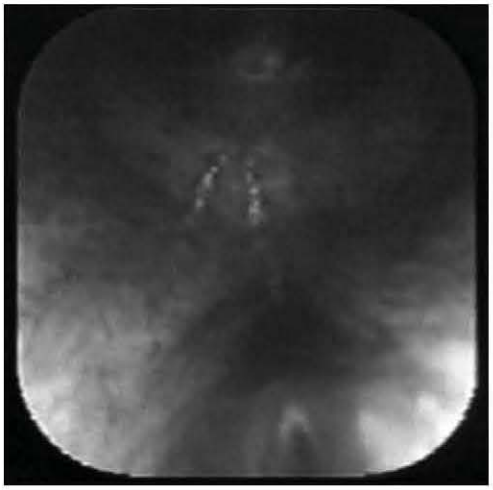

FIGURE 4 Endoscopic view of a urethral rent after collection.

of the urethra at the level of the ischial arch, which communicates with the corpus spongiosum penis (Figure 4).
- Examination after collection may demonstrate bleeding from the rent.
  - Double-contrast radiography of the penis may demonstrate urethral strictures or luminal defects.
  - Cytologic samples obtained from the urethra after collection may demonstrate viral inclusion bodies or neoplastic cells.

TREATMENT

THERAPEUTIC GOAL(S)

Elimination of erythrocytes in the ejaculate to restore or improve fertility

ACUTE/CHRONIC GENERAL TREATMENT

- Sexual rest (required with all treatments)
- Systemic antiinflammatory medications
- Traumatic lesions may be treated by washing the penis and applying appropriate topical medications or ointments.
- Bacterial urethritis may be treated with antimicrobial therapy based on culture and sensitivity results of collected samples.
- If blood contamination is minimal, semen may be collected in extender and washed before use.
- Formalin IV has been used as a last resort, but bleeding recurred when treatment was stopped.
- Surgical treatment by temporary subischial urethrotomy
  - Relieves the buildup of pressure in the corpus spongiosum penis
  - ± Topical application of antiinflammatories or steroids into the urethrotomy site
  - Return to sexual function after treatment of a urethral rent with a buccal mucosal urethroplasty via subischial urethrotomy has been reported recently.

POSSIBLE COMPLICATIONS

- From urethrotomy: Postoperative hemorrhage or infection (incisional infection, cystitis, or orchitis); urethral fistula, diverticulum, or stricture formation; dysuria
- Loss of libido
- Ejaculatory disorders

RECOMMENDED MONITORING

- Examination via videoendoscopy is suggested before return to sexual function to evaluate the urethral mucosa integrity.
- Collection and evaluation of semen for residual hemospermia is recommended before breeding.

ElibeVet.com

PROGNOSIS AND OUTCOME

- Variable because of low numbers of stallions treated and evaluated by these methods
- Subischial urethrotomy has returned some stallions to breeding but has not shown to be reliably effective in treating urethral rents.
- Penile lacerations and cutaneous habronemiasis carry better prognoses for return to sexual function.

Hendra Virus

BASIC INFORMATION

DEFINITION

Exotic pneumotropic and neurotropic virus resulting in severe respiratory and neurologic signs and often death of infected horses

SYNONYM(S)

- Equine Morbillivirus
- Equine acute respiratory syndrome

EPIDEMIOLOGY

RISK FACTORS Mainly relate to bat exposure, including outdoor housing and feeding under trees and bats roosting in barns.

CONTAGION AND ZOONOSIS

- *Pteropus* fruit bats are natural hosts and are not affected by clinical disease.
- Transmission to horses is rare; the virus is not highly contagious between horses.
- Exposure to bat saliva, urine, aborted fetuses, and reproductive fluids are thought to result in transmission from bat to horse, possibly through contaminated food or water.
- Aerosol transmission to and between horses is not a primary method of spread; rather, the virus is possibly spread through human fomites.
- Disease in humans is rare, but Hendra virus is zoonotic, resulting in frequently fatal infection in humans exposed to infected equine tissues or bodily fluids.

GEOGRAPHY AND SEASONALITY All known outbreaks have occurred in Australia.

CLINICAL PRESENTATION

PHYSICAL EXAM FINDINGS

- High fever
- Tachypnea and tachycardia
- Respiratory distress with blood-tinged, foamy nasal and oral discharge
- Neurologic signs, including head pressing, ataxia, and tonic spasms of the neck and hind limb muscles
- Collapse
- Death within 36 hours in horses that fail to survive
- Incubation period is 6 to 10 days

ETIOLOGY AND PATHOPHYSIOLOGY

- Closely related to *Nipah* virus from Malaysia, only two members of the genus Henipavirus
- Enveloped, single-stranded RNA virus
- Pneumotropic and probably neurotropic
- Little is known about portal of entry, distribution and persistence of virus in body, and routes of excretion.
- The virus attacks vascular endothelial cells, resulting in pulmonary edema.
- The pathogenesis in neurologic tissues is likely similar.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute African horse sickness
- Virulent equine influenza

INITIAL DATABASE

- Not many diagnostic tests are performed in most cases because efforts are focused on triage care.
- Diagnosis is generally made on necropsy.

ADVANCED OR CONFIRMATORY TESTING

- Characteristic immunofluorescence and immunoperoxidase staining of tissues histopathologically
- Virus isolation can be performed antemortem with blood, nasal swabs, urine, or tissues and can be more effectively isolated postmortem from the lung, liver, spleen, or brain.
- Polymerase chain reaction, electron microscopy, and immunohistochemistry can be used as well to detect organisms.
- Serum neutralization, enzyme-linked immunosorbent assay, and indirect fluorescent antibody tests can be used for serology.

(Courtesy Gary Crameric, CSIRO Livestock Industries' Australian Animal Health Laboratory. From Sellon DC, Long MT: *Equine infectious diseases*. St Louis, 2007, Saunders Elsevier.)

TREATMENT

THERAPEUTIC GOAL(S)

None. Treatment is not pursued after a diagnosis of Hendra virus infection is made because of the serious zoonotic potential.

ACUTE GENERAL TREATMENT

- No specific therapy
- Before diagnosis and subsequent euthanasia, horses are usually treated with supportive care.

PROGNOSIS AND OUTCOME

- There is a 70% fatality rate in reported outbreaks because of the virus itself.
- There is a 100% death rate because of euthanasia of surviving horses.

PEARLS & CONSIDERATIONS

COMMENTS

- Because of the severity of disease and potential for zoonotic transmission, horses diagnosed with Hendra virus are euthanized if they do not die acutely from disease.
- It is unknown whether the virus would persist in recovered animals, resulting in a carrier state.
- Hendra virus is considered a Biocontainment Level 4 agent.

PREVENTION

- No vaccine is available.
- Prevent exposure to bats.
- Early diagnosis of potential cases and containment via euthanasia are recommended.
- Serologic surveillance of potentially exposed horses is also recommended.

Hepatic Abscesses

BASIC INFORMATION

DEFINITION

Hepatic abscesses are chronic focal to multifocal areas of infection that are relatively uncommon in horses. They may develop as a sequela to bacterial invasion of the liver.

SYNONYM(S)

Liver abscess

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS

- Bacterial hepatitis
- Cholangitis
- Cholangiohepatitis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Signs of hepatic abscessation are typically vague and not indicative of primary hepatic disease.
- Weight loss from reduced appetite is often present.

PHYSICAL EXAM FINDINGS

- Physical examination of horses with hepatic abscessation generally reveals signs of chronic infection, such as poor body condition, lethargy, fever, and dull haircoat.

ETIOLOGY AND PATHOPHYSIOLOGY

- In foals, hepatic abscessation may develop as a sequela to bacteriemia or ascending infection through the umbilical vein secondary to omphalophlebitis.
- In mature horses, bacteremia and septicemia are uncommon, so hepatic

ElibeVet.com

abscesses are more like to develop secondary to ascending infection of the biliary tract or infection that originates in the intestinal tract or mesenteric lymph nodes and is carried to the liver via the portal blood.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hepatic abscessation must be differentiated from any chronic infectious disease or chronic illness.
- Other causes of chronic hepatic disease that may have a similar clinical presentation include:
  - Hepatic neoplasia
  - Cholangitis or cholangiohepatitis
  - Cholelithiasis
  - Chronic active hepatitis
  - Chronic megalocytic hepatopathy

INITIAL DATABASE

- Complete blood count: Anemia of chronic disease, mature neutrophilia
- Fibrinogen concentration: Increased
- Serum total protein concentration: Increased from hyperglobulinemia
- Liver enzyme activities (ie, sorbitol dehydrogenase, gamma glutamyltransferase): Typically within normal limits unless extensive hepatic abscessation is present
- Serum bile acid concentration: Typically within normal limits unless extensive hepatic abscessation is present

ADVANCED OR CONFIRMATORY TESTING

- Transabdominal ultrasonography of the liver may reveal focal changes in echogenicity in areas of abscessation.
- Ultrasound-guided aspiration of hepatic abscesses may reveal suppurative or septic purulent inflammation.

TREATMENT

THERAPEUTIC GOAL

The primary goal of treatment is to eliminate the bacterial agent responsible for inciting the hepatic abscess.

ACUTE GENERAL TREATMENT

- Long-term antimicrobial therapy is warranted.
- When possible, antimicrobial therapy should be guided by culture results obtained from percutaneous aspiration or hepatic biopsy.

POSSIBLE COMPLICATIONS

Hepatic abscesses could rupture spontaneously or during attempts to aspirate or biopsy, causing septic peritonitis.

RECOMMENDED MONITORING

Antimicrobial therapy should be continued until resolution of clinical signs and laboratory indications of infection.

PROGNOSIS AND OUTCOME

- The prognosis is variable and depends on the duration and degree of abscessation.
- Extensive or widespread abscessation warrants a poor to guarded prognosis.

PEARLS & CONSIDERATIONS

Common abdominal abscess isolates in horses include *Streptococcus equi* subsp. *equi*, *Streptococcus equi* subsp. *zooepidemicus*, and *Corynebacterium pseudotuberculosis*.

AUTHOR & EDITOR: **MICHELLE HENRY BARTON**

Hepatic Amyloidosis

BASIC INFORMATION

DEFINITION

A rare disorder of protein folding in which normally soluble proteins are deposited as insoluble fibrils that progressively disrupt tissue structure and impair function

EPIDEMIOLOGY

SPECIES, AGE, SEX Affected animals tend to be mature, although some may be relatively young (ie, 3–4 years of age).

ASSOCIATED CONDITIONS AND DISORDERS

- The condition may develop either locally or systemically; the liver is commonly affected in horses with systemic amyloidosis.
- Hepatic amyloidosis occurs after repeated or prolonged inflammatory stimulation and has been most frequently reported in horses used for hyperimmune serum production.
- Hepatic amyloidosis has also been described in horses with severe strongylosis, peritonitis, chronic pleuropneumonia, tuberculosis, and neoplasia.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Hepatic amyloidosis typically occurs secondary to recurrent acute or chronic infections, inflammatory diseases, or neoplasia. History and primary complaints are therefore often related to the underlying disease.
- Chronic weight loss is common.
- Horses used for serum production reportedly show few, if any, clinical signs despite severe liver amyloid deposition.

PHYSICAL EXAM FINDINGS

- Clinical signs related to the underlying disease tend to dominate the clinical picture. Clinical signs directly related to amyloidosis depend on the organ distribution of the amyloid deposition and may be caused by either functional disturbances or mechanical alterations because of organ enlargement.
  - May be found dead after hepatic (or splenic) rupture without prior clinical signs
  - Poor body condition
  - Nephrotic syndrome, proteinuria, and hypoproteinemia are features of amyloidosis in many species and may occur in some horses used for serum production.

ETIOLOGY AND PATHOPHYSIOLOGY

- Amyloidosis may be systemic or localized and life threatening or merely an incidental finding. Extracellular amyloid deposition occurs as a result of protein misfolding, disrupting tissue structure and function.
- The amyloidoses are classified by the type of protein deposited; in human medicine, at least 23 different proteins have been implicated.
- AA- and AL-type amyloidosis are most commonly reported in equine cases.
- Both systemic and localized disease occur in horses.
- The protein in AA amyloidosis (secondary or reactive amyloidosis) is derived from serum amyloid A (SAA), which is synthesized by hepatocytes

ElibVet.com

in response to inflammatory stimulation.
- Systemic amyloidosis in horses usually involves AA amyloid.
- Sustained overproduction of SAA is required for development of AA amyloidosis; however, amyloidosis occurs only in a small proportion of patients with chronic inflammatory disorders.
- The protein in AL amyloidosis (primary or immunocytic amyloidosis) is derived from the variable region of immunoglobulin light chains.
- AL amyloidosis is the most common form in humans and is often associated with myeloma.
- AL amyloidosis in horses is usually localized and characterized by firm, circumscribed nodules in the nasal cavity and subcutis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hepatic amyloidosis occurs secondary to a sustained inflammatory stimulus. Differential diagnoses depend on the clinical signs of the underlying disease. Hepatic amyloidosis must be differentiated from other forms of chronic hepatic disease.

INITIAL DATABASE

- Complete blood count: Anemia, leukocytosis
- Fibrinogen concentration: Increased
- Gamma glutamyltransferase activity: Increased
- Serum bile acid concentration: May be normal to increased
- Serum total protein concentration: Increased because of hypergammaglobulinemia
- Albumin concentration: Decreased
- Urinalysis: Proteinuria if renal involvement
- Abdominocentesis
  - Hemoperitoneum in animals with a ruptured liver or spleen
  - Increased leukocyte counts and protein concentrations are expected when peritonitis is the underlying disease.
- Fecal egg counts: Strongylosis has been associated with hepatic amyloidosis.

ADVANCED OR CONFIRMATORY TESTING

- Liver biopsy
  - Amyloid appears as hyaline aggregates in hematoxylin and eosin–stained tissues.
  - Amyloid is detected as green birefringence of Congo Red–stained tissues viewed under polarized light.
- AA and AL amyloid can be differentiated by treatment of stained tissue sections with potassium permanganate.
  - Tissue containing AA amyloid loses its green birefringence.
  - Tissue containing AL amyloid continues to appear green.

TREATMENT

THERAPEUTIC GOAL(S)

Treatment should be directed toward the underlying disease and attempts made to reduce inflammation. However, systemic amyloidosis with amyloid deposits in the viscera is usually fatal. Therapies are being developed for use in human medicine that prevent amyloid deposition or enhance its clearance.

ACUTE GENERAL TREATMENT

None is usually required because amyloidosis occurs secondary to chronic conditions. Animals presenting with signs of liver failure may require general supportive care until a diagnosis can be made.

PROGNOSIS AND OUTCOME

The prognosis is grave after significant amyloid accumulates within the viscera.

PEARLS & CONSIDERATIONS

Amyloidosis should be considered in animals with chronic inflammatory disease and signs of hepatic (or renal) dysfunction.

EDITOR: **MICHELLE HENRY BARTON**

Hepatic Encephalopathy

BASIC INFORMATION

DEFINITION

Hepatic encephalopathy occurs when there is significant loss of normal hepatic function to the degree that cerebral function is secondarily compromised. Hepatic encephalopathy is potentially reversible, depending on the underlying cause of liver disease.

SYNONYM(S)

Hepatoencephalopathy

EPIDEMIOLOGY

RISK FACTORS Hepatic encephalopathy may accompany either acute or chronic hepatic disease.

ASSOCIATED CONDITIONS AND DISORDERS Hepatic encephalopathy must be differentiated from other causes of acute or chronic cerebral disease.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Initial clinical signs may manifest only as subtle behavioral changes that are recognized by those familiar with the patient.
- Advancing clinical signs:
  - Depression and anorexia
  - Head pressing
  - Aimless circling or wandering
  - Ataxia
  - Persistent yawning
  - Excessive somnolence and lack of responsiveness (eg, standing for hours with food in the mouth but not chewing)
  - Periods of aggressiveness or violent behavior (eg, excessive pawing, biting), interspersed with periods of stupor
  - Although atypical of hepatic encephalopathy, seizures may occur in the late stages.

PHYSICAL EXAM FINDINGS

- Other signs of hepatic disease may be present, including icterus, hepatic photosensitization, weight loss, and coagulopathy.
- A complete neurologic examination should be performed. Cranial nerve function is typically intact, although bilateral laryngeal paralysis may occur. In addition to the behavioral changes

ElibeVet.com

listed above, ataxia and central blindness (lack of a menace response with normal pupillary light reflexes) may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

The cause of hepatic encephalopathy is complex, incompletely understood, and likely multifactorial. Many mechanisms of altered cerebral function during hepatic insufficiency have been proposed, including:

- Acute astrocyte swelling, cytotoxic cerebral edema, and intracranial hypertension
- Gastrointestinal (GI)-derived neurotoxins that are incompletely cleared by the failing liver (eg, increased blood ammonia, mercaptans, short chain fatty acids, and phenol concentrations)
- Augmented activity of cerebral inhibitory neurotransmitter systems such as γ-aminobutyric acid, serotonin, and benzodiazepine (eg, glutamate) with concurrent depression of excitatory pathways
- Increased inflammatory cytokine expression and neurosteroid synthesis
- False neuroinhibitory transmitter accumulation (eg, phenylethanolamine, serotonin, octopamine) in the brain as a consequence to an increased ratio of aromatic amino acid (phenylalanine, tyrosine, tryptophan) to branch chain (valine, leucine, isoleucine) amino acids in the blood
- Impaired central nervous system metabolism secondary to energy depletion

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hepatic encephalopathy must be differentiated from other causes of acute and chronic cerebral disease or altered behavior, including:

- Head trauma
- Viral encephalopathies
- Leukoencephalomalacia
- Brain abscess or neoplasia
- Equine protozoal myeloencephalitis
- Parasitic larval migrans
- Fluphenazine administration
- Heavy metal toxicosis
- Hypocalcemia
- Uremic encephalopathy

INITIAL DATABASE

The diagnosis of hepatic encephalopathy is based on the presence of clinical signs of cerebral dysfunction in conjunction with laboratory diagnostic evidence of hepatic insufficiency.

- Serum bile acid concentration: Increased
- Liver-specific enzymes (gamma glutamyltransferase, sorbitol dehydrogenase): Generally increased, but may be normal with end-stage fibrotic diseases of the liver
- Blood urea nitrogen (BUN) concentration: Decreased
- Serum total protein: Normal to increased in chronic hepatic disease caused by hyperglobulinemia
- Albumin: Normal to decreased
- Ammonia: Increased
- Clotting profile: Prothrombin time, activated partial thromboplastin time may be normal to increased

ADVANCED OR CONFIRMATORY TESTING

- Hepatic clearance of pharmaceuticals is prolonged
- Branched chain amino acid to aromatic amino acid ratio in the blood: Decreased
- Cerebrospinal fluid analysis: Normal
- Hepatic ultrasonography or liver biopsy: See Diagnostic Imaging of the Liver and Liver Biopsy in Section II).
- At necropsy, patients with hepatic encephalopathy may have increased numbers and size of astrocytes in the gray matter of the cerebrum (ie, Alzheimer type II changes).

TREATMENT

THERAPEUTIC GOAL(S)

The general therapeutic goals of hepatic encephalopathy are to stabilize the underlying liver disease when possible and to reestablish normal blood and brain concentrations of substances that alter neurofunction.

ACUTE GENERAL TREATMENT

- When sedation is necessary to control behavior, small doses of xylazine and detomidine should be used.
- Acute severe hepatic encephalopathy is often accompanied by cerebral edema; thus, the following treatments have been recommended:
  - Hypertonic saline
  - Mannitol: 0.5 to 1 g/kg body weight given slowly over 30 minutes
  - Vitamin E: 25 IU/kg/d
  - Dimethyl sulfoxide: 1 g/kg IV q2h diluted in fluids to 10%
- Dehydration and fluid needs may need to be addressed.
  - Even in normoglycemic patients, a continuous rate infusion of 5% dextrose (2 mL/kg/hr) can be beneficial, and if continued for more than 24 hours, 2.5% to 5% dextrose in half-strength saline or lactated Ringer's solution with supplemental potassium should be considered.
  - 0.9% saline may help enhance urinary clearance of ammonia.
  - Bicarbonate replacement in acidotic patients should be given with caution because it may increase blood levels of ammonia.
- Treatments to decrease GI-derived neurotoxins, such as ammonia, include:
  - PO administration of mineral oil
  - Oral administration of antimicrobials, including neomycin (10–100 mg/kg PO q6h) and metronidazole (10–15 mg/kg PO q12h)
  - Lactulose: 333 mg/kg PO q8h
  - Administration of probiotics containing *Lactobacillus acidophilus*
- Antiinflammatory therapy to control cytokine production may be beneficial and could include the use of flunixin meglumine, pentoxifylline, and dimethyl sulfoxide.
- Benzodiazepine antagonists (flumazenil) and dopamine agonists (bromocriptine) have been used in human patients with hepatic encephalopathy.

CHRONIC TREATMENT

- Drugs that have been shown to reduce hepatic fibrosis in human patients include pentoxifylline, steroids, colchicine, and cyclosporine. Pentoxifylline can be safely given to horses at 8 to 16 mg/kg PO q8–24h, although its efficacy in controlling hepatic fibrosis in this species is unknown.
- Dietary management to reduce ammonia formation is targeted by feeding rations high in carbohydrate and low in protein but rich with branched chain amino acids. Examples include beet pulp, sweet feeds, sorghum, bran, milo, oats, or grass hay. Branched chain amino acids supplements are available from several commercial sources.

DRUG INTERACTIONS

- Diazepam is contraindicated because it may enhance the neuroinhibitory response.

POSSIBLE COMPLICATIONS

- Seizures or uncontrolled maniacal behavior
- Coma
- Altered blood levels of drugs that rely on hepatic metabolism

RECOMMENDED MONITORING

- Easy to monitor tests of hepatic function include blood concentrations of ammonia, BUN, and serum bile acids.

PROGNOSIS AND OUTCOME

- Patients with severe hepatic fibrosis, especially bridging

ElibVet.com

hepatic fibrosis, have a poor to grave prognosis.

PEARLS & CONSIDERATIONS

- The severity of hepatic encephalopathy correlates with the severity of hepatic insufficiency but does not correlate with the reversibility of the underlying disease.

AUTHOR & EDITOR: **MICHELLE HENRY BARTON**

Hepatic Lipidosis and Hyperlipemia

BASIC INFORMATION

DEFINITION

- Hepatic lipidosis is a result of excess triglyceride deposition in the liver. The liver plays a critical role in lipid metabolism and is responsible for processing chylomicrons, volatile fatty acids, and free fatty acids (FFAs) when fat is mobilized from adipose tissue. When the rate of hepatic triglyceride formation exceeds the oxidation of fatty acids and release of very low-density lipoprotein (VLDL) into the peripheral circulation, hepatic lipidosis ensues.
- Hyperlipemia is characterized by visibly cloudy serum and serum triglyceride levels of 500 mg/dL or higher. Hyperlipidemia refers to serum triglyceride levels below 500 mg/dL. The serum remains clear, and it is not typically associated with fatty infiltration of the liver.

SYNONYMS

- Fatty liver disease
- Hyperlipemia syndrome

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION

- Ponies (especially Shetland and mare ponies), American Miniature horses, and donkeys are predisposed
- Occasionally seen in other breeds (Quarter Horses, Tennessee Walking Horses, Paso Finos) secondary to the development of a negative energy balance

RISK FACTORS

- Obesity
- Stress
- Pregnancy or hormonal imbalance
- Lactation
- History of weight loss or decreased caloric intake
- Negative energy balance
- An underlying illness of several days' duration
- Winter season or ingestion of poor-quality feed

GEOGRAPHY AND SEASONALITY

- Late gestation and early lactation during the winter months in conjunction with poor pasture availability in winter depending on geography
- No true geographic predilection

ASSOCIATED CONDITIONS AND DISORDERS

- Clinical signs of hepatic lipidosis can be indistinguishable from the clinical signs of liver disease or liver failure from other causes.
- Signs of the predisposing primary disease may overshadow other signs. The most commonly reported predisposing primary diseases include enterocolitis, endotoxemia, pituitary adenoma, parasitism, azotemia, and neonatal septicemia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hyperlipidemia refers to an increased serum triglyceride concentration (typically <500 mg/dL) without the presence of lipemic (cloudy white) serum or liver disease. Hyperlipemia is characterized by cloudy serum and triglyceride concentrations of 500 mg/dL or higher. Prolonged hyperlipemia results in fatty infiltration of the liver and subsequent signs of liver disease.

HISTORY, CHIEF COMPLAINT

- Typically obese
- Recent history of stress or weight loss
- Commonly in late pregnancy or early lactation
- Owners typically report acute anorexia and depression.

PHYSICAL EXAM FINDINGS

- Combination of two or more of these signs is likely:
  - Icterus
  - Anorexia
  - Depression
  - Weakness
  - Mild colic
  - Diarrhea
  - Recumbency
  - Muscle weakness
  - Fever
  - Ataxia
  - Dependent edema
- Clinical signs of liver failure, such as hepatic encephalopathy, bleeding, and endotoxemia, may predominate in severe cases. Sudden death caused by hepatic rupture is reported rarely.

ETIOLOGY AND PATHOPHYSIOLOGY

- Negative energy balances that may occur during late gestation, early lactation, starvation, or secondary to another primary disease, may result in hyperlipemia caused by fatty acid mobilization.
- Glucose is made in the liver from fatty acids and amino acids and is stored as glycogen.
- When glycogen stores are depleted because of a negative energy balance, fatty acids are oxidized to provide energy.
- Hormone-sensitive lipase is activated, which converts adipose to FFAs, nonesterified fatty acids, and glycerol.
- Increased mobilization of FFAs results in FFA oxidation, increased triglyceride synthesis, and production of VLDLs (which contain triglycerides) for release into the peripheral circulation.
- The equine liver is efficient in synthesizing and exporting VLDLs into the peripheral circulation. Endothelial lipoprotein lipase is the enzyme responsible for removing VLDLs from the blood back into adipose tissue and is increased in horses with hyperlipemia.
- The overproduction of VLDLs by the liver is responsible for the hyperlipemia. Hepatic lipidosis results from fatty acid mobilization and triglyceride synthesis that exceeds the liver's rate of oxidation and VLDL secretion.

 ElibeVet.com

- Liver function is disrupted by excess triglyceride infiltration, and liver failure and hepatic rupture have been reported in severe cases.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differential diagnoses include other causes of liver disease in horses and ponies

- Toxic hepatopathies
- Theiler's disease
- Cholangiohepatitis or cholelithiasis
- Chronic active hepatitis
- Pyrrolizidine alkaloid toxicosis
- Hepatic neoplasia
- Hepatic abscess

INITIAL DATABASE

- A complete blood count (CBC), serum chemistry profile with liver enzymes, triglyceride levels, and serum bile acid concentration are recommended for any obese pony, Miniature horse, or donkey with signs of depression, anorexia, icterus, and ataxia.
- Serum chemistry profile:
- CBC: May be normal or have abnormalities associated with underlying disease
- Serum chemistry profile
  - Blood glucose: Typically decreased but may be normal or increased
  - Gamma glutamyltransferase: Variably increased
  - Triglycerides: Above 500 mg/dL consistent with lipemia
  - Serum bilirubin: Variably increased
  - Serum bile acids: Increased if liver function is impaired
  - Metabolic acidosis is possible
  - Lipemia may falsely increase serum creatinine.
  - Blood ammonia: May be increased with liver failure
  - Albumin: May be decreased

ADVANCED OR CONFIRMATORY TESTING

- Diagnosis is confirmed by the presence of increased triglyceride levels and evidence of hepatic disease with increased liver enzymes and serum bile acids in addition to ultrasonography (see "Diagnostic Imaging of the Liver" in Section II) or histopathologic evidence of fatty infiltration of the liver.
- Liver biopsy with evidence of fatty infiltration confirms diagnosis.
- Bromsulphalein clearance may be prolonged.
- PO and IV glucose tolerance tests may reveal glucose intolerance caused by insulin insensitivity.

TREATMENT

THERAPEUTIC GOALS

The goals of treatment include elimination of the negative energy balance and improving energy intake, treatment of liver disease or failure, treatment of concurrent disease, elimination of stress, inhibition of fat mobilization from adipose tissue, and increasing triglyceride uptake by peripheral tissues.

ACUTE GENERAL TREATMENT

- Supportive treatment should include a concentrate feed and high-quality pasture or hay, as well as treatment for liver failure (see the Treatment section in "Hepatic Encephalopathy" in this section).
- Every effort should be made to encourage voluntary enteral nutrition. Enteral nutrition can also be provided via nasogastric intubation of a feed slurry or an enteral diet such as Equine Critical Care Meals (MD's Choice, Inc., Louisville, TN).
- A continuous rate infusion (CRI) of 5% dextrose at a rate of 2 mL/kg/h should be administered to anorectic horses.
- Partial parenteral nutrition with 50% dextrose and 8.5% amino acids is recommended in horses in which enteral nutrition is not possible.
- Treat concurrent disease when appropriate.
- Consider early weaning of the foal if the mare is lactating to reduce energy demand.
- Provide supportive treatment for hepatic failure such as antiinflammatory drugs (flunixin meglumine, dimethyl sulfoxide, pentoxifylline), lactulose, and neomycin or other oral antibiotics that may help reduce the production of ammonia or other enteric toxins.
- Insulin therapy may help control hyperglycemia. Protamine zinc insulin has been suggested at 15 to 30 IU IM q12h for 3 days in combination with oral glucose (100 g) q12h. Insulin has also been used as a CRI at 0.02 to 0.2 U/kg/h. Regular blood glucose monitoring should be performed.
- Metformin (15–30 mg/kg PO q12h) may be used as an unproven but potentially helpful adjunctive therapy in ponies with insulin resistance and hepatic lipidosis.
- Heparin potentiates the activity of lipoprotein lipase, which enhances the rate of triglyceride removal from the blood. Lipoprotein lipase activity is already increased in affected horses, so heparin may not provide additional benefit. Suggested dosages of heparin range from 40 to 250 IU/kg BID.

CHRONIC TREATMENT

Ensure resolution of negative energy balance and provide high-quality nutrition to prevent relapse.

POSSIBLE COMPLICATIONS

- Permanent liver failure caused by fatty infiltration is a severe and life-threatening complication.
- Hepatic rupture has been reported in some cases.
- Ketosis rarely develops.

RECOMMENDED MONITORING

- Monitor blood glucose concentrations because some horses will have glucose intolerance, which may potentiate acidosis and result in hypokalemia.
- Monitor triglyceride levels, liver enzymes, and serum bile acids for response to treatment.
- If heparin therapy is used, monitor hemostasis.
- If liver failure is present, monitor signs of hepatic encephalopathy and blood ammonia levels.

PROGNOSIS AND OUTCOME

- Guarded to poor prognosis
- Treat primary illness if identified.
- Most Miniature horses with triglyceride levels below 1200 mg/dL survive.

PEARLS & CONSIDERATIONS

COMMENTS

Prevention through management and early recognition through client education can significantly reduce the incidence of this condition.

PREVENTION

Provide appropriate nutrition without inducing obesity, avoid or minimize stress, and provide good management and routine health care.

CLIENT EDUCATION

- Educate owners about the risk associated with obesity. It is important to provide good management and routine health care in conjunction with an appropriate diet.
- Improve owner awareness about anorexia and associated signs, especially during late gestation and early lactation, which will result in earlier recognition and treatment of disease.

AUTHOR: **AMANDA MARTABANO HOUSE**
EDITOR: **MICHELLE HENRY BARTON**

Hepatitis, Bacterial

BASIC INFORMATION

DEFINITION

Primary bacterial hepatitis (inflammation of the liver caused by bacterial infection) and primary bacterial cholangiohepatitis (inflammation of the liver and biliary system) are infrequent causes of hepatic disease in adult horses.

EPIDEMIOLOGY

SPECIES, AGE, SEX
- Middle-aged to older horses
- Neonatal foals

ASSOCIATED CONDITIONS AND DISORDERS Secondary septic or nonseptic peritonitis may be present.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Depression, weakness, anorexia, colic, and weight loss in chronic cases

PHYSICAL EXAM FINDINGS
- Fever, weight loss, and variable icterus.
- Clinical signs of hepatoencephalopathy may be present.

ETIOLOGY AND PATHOPHYSIOLOGY
- The etiopathogenesis of bacterial hepatitis is uncertain. Retrograde bacterial infection from the small intestine is the probable cause in mature horses as a sequela to biliary stasis, cholelithiasis, chronic active hepatitis, intestinal obstruction, and proximal enteritis.
- The most common isolates associated with ascending bacterial hepatitis in mature horses are enteric organisms, including *Escherichia coli, Salmonella, Klebsiella, Citrobacter, Aeromonas,* and *Acinetobacter* spp.
- Hematogenous dissemination secondary to sepsis is the probable cause in neonatal foals. Bacterial sepsis in foals may result in focal to multifocal bacterial hepatitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cholelithiasis
- Theiler's disease
- Tyzzer's disease
- Chronic active hepatitis

INITIAL DATABASE

- Leukocytosis, characterized primarily by a mature neutrophilia
- Hyperfibrinogenemia
- Sorbitol dehydrogenase (SDH), arginase, and gamma glutamyltransferase (GGT) activity: variable increases

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis is based on histopathologic findings on liver biopsy (primarily neutrophilic infiltration with bacterial invasion) and bacterial growth on liver biopsy.

TREATMENT

THERAPEUTIC GOAL(S)

Control bacterial replication to prevent advanced hepatic damage and fibrosis.

ACUTE GENERAL TREATMENT

- Provide general and supportive care with IV balanced fluids.
- Nonsteroidal antiinflammatory drugs (flunixin meglumine) may be indicated.
- Antimicrobial therapy should be based on culture and sensitivity results and should continue until resolution of clinical and laboratory abnormalities: procaine penicillin G 22,000 IU/kg IM q12h and gentamicin 6.6 mg/kg IM q24h; ceftiofur 2.2 to 4.4 mg/kg IM q12h; ampicillin 20 mg/kg IV q6–8h; chloramphenicol 50 mg/kg PO q6h; enrofloxacin 7.5 mg/kg PO q24h; trimethoprim-sulfa 20 to 30 mg/kg PO q12h.

RECOMMENDED MONITORING

Recheck complete blood cell count and serum biochemical indices of hepatobiliary disease before discontinuing antimicrobial therapy.

PROGNOSIS AND OUTCOME

The prognosis is good with appropriate antimicrobial and supportive medical therapy.

PEARLS & CONSIDERATIONS

Primary bacterial hepatitis (Tyzzer's disease) is uncommon.

SUGGESTED READING

EDITOR: **MICHELLE HENRY BARTON**

ElibeVet.com

Hepatitis, Chronic Active

BASIC INFORMATION

DEFINITION

Chronic active hepatitis is a general term embracing any active, progressive liver disease characterized by a marked inflammatory response with concurrent evidence of longstanding disease (ie, fibrosis). The primary histopathologic feature of chronic active hepatitis is periportal infiltration with inflammatory cells accompanied by different stages of hepatocellular necrosis, biliary hyperplasia, and fibrosis.

EPIDEMIOLOGY

SPECIES, AGE, SEX Suppurative chronic active hepatitis has been reported in foals as young as 2 months; however, chronic active hepatitis, particularly the form characterized by mononuclear infiltrate, is more prevalent in adult horses (4–18 years).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most commonly subtle and gradual in onset.
- Two forms of chronic active hepatitis are described based on the predominant cell population within the liver inflammatory infiltrate:
  - Mononuclear cell infiltration.
  - Neutrophilic infiltration, indicative of a suppurative hepatitis. This type of hepatitis is frequently associated with biliary stasis and hyperplasia and is consistent with a histopathologic diagnosis of cholangitis or cholangiohepatitis (see also "Cholangiohepatitis, Chronic, and Biliary Fibrosis" in this section).

HISTORY, CHIEF COMPLAINT Owners may report depressed mentation, inappetence, weight loss, signs of mild to moderate abdominal discomfort, and loose stools.

PHYSICAL EXAM FINDINGS

- Vital signs may be normal or patient may be febrile
- Icterus
- Mild dehydration
- Moist exfoliative coronary band dermatitis (uncommon)
- Photosensitization (uncommon)

ETIOLOGY AND PATHOPHYSIOLOGY Idiopathic; the etiology is often undetermined. Possible causes include:

- Autoimmune disease
- Viral infection
- Bacterial infection (hematogenous or ascending from the gastrointestinal tract)
- Toxic insult
- Adverse drug reaction
- Based on the distribution of the lesions predominantly in the area surrounding the portal triad, delivery of noxious agents (eg, bacteria, viruses, endotoxins, toxic agents, inflammatory mediators, or a combination of these) via the portal vein is hypothesized. The presence of inflammatory cells in the periportal area would then be explained by extravasation from the hepatic arterioles or lymphatic vessels in response to the primary insult.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Toxic hepatopathy
- Theiler's disease
- Biliary obstruction secondary to acute or chronic colon displacement
- Cholelithiasis
- Bacteria hepatitis or cholangiohepatitis
- Hepatic neoplasia
- Amyloidosis
- Liver parasites

INITIAL DATABASE

- Packed cell volume: Normal or increased from hemoconcentration or erythrocytosis induced by liver disease
- Serum total protein concentration: Normal or increased (from dehydration or hyperglobulinemia)
- Fibrinogen concentration: Normal or increased
- Sorbitol dehydrogenase (SDH) activity: Increased; may be normal
- Aspartate aminotransferase (AST), gamma glutamyltransferase (GGT), alkaline phosphatase (ALP) activity: Increased
- Serum total bilirubin concentration: Increased; may be normal in rare cases
- Bile acids concentration: Normal to increased

ADVANCED OR CONFIRMATORY TESTING

- Plasma ammonia concentration may be increased.
- Clotting profile: Prothrombin time and activated partial thromboplastin time may be increased.
- Transabdominal ultrasonographic examination of the liver:
  - May be normal.
  - Liver size may be smaller or larger than normal.
  - Increased liver parenchyma echogenicity compared with adjacent parenchymatous organs (spleen).
- Ultrasound-guided liver biopsy:
  - Histopathology
    - Periportal infiltration
    - Mononuclear cells (histiocytes, lymphocytes and plasma cells)
    - Neutrophils (see also "Cholangiohepatitis, Chronic, and Biliary Fibrosis" in this section)
    - Hepatocellular degeneration or necrosis (or both)
    - Biliary hyperplasia
    - Fibrosis
  - Bacterial culture of liver tissue
    - Most commonly negative in the presence of mononuclear infiltrate
    - May be positive with suppurative inflammation (see also "Cholangiohepatitis, Chronic, and Biliary Fibrosis" in this section)
  - Toxicology screen of liver tissue

TREATMENT

THERAPEUTIC GOAL(S)

Treatment of the form of chronic active hepatitis characterized by mononuclear cell infiltrate is aimed at stopping ongoing inflammation and preventing fibrosis. In the presence of neutrophilic infiltrate and especially with a positive bacterial culture result, therapy is also aimed at treatment of bacterial hepatitis.

ACUTE GENERAL TREATMENT

- IV fluids if the horse is febrile and dehydrated
- Flunixin meglumine (1.1 mg/kg IV) to control signs of abdominal pain

CHRONIC TREATMENT

- Antimicrobial therapy (potentiated sulfonamides, ceftiofur, penicillin and gentamicin, enrofloxacin or ampicillin, alone or in association with metronidazole; chloramphenicol).
- Corticosteroids if the inflammatory infiltrate is represented by histiocytes, lymphocytes, and plasma cells and liver biopsy culture results are negative.
  - Dexamethasone: 0.05 to 0.1 mg/kg IV q24h for 3 to 5 days; decreased over the following 7 to 14 days
  - Oral prednisolone (1–2 mg/kg q24h) after initial dexamethasone therapy; may need to continue for weeks to months
- S-adenosylmethionine (SAMe): 5 g PO q24h; the bioavailability of crushed pills is questionable in horses.

ElibeVet.com

- Prevention of hepatic fibrosis.
  - Pentoxifylline: 8 to 16 mg/kg PO q8–12h
  - Colchicine: 0.03 mg/kg PO q24h; there have been anecdotal reports of presumed toxicity
- Also see treatment for "Hepatic Encephalopathy" in this section.

POSSIBLE COMPLICATIONS

- Immune suppression caused by long-term steroid therapy
- Laminitis
- Diarrhea

RECOMMENDED MONITORING

- GGT, AST, ALP, serum bile acids
- Repeat liver biopsy

PROGNOSIS AND OUTCOME

- Good prognosis with early diagnosis and treatment of bacterial infection and suppurative hepatitis
- Guarded long-term prognosis of hepatitis characterized by mononuclear infiltrate and fibrosis

PEARLS & CONSIDERATIONS

Autoimmune hepatitis characterized by histiocytic and lymphoplasmacytic infiltrate is described in human and small animal medicine. Even if a similar pathogenesis is suspected in horses, the disease is not well described and understood in the equine species.

AUTHOR: **ALESSANDRA PELLEGRINI-MASINI**

EDITOR: **MICHELLE HENRY BARTON**

Hepatopathy, Chronic Megalocytic

BASIC INFORMATION

DEFINITION

Chronic megalocytic hepatopathy is caused by ingestion of pyrrolizidine alkaloid–containing plants (*Senecio jacobaea, S. vulgaris, S. longilobus, S. riddellii, S. spartioides, S. integerrimus, Amsinckia intermedia, Crotalaria sagittalis, C. spetabilis, Heliotropium europaeum, Echium plantagineum*), resulting in the delayed onset of chronic progressive liver failure.

SYNONYM(S)

Pyrrolizidine alkaloid toxicity

EPIDEMIOLOGY

RISK FACTORS

- Overgrazed pasture
- Hay harvested with pyrrolizidine alkaloid–containing plants

GEOGRAPHY AND SEASONALITY

- The disease occurs worldwide and is the most common cause of hepatic failure in horses in certain parts of the United States.
  - *S. jacobaea, S. vulgaris:* Pacific Coast
  - *A. intermedia:* West
  - *C. sagittalis, C. spetabilis, H. europaeum:* Southeast

ASSOCIATED CONDITIONS AND DISORDERS Clinical signs of chronic megalocytic hepatopathy may be indistinguishable from other chronic liver disorders.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic (most common): Insidious onset of signs that is usually delayed 1 to 3 months after ingestion of plants containing pyrrolizidine alkaloids.
- Despite a delay in development of signs from time of exposure, the onset of signs may be acute.
- If consumption of toxic plants is excessive, the onset of signs may be acute.

HISTORY, CHIEF COMPLAINT Owners may observe weakness, weight loss, lethargy, anorexia, head pressing, yawning, or depression. The horse may have a history of being fed pyrrolizidine alkaloid–contaminated hay or exposure to an overgrazed pasture.

PHYSICAL EXAM FINDINGS

- Icterus, photosensitivity dermatitis, weight loss, hepatic encephalopathy, petechiae (rarely).
- Diarrhea, edema, polydipsia, polyuria, hemolysis, and laryngeal hemiplegia may occur late in the disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Pyrrolizidine alkaloids are metabolized by hepatic microsomal enzymes to pyrrole derivatives.
- Pyrroles inhibit cellular replication and protein synthesis, resulting in cells that cannot divide and instead continue to grow (formation of megalocytes).
- Megalocytes are eventually replaced by fibrosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Aflatoxicosis
- Clover toxicity
- Cholelithiasis
- Chronic active hepatitis
- Cholangiohepatitis
- Hepatic neoplasia

INITIAL DATABASE

- Complete blood count: Leukocytosis characterized by neutrophilia, left shift, hyperfibrinogenemia
- γ-glutamyltransferase (GGT) and alkaline phosphatase (ALP) activity: Increased
- Aspartate aminotransferase (AST) and sorbitol dehydrogenase (SDH) activity: Increased to normal
- Hyperglobulinemia
- Serum bile acids concentration: Increased
- Total and direct bilirubin concentrations: Increased
- Coagulation times: May be prolonged
- Plasma ammonia concentration: May be increased
- Urinalysis: Bilirubinuria

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography: Hepatic atrophy, distended bile ducts
- Liver biopsy: Periportal to extensive fibrosis, megalocytosis, biliary hyperplasia, bile stasis, hepatocellular necrosis

TREATMENT

THERAPEUTIC GOAL(S)

Palliation

ACUTE GENERAL TREATMENT

- IV fluids may be required in animals that are febrile and dehydrated. Dextrose may be added for patients that are anorectic.
- Nonsteroidal antiinflammatory drugs (NSAIDs): flunixin meglumine

ElibeVet.com

(1.1 mg/kg PO or IV q12h) or phenylbutazone (2.2 mg/kg PO q12h).
- Nutritional support (low-protein diet with a high content of branched-chain amino acids).
- If hepatic encephalopathy is present, see treatment for "Hepatic Encephalopathy" in this section.

CHRONIC TREATMENT

- Nutritional support, including removal from hay or pasture.
- S-adenosylmethionine (SAMe): 5 g PO q24h; the bioavailability of crushed pills is questionable in horses.
- Colchicine: 0.03 mg/kg PO q24h, although there have been anecdotal reports of toxicity.
- NSAIDs (flunixin meglumine and phenylbutazone), prednisolone (0.5–1.0 mg/kg PO q24h), dexamethasone (0.05–0.10 mg/kg PO q24h).
- Antifibrotics: Pentoxifylline (8–16 mg/kg PO q8–12h).

POSSIBLE COMPLICATIONS

- Hepatic encephalopathy
- Photosensitivity dermatitis

RECOMMENDED MONITORING

- Monitor GGT activity and serum bile acids concentrations every 2 to 3 weeks.
- Perform serial liver biopsies (q2–3mo).

PROGNOSIS AND OUTCOME

- Fair to grave, depending on the degree of megalocytosis and fibrosis.
- The presence of bridging fibrosis is considered invariably fatal.

PEARLS & CONSIDERATIONS

COMMENTS

- Frequently, the onset of clinical signs is delayed (1 month to 1 year after consumption).
- Consumption of 2% to 5% of body weight over 1 to 3 days may result in acute toxicity.

PREVENTION

Avoid contaminated hay and overgrazed pastures.

CLIENT EDUCATION

Remove the source of pyrrolizidine alkaloid (reseed pasture, provide a new source of hay).

Herbicide Toxicosis

BASIC INFORMATION

DEFINITION

- Condition resulting from ingestion of products used to destroy plants
- Most herbicides have been developed to be selective to plants and have low mammalian toxicity.
- However, arsenicals and paraquat can cause potentially serious toxicosis in horses if ingested. The use of these types of herbicides has greatly declined, but they still may be in use in some areas of the country.

SYNONYMS

- Arsenic-based herbicides include MSMA (monosodium methanearsonate); DSMA (disodium methanearsonate); arsenic trioxide; sodium arsenite; and arsenates of sodium, potassium, calcium, and lead.
- Bipyridyl (dipyridyl) herbicides include paraquat and diquat.
- Glyphosate (glyphosate-isopropylamine, glyphosate-isopropylammonium, glyphosate sesquiodium, glyphosate-trimesium) is an organophosphorus herbicide, but it has no anticholinesterase activity.
- Phenoxy-type herbicides include 2,4-D (2,4-dichlorophenoxyacetic acid), MCPA (2-methyl-4-chlorophenoxyacetic acid, MCPP (2-(4 chloro-2-methoxy) propionic acid), and dicamba (3,6-dichloro-2-methoxybenzoic acid).
- Pyridine herbicides include trichlopyr.
- Triazine herbicides include atrazine, simazine, and propazine.

EPIDEMIOLOGY

RISK FACTORS Horses grazing pastures adjacent to areas where herbicides are sprayed (eg, power lines, crop fields) may be exposed to overspray or to treated plants along fence lines.

GEOGRAPHY AND SEASONALITY More commonly used during times of rapid plant growth (eg, spring, summer); may also be used in fall as defoliants on crops

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most herbicides, with the exceptions stated below, are of low mammalian toxicity and are unlikely to cause clinical problems if horses graze on treated plants.
- Most herbicides are gastrointestinal (GI) irritants and can cause inappetence, colic, and diarrhea if horses are exposed to large amounts of concentrated product (eg, ingested from container).
- Arsenic-based herbicides cause severe GI hemorrhage, resulting in severe colic, hypovolemia, prostration, and death.
- Paraquat is a caustic compound that causes dermal and alimentary tract erosion and ulceration and can cause rapidly progressive pulmonary fibrosis as well as renal failure.

HISTORY, CHIEF COMPLAINT History of grazing on recently treated plant material or having access to concentrated product

PHYSICAL EXAM FINDINGS

- Most herbicides: No specific findings are expected in cases of horses grazing treated pastures; if large quantities of concentrated product have been directly ingested, diarrhea or evidence of colic (sweating, agitation, tachycardia) may be seen.
- Arsenic-based herbicides: Severe abdominal discomfort, central nervous system depression, watery to bloody diarrhea, weakness, shock. Death may occur acutely, or signs may progress to include cardiac arrhythmias, pulmonary edema, and acute renal failure.
- Paraquat: Oral and/or esophageal ulceration, dermal ulceration, abdomi-

ElibeVet.com

nal discomfort, diarrhea; within days, development of renal insufficiency (polyuria, polydipsia) and progressive respiratory insufficiency (dyspnea, cyanosis)

ETIOLOGY AND PATHOPHYSIOLOGY

- Arsenic-based herbicides: Corrosive effects on GI mucosa along with severe vasculitis of capillary beds results in severe GI hemorrhage, hypovolemia, and possibly pulmonary edema.
- Paraquat: Predominantly isolated to the lung, where production of oxygen-derived free radicals causes damage to alveolar epithelium with subsequent pulmonary fibrosis. The presence of oxygen accelerates the development of pulmonary lesions.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Most herbicides: Other causes of mild GI irritation or discomfort
- Arsenic-based herbicides: Colitis X, salmonellosis, other causes of acute hemorrhagic gastroenteritis
- Paraquat: Other causes of alimentary ulceration or pulmonary dysfunction (eg, chronic obstructive pulmonary disease)

INITIAL DATABASE

- Most herbicides: Serum electrolytes if severe diarrhea is present
- Arsenic-based herbicides: Serum chemistry panel (renal values), complete blood count (CBC), acid-base status, urinalysis
- Paraquat: Serum chemistry (renal and liver values), CBC, and urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Most herbicides: None
- Arsenic-based herbicides: Serum and urine arsenic levels are rarely diagnostic; elevated arsenic levels in the kidney and liver; elevated arsenic levels in hair (chronic exposures)
- Paraquat: Detection of paraquat in the blood or urine (first 30 hours); "classic" histopathologic lesions in lung tissue; detection of paraquat in lung tissue

TREATMENT

THERAPEUTIC GOAL(S)

- Most herbicides: Manage diarrhea and correct any electrolyte imbalances.
- Arsenic-based herbicides: Manage shock and pulmonary edema, correct hypovolemia and acid-base imbalances, minimize renal injury, and manage pain.
- Paraquat: Prevent absorption, minimize renal injury, and manage pain and alimentary injury.

ACUTE GENERAL TREATMENT

- Asymptomatic
  - Most herbicides: Dilute with water; monitor for signs of GI discomfort.
  - Arsenic-based herbicides and paraquat: Cathartics (magnesium sulfate), activated charcoal via nasogastric tube, IV fluids (maintain hydration, protect renal function)
- Symptomatic
  - Most herbicides: Symptomatic treatment as needed for GI discomfort
  - Arsenic-based herbicides: IV fluids (monitor closely for pulmonary edema), pain medication, general supportive care (prevention of secondary infections, dietary alterations)
    - Chelation with dimercaprol (3 mg/kg IM q4h) has questionable efficacy in horses.
    - The GI tract must be free of arsenic before chelation or the chelator will pull more arsenic into the blood.
  - Paraquat: IV fluid diuresis (enhance elimination), GI protectants, pain medication, monitor blood gases, prevent secondary infections

CHRONIC TREATMENT

- Arsenic-based herbicides: Management of residual renal insufficiency, dietary alterations
- Paraquat: Management of residual renal or pulmonary insufficiency

DRUG INTERACTIONS

- Paraquat: Oxygen therapy is contraindicated because it accelerates free radical production and pulmonary fibrosis.

POSSIBLE COMPLICATIONS

- Arsenic-based herbicides: Permanent renal insufficiency
- Paraquat: Permanent pulmonary and/or renal insufficiency, esophageal strictures, gastric ulceration with secondary peritonitis

RECOMMENDED MONITORING

- Arsenic-based herbicides: Renal values, acid-base status, electrolytes
- Paraquat: Renal and liver values, acid-base status, electrolytes, oxygen saturation, pulmonary function

PROGNOSIS AND OUTCOME

- Most herbicides: Excellent prognosis because GI irritation is expected to be self-limiting
- Arsenic-based herbicides: Guarded to poor prognosis depending on the amount ingested and the severity of signs
- Paraquat: Prognosis is poor in horses developing signs after exposure.

PEARLS & CONSIDERATIONS

COMMENTS

- As they wilt, plants that have been treated with herbicides may become more attractive to horses, which can increase the likelihood that horses will ingest toxic plants that they would normally avoid. Therefore, many herbicide manufacturers recommend a "graze-out" period (usually 2–3 weeks) during which horses should not be allowed to graze on treated areas.

PREVENTION

- Keep containers of herbicides away from areas to which horses have access.
- Follow label directions regarding the use of herbicides in areas near grazing animals.
- Follow graze-out recommendations to prevent toxicosis from toxic plants in treated areas.

CLIENT EDUCATION

- Because of the past use of highly toxic herbicides, such as paraquat, horse owners frequently suspect herbicides as the cause of any illness that a horse may develop. However, with the advent of modern herbicides that target biochemical mechanisms unique to plants, the likelihood of herbicide-induced toxicosis is very low unless older herbicides such as arsenicals or paraquat are involved.

ElibeVet.com

Hernia, Diaphragmatic

BASIC INFORMATION

DEFINITION

Protrusion of an organ or tissue through a defect in the diaphragm

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Etiology: May be congenital or acquired
  - Congenital: Often small hernias with smooth, round edges
  - Acquired: Often larger hernias with torn edges and often originating at the dorsal body wall
- Location: Peritoneal pericardial or peritoneal pleural

HISTORY, CHIEF COMPLAINT

- Variable
  - May be an incidental finding at necropsy
  - May have low-grade, intermittent colic signs
  - May have acute severe episode of colic or respiratory distress

PHYSICAL EXAM FINDINGS

- Temperature is normal unless the patient is severely compromised.
- The patient often has tachycardia.
- The respiratory rate may be normal or may be markedly elevated; borborygmi are often audible in the thorax.
- The mucous membranes are variable from pink and moist to pale to toxic-appearing depending on the severity of compromise.
- Colic signs are variable from mild, intermittent pain to acute, severe abdominal crisis.
- Hydration is variable depending on the severity of systemic compromise.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital diaphragmatic hernias result from failed fusion of the four embryonic components of the diaphragm.
- Acquired diaphragmatic hernias result from trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Mild, intermittent colic
  - Nonstrangulating large intestinal disease: Large colon displacement or sand colic
  - Nonstrangulating small intestinal lesion: Stricture
  - Nonstrangulating gastric lesion: Gastric impaction or gastric ulcers
  - Peritonitis
- Severe colic
  - Strangulating small intestinal lesion: Strangulating lipoma
  - Strangulating large intestinal lesion: Large colon volvulus
- Respiratory crisis
  - Acute pneumothorax
  - Pleural effusion
  - Pleuropneumonia
  - Hemothorax

INITIAL DATABASE

- Nasogastric intubation: Reflux production is variable depending on the area of intestine within the thorax; in general, reflux is present if there is strangulated small bowel within the thorax.
- Rectal examination: Frequently normal. If the intestine is obstructed, then the practitioner may feel distension of the oral segment (commonly the small intestine). An "empty" feeling within the abdomen may sometimes be appreciated because of displacement of abdominal contents.
- Complete blood count: Normal initially but demonstrates leukopenia or leukocytosis with time if the patient has an acute crisis.
- Peritoneal fluid: Frequently normal initially. Sometimes remains normal as strangulated bowel is sequestered in thorax but may become serosanguinous with elevated total protein and white blood cell counts.
- Transabdominal ultrasonography: Often normal unless there is strangulated bowel; may then see peritoneal effusion and distension of bowel oral to strangulated segment.
- Transthoracic ultrasonography: Can identify abdominal contents within the thorax. Can sometimes identify lack of diaphragmatic contour, especially if a ventral hernia is present.
- Radiography: May appreciate abdominal contents within the thorax or may just identify radiopacity at the ventral thorax.

TREATMENT

THERAPEUTIC GOALS

- Stabilize the patient.
- Remove the herniated bowel from the thorax with or without resection and anastomosis depending on whether the patient has a compromised bowel or not.
- Repair the diaphragmatic defect.

ACUTE GENERAL TREATMENT

After clinical signs become apparent, prevention of recurrence requires surgical intervention.

- Dorsal recumbency under general anesthesia using positive-pressure ventilation.
- Reduce herniated bowel with or without resection and anastomosis depending on whether the patient has compromised bowel. Tilting the horse can facilitate reduction.
- Attempt repair of defect.
  - Small defects (<5 cm) can be sutured with a large-diameter suture in a simple continuous pattern. Ventrally positioned defects are easier to repair this way.
  - Larger defects may require repair with synthetic mesh.
  - Dorsally positioned defects may require a thoracotomy for repair.
  - Some defects prove impossible to repair in dorsal recumbency.
- Evacuate pneumothorax.
  - Maximum inflation of the lungs during closure of the abdominal incision.
  - Place chest tube and Heimlich valve.

CHRONIC TREATMENT

- Postoperative treatment:
  - Management of pneumothorax
  - If the defect proved impossible to repair through ventral midline incision, other methods of repair are occasionally attempted.
- Routine postoperative care:
  - IV fluid therapy
  - IV antibiotics
  - IV antiinflammatory drugs and analgesics with or without antiendotoxic agents
  - Stall rest

POSSIBLE COMPLICATIONS

- Hernia repair breakdown and recurrence
- Pneumothorax
- Pleuropneumonia
- Peritonitis
- Endotoxemia
- Adhesions
- Ileus
- Jugular thrombophlebitis
- Diarrhea
- Pyrexia
- Incisional infection
- Recurrent colic

RECOMMENDED MONITORING

- Pain
- Respiratory rate and effort

ElibEVet.com

- Mentation
- Fecal output

PROGNOSIS AND OUTCOME

- Horses undergoing diaphragmatic hernia repair have a guarded prognosis.
- Hernias are not always amenable to repair.
- Hernia repairs are at a high risk of dehiscence.
- Hernias can recur in another location.

Hernia, Incisional

BASIC INFORMATION

DEFINITION

Protrusion of an organ or tissue through the ventral abdominal wall

SYNONYM(S)

- Ventral midline hernia
- Ventral abdominal hernia

EPIDEMIOLOGY

RISK FACTORS

- Ventral midline incisions such as for exploratory celiotomy or for umbilical herniorrhaphy
  - Incisional infection
  - Incisional trauma (especially in the recovery stall)
  - Poor tissue viability
  - Poor tissue apposition

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Swelling and lack of normal definition of ventral abdominal midline

PHYSICAL EXAM FINDINGS

- Nonpainful, fluctuant swelling of ventral midline; may be one or multiple hernias and therefore swellings
- Occasionally, incisional infection is still present characterized by discharge, heat, pain on palpation, and edema.
- Horses are otherwise normally systemically stable.
  - Normal heart rate, temperature, respiratory rate, and mucous membranes
  - Normal mentation and appetite
  - Audible borborygmi and normal fecal output

ETIOLOGY AND PATHOPHYSIOLOGY Incisional hernias are associated with failure of normal healing of the linea alba.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Incisional infection
- Incisional edema
- Incisional dehiscence

INITIAL DATABASE

- Complete blood count: Frequently normal
- Peritoneal fluid: Frequently normal initially
- Ultrasonography (transcutaneous of ventral midline): Body wall thickness decreased or absent

TREATMENT

THERAPEUTIC GOAL(S)

- Monitor hernia for deterioration: Enlargement, signs of incarceration, or signs of systemic compromise
- Facilitate optimal abdominal wall strength and cosmesis
  - Abdominal support and strengthening
  - Surgical repair

ACUTE GENERAL TREATMENT

- Conservative management: Eliminate any residual infection.
  - Facilitate ventral drainage
    - Prevent pooling of purulent material (express any pus from the incision twice daily).
    - Keep incisions clean.
    - Consider the use of a supportive belly band; however, this must be changed frequently to cleanse and facilitate drainage.
    - Perform culture for bacterial sensitivity.
    - Treat with appropriate antibiotics if nonresponsive.
  - Supportive belly bands may decrease tension on the body wall.
  - Commencing turnout and exercise may improve the strength of the body wall after sufficient time for healing has occurred.
- Surgical management: This is indicated if the hernia fails to heal or continues to enlarge after exercise has commenced.

CHRONIC TREATMENT

- Conservative management
  - Continue belly bands for support and continue exercise program.
  - Although not cosmetically perfect, many horses perform at or beyond their previous levels of performance with hernias.
- Surgical management can be considered if the hernia enlarges or there is a risk of strangulation or body wall failure. Herniorrhaphy should not be performed until all infection is resolved.
- Large defects may require prosthetic reconstruction with a synthetic mesh.

POSSIBLE COMPLICATIONS

- Repeat incisional hernia
- Local infection
- Peritonitis
- Endotoxemia
- Adhesions
- Jugular thrombophlebitis
- Diarrhea
- Pyrexia
- Incisional infection
- Recurrent colic

RECOMMENDED MONITORING

- Pain
- Hernia or incisional swelling, pain, or discharge
- Mentation
- Fecal output

PROGNOSIS AND OUTCOME

- Most incisional hernias are treated conservatively and only pose a cosmetic defect.

ElibEVet.com

- There is a risk of incisional hernia recurrence after incisional herniorrhaphy.

PEARLS & CONSIDERATIONS

- Incisional hernia rate after exploratory celiotomy has been reported as high as 16%.
- Horses that develop incisional hernias normally demonstrate signs by 4 months after surgery.

AUTHOR: **CERI SHERLOCK**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Hernia, Inguinal

BASIC INFORMATION

DEFINITION

- Protrusion of an organ or tissue through the inguinal ring into the inguinal canal
- Indirect hernia is the most common form of inguinal hernia in equines. The small intestine passes through the vaginal ring into the inguinal canal and can extend into the scrotum. It is a congenital condition in foals and an acquired condition in adults.
- Direct hernia is less common and involves the small intestine and occasionally the testicle passing through a rent in the peritoneum adjacent to the vaginal ring into the inguinal region and scrotum, exterior to the vaginal tunic.

SYNONYMS

- Scrotal hernia (although by definition, the organ or tissue has passed through the inguinal canal into the scrotum)
- Caudal abdominal hernias

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young colts
- Stallions
- Congenital inguinal or scrotal hernia: Seen shortly after birth
- Acquired inguinal hernia: Intact male older than 1 year; may occur in geldings but very uncommon

GENETICS AND BREED PREDISPOSITION

- Congenital: Standardbreds and heavier breeds (eg, Shires) may be more frequently affected.
- Acquired: Standardbreds, Tennessee Walking Horses, and American Saddlebreds are most commonly affected.

RISK FACTORS

- Intact males
- Straining in the foal
- Breeding and strenuous exercise
- Enlarged internal inguinal ring

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Foals
  - Congenital inguinal hernias
  - Seen in young colt foals
  - Often bilateral
    - Often indirect (contents pass through vaginal ring into vaginal tunic)
    - May involve rupture of the common vaginal tunic so contents escape subcutaneously
    - Rarely direct (contents pass through a weakness that creates a defect in the body wall
- Adults
  - Acquired hernias
  - Seen in mature stallions

HISTORY, CHIEF COMPLAINT

- Indirect congenital hernias in foals present with scrotal enlargement shortly after birth. Signs of colic are not common.
- Direct inguinal hernias usually present within the first 24 to 48 hours of parturition because of an increased abdominal pressure and are commonly accompanied with signs of abdominal discomfort.
- Acquired inguinal hernias in adult horses present with clinical signs consistent with moderate to severe colic.
- Swelling is present on the axial thigh if the hernia is direct or the common vaginal tunic is ruptured.
- Associated edema and skin excoriations may be caused by a subcutaneous position of the bowel.

PHYSICAL EXAM FINDINGS

- Inguinal hernias in foals are most commonly nonstrangulating and can be reduced, but inguinal hernias in adults are most commonly strangulating and cannot be reduced; physical examination findings reflect the systemic status.
- Congenital
  - Foals with indirect hernias usually present with normal physical findings.
  - Enlarged normothermic scrotum; scrotal herniation is usually reducible
  - Foals with direct hernias may present for signs of abdominal discomfort and scrotal enlargement. The scrotal enlargement is nonreducible and is confined to more of the subcutaneous space as well as the scrotum.
- Acquired
  - Moderate to severe abdominal pain
  - Tachycardia
  - Tachypnea
  - Normothermic
  - Pale, tacky mucous membranes with prolonged capillary refill time
  - Reduced or absent borborygmi
  - Scrotal palpation reveals swollen cool scrotum on the affected side. Early in the entrapment, scrotal palpation may be normal.

ETIOLOGY AND PATHOPHYSIOLOGY

- Inguinal hernias in foals are mostly congenital. An enlarged vaginal process is believed to be associated with an excessive enlargement of the gubernaculum during descent of the testicle, resulting in abnormal enlargement of the vaginal ring. They may be associated with increased intraabdominal pressure (ie, trauma or straining).
- Inguinal hernias in adults are acquired. They are associated with increased abdominal pressure during breeding, exercise, or trauma resulting in herniation of the small intestine through the vaginal ring.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of strangulating obstruction of the small intestine
  - Small intestinal volvulus
  - Epiploic foramen entrapment
  - Gastrosplenic entrapment
- Strangulating lipoma
- Testicular thrombosis

ElibEVet.com

- Orchitis
- Testicular seroma
- Scrotal hematoma
- Torsion of the spermatic cord
- Testicular neoplasia
- Umbilical hernia

INITIAL DATABASE

- Complete blood count: Variable depending on systemic compromise
- Peritoneal fluid: Normal initially but may become serosanguineous with an elevated protein content and white blood cell count with time if strangulated bowel present
- Rectal palpation (adults): Palpable structures entering the internal inguinal ring; most commonly small intestine with distended small intestine coursing to the ring
- Ultrasonography (transabdominal): Possibly small intestinal distension if involved in the inguinal hernia
- Ultrasonography (transcutaneous of inguinal and scrotal region): Intestines within scrotum ± subcutaneously. Edema of the testicle and spermatic cord are common because of vascular compromise. Peritoneal effusion is often seen.

TREATMENT

THERAPEUTIC GOAL(S)

- Monitor hernia for deterioration (enlargement, signs of incarceration or signs of systemic compromise).
- Remove any predispositions (eg, straining).
- Attain closure of the inguinal hernia.
  - Repeated manual reduction
  - Surgical repair
- Congenital
  - Manual reduction of scrotal hernia and maintenance until spontaneous permanent resolution
- Acquired
  - Correction of metabolic derangements
  - Pain management
  - Reduction of inguinal hernia
  - Castration of the affected testicle

ACUTE GENERAL TREATMENT

- Reducible hernias in foals
  - Confine to a stall.
  - Reduce hernia manually several times per day (sometimes easier in recumbency).
  - Occasionally compressive inguinal bandages (figure 8 pattern) are necessary in larger hernias.
  - If conservative therapy is not successful or the hernia becomes nonreducible, surgical intervention is required.
  - A routine inguinal approach is made and the hernia reduced. Closed castration is recommended, and the external inguinal rings are closed.
  - Laparoscopic reduction and closure of the internal inguinal ring and testicular preservation have been reported.
- Nonreducible hernias in foals or adults
  - Surgical reduction ± resection of compromised bowel and herniorrhaphy: Dorsal recumbency under general anesthesia
  - Two approaches are usually required for successful reduction of the hernia, a ventral midline and inguinal approach.
  - Depending on the duration of the colic, after the entrapment is reduced and the affected loop is replaced back into the abdomen, allowing for reperfusion of the segment, intestinal viability may improve significantly, eliminating the need for resection and anastomosis. If intestinal viability does not return, resection of the segment is necessary. If the ileum is involved, a jejunocecostomy may be required.
  - Bilateral castration should be discussed with the owner because of the risk, although small, of herniation through the non-affected side. Hemicastration and preservation of the opposite testicle are often performed in breeding stallions.
- Partial or complete laparoscopic closure of the internal inguinal ring with or without testicular preservation has also been reported in adults.

CHRONIC TREATMENT

- Reducible hernias in foals: Continue manual reduction several times daily for 3 to 6 months or until there are signs of incarceration or enlargement or colic.
- Surgical herniorrhaphy and castration are recommended if the hernia is still present at 3 to 6 months.
- After herniorrhaphy
  - Castration is recommended. (Horses may otherwise reherniate and can herniate through the contralateral ring subsequently.)
  - Stall rest is required for 30 to 45 days.

POSSIBLE COMPLICATIONS

- Repeat herniation (incisional hernia)
- Local infection
- Peritonitis
- Endotoxemia
- Adhesions
- Reobstruction
- Jugular thrombophlebitis
- Diarrhea
- Pyrexia
- Incisional infection
- Recurrent colic

RECOMMENDED MONITORING

- Pain
- Hernia or incisional swelling, pain, or discharge
- Mentation
- Fecal output

PROGNOSIS AND OUTCOME

- Congenital inguinal hernias in foals may resolve spontaneously, and strangulation is rare.
- The prognosis for horses with strangulating lesions is variable and depends on the severity of compromise of the bowel.

PEARLS & CONSIDERATIONS

- The predisposition of foals for reducible nonstrangulating inguinal hernias is probably associated with the relatively short and wide inguinal ring compared with adult horses.
- Even if an inguinal hernia spontaneously corrects in a foal, care should be taken during castration because the horse is still at risk of evisceration subsequent to castration.
- An inguinal hernia should always be considered in intact males with colic, especially if predisposed by breed.
- Direct herniation is rare.
- The small intestine can often be felt rectally passing through the vaginal ring. Slight tension placed on the affected mesentery elicits a painful response.
- The condition may occur in geldings, but it is very rare.
- Congenital inguinal or scrotal hernias in neonates seldom cause strangulation and resolve spontaneously with conservative therapy by 3 to 6 months of age.

ElibeVet.com

Hernia, Lateral Abdominal

BASIC INFORMATION

DEFINITION

Protrusion of an organ or tissue through a defect in the body wall

SYNONYM(S)

Body wall hernias

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Closed abdominal wall hernia
- Open abdominal wall hernia

HISTORY, CHIEF COMPLAINT

- May have a history of known trauma
- Horse demonstrates alteration of the normal contour of the body wall with or without a wound
- May have low-grade colic signs and appear distressed or reluctant to move

PHYSICAL EXAM FINDINGS

- Abnormal contour and swelling in the area of the hernia
  - Associated edema
  - Thin feeling to the body wall
  - The intestines may be palpable or visible subcutaneously, especially in foals
- Temperature generally normal
- May have normal heart rate or be tachycardic
- Respiratory rate may be normal or mildly elevated
- Mucous membranes are variable from pink and moist to pale and tacky
- Colic signs are variable; may be absent or demonstrate mild colic signs
- Hydration variable

ETIOLOGY AND PATHOPHYSIOLOGY

- Trauma (eg, hit by a car, impact with a solid object such as a fence post or a kick)
- May be associated with dystocia in foals

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Edema
- Local infection
- Prepubic tendon rupture
- Inguinal, incisional, or umbilical hernia

INITIAL DATABASE

- Complete blood count: Generally normal
- Peritoneal fluid: May demonstrate mild elevations in protein and white blood cell counts. Hemoabdomen may also be present associated with underlying trauma.
- Transabdominal ultrasonography: Bowel often normal unless it becomes herniated through the body wall defect; peritoneal effusion is frequently present; body wall defect visible with lack of definition of normal muscular layers and hemorrhage and edema associated with the trauma
- Hernia may be palpable rectally depending on its position.

TREATMENT

THERAPEUTIC GOAL(S)

- Stabilize the patient.
- Initiate wound management if applicable and prevent further contamination using a bandage.
- Surgical repair
  - Provide analgesia and antiinflammatory drugs.
  - Promote repair of the defect.
    - If it is a nonpenetrating injury, support the defect in the abdominal wall to allow fibrosis and scarring of the area.
    - Surgical repair is sometimes necessary but is preferentially performed after 60 days.

ACUTE GENERAL TREATMENT

- Penetrating wounds
  - Wound management, including antibiotics
  - Surgical closure to prevent evisceration and peritonitis
- Nonpenetrating wounds
  - Small defects
    - Local therapy to minimize swelling (eg, hydrotherapy)
    - Antiinflammatory drugs and analgesics
    - Supportive bandages
    - Stall rest
  - Large defects: Surgical reconstruction may be indicated and may require synthetic mesh placement.

CHRONIC TREATMENT

Consider direct suture apposition after 60 days if residual body wall defects remain. This allows fibrosis of tissues, which therefore has improved suture-holding strength.

POSSIBLE COMPLICATIONS

- Hernia repair breakdown and recurrence
- Peritonitis
- Endotoxemia
- Adhesions
- Ileus
- Jugular thrombophlebitis
- Diarrhea
- Pyrexia
- Incisional infection
- Recurrent colic

RECOMMENDED MONITORING

- Pain
- Body contour
- Colic
- Mentation
- Local swelling, heat or pain on palpation

PROGNOSIS AND OUTCOME

- Prognosis is variable. Most are nonpenetrating and do not involve strangulation of bowel. These defects frequently fibrose and effectively repair themselves.
- Penetrating defects have a high risk of peritonitis, adhesions, and local wound infection

ElibeVet.com

Hernia, Umbilical

BASIC INFORMATION

DEFINITION

Protrusion of an organ or tissue through a defect in the normal abdominal wall at the umbilicus

EPIDEMIOLOGY

SPECIES, AGE, SEX Affects foals
RISK FACTORS Females are more commonly affected.
ASSOCIATED CONDITIONS AND DISORDERS Umbilical cord infection

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
Classifications
- Size
- Shape
- Contents of the hernial sac
- Reducible or nonreducible

HISTORY, CHIEF COMPLAINT
- Swelling around the umbilicus: May be permanent or intermittent
- If a foal has an incarcerated, strangulated bowel, the foal will demonstrate inappetence, lethargy, and colic signs, and the hernia may have recently increased in size, becoming irreducible.

PHYSICAL EXAM FINDINGS
- Nonincarcerated hernia
  - Soft, reducible hernia
  - Most commonly normothermic
  - Normal heart rate
  - Normal mentation
  - Mucous membranes pale pink and moist
  - Normal borborygmi
  - Normal fecal output
  - Normal hydration
- Incarcerated or nonreducible hernia
  - May be firm
  - If painful and warm or edematous, often strangulated incarcerated hernia
  - May demonstrate colic signs (definitely if strangulated)
  - May demonstrate tachycardia (definitely if strangulated)
  - May be normothermic but often hyperthermic or hypothermic depending on systemic status
  - Often depressed and lethargic
  - Mucous membranes variable: May be pale pink and moist but progress to toxic with time
  - Often decreased or absent borborygmi
  - Normal or decreased fecal output
- Depending on complete occlusion of bowel or partial involvement in the hernia (Richter's hernia): Variable hydration

ETIOLOGY AND PATHOPHYSIOLOGY
- Most are congenital
- May have a hereditary component
- May be associated with trauma to the umbilical cord at birth
- May be associated with neonatal excessive straining
- May be associated with umbilical cord infection

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Umbilical infection
- Patent urachus
- Local infection
- Inguinal hernia

INITIAL DATABASE

- Nonincarcerated
  - Complete blood count: Frequently normal
  - Peritoneal fluid: Normal
  - Palpation reveals a soft, reducible hernia with well defined hernial ring.
  - Ultrasonography demonstrates a defect in the body wall but normal motile intestines close by defect.
- Incarcerated
  - Leukopenia or leukocytosis common; occasionally normal
  - Peritoneal fluid has increasing total protein and white blood cell counts with time
  - Palpation reveals a firm, swollen, nonreducible hernia that is painful to palpation, especially if strangulated.
  - Ultrasonography demonstrates a defect in the body wall containing intestine, which frequently demonstrates thickened walls if strangulated.
  - Radiography may be helpful to identify contents of hernial sac.
  - Gas may be visible within loops of bowel.

TREATMENT

THERAPEUTIC GOAL(S)

- Monitor hernia for deterioration: Enlargement, signs of incarceration, or signs of systemic compromise
- Attain closure of the umbilical hernia.
  - Repeated reduction
  - Surgical repair

ACUTE GENERAL TREATMENT

- Reducible hernias smaller than 10 cm in diameter
  - Reduce the hernia manually.
  - Occasionally, compressive belly bandages can be worn and are tolerated by foals.
- Reducible hernias larger than 10 cm in diameter: Surgical herniorrhaphy
- Risks of strangulation high
- Nonreducible hernias with signs of incarceration: Surgical herniorrhaphy ± resection of compromised bowel

CHRONIC TREATMENT

- Reducible hernias smaller than 10 cm in diameter: Continue manual reduction at least daily for 4 months or until signs of incarceration or enlargement
- Most hernias smaller than 5 cm in diameter regress.
- Herniorrhaphy is recommended if the hernia still present at 4 months or deterioration of the hernia is noted.
- After herniorrhaphy
  - Belly band application may aid decrease in dead space at surgery site.
  - Stall rest is required for 30 to 45 days.

POSSIBLE COMPLICATIONS

- Repeat herniation (incisional hernia)
- Local infection
- Peritonitis
- Endotoxemia
- Adhesions
- Reobstruction
- Jugular thrombophlebitis
- Diarrhea
- Pyrexia
- Incisional infection
- Recurrent colic

RECOMMENDED MONITORING

- Pain
- Hernia or incisional swelling, pain, or discharge
- Mentation
- Fecal output

PROGNOSIS AND OUTCOME

- Hernias are predominantly a cosmetic defect and are rarely life threatening; however, incarceration of bowel within the hernia does become a life-threatening condition.
- Good prognosis if the hernia is smaller than 5 cm in diameter.

ElibEVet.com

- Frequently close spontaneously as foal grows: Poor prognosis for spontaneous closure if the hernia is larger than 10 cm in diameter

PEARLS & CONSIDERATIONS

Umbilical hernias are the most common type of hernia in horses. The estimated occurrence is 0.5% to 2% of foals.

Herpesvirus

BASIC INFORMATION

DEFINITION

- Equine herpesviruses (EHVs) are ubiquitous enveloped DNA viruses that have a major economic and welfare impact on the horse industry worldwide.
- Nine EHVs have been characterized. Five (EHV-1 to EHV-5) infect domestic horses, and two (EHV-6 and EHV-9) are associated with infections in wild Equids, including asses and zebra.
- EHV-1 through EHV-5 may be further classified into viral subfamilies on the basis of their genetic sequence:
  - *α-Herpesviridae:* EHV-1, EHV-3, and EHV-4
  - *γ-Herpesviridae:* EHV-2 and EHV-5
- In domestic horses, EHV-1 is associated with respiratory disease, abortion, and neurologic disease.
- EHV-2 has not been convincingly associated with pathology in horses as a primary etiologic agent, but some evidence suggests that it may be associated with keratoconjunctivitis in young horses and superficial keratopathies in adult horses.
- EHV-3 causes coital exanthema, a venereal disease of stallions and mares (see "Venereal Diseases in the Stallion: Viruses," in this section).
- EHV-4 is associated primarily with respiratory tract disease in horses.
- EHV-5 is epidemiologically associated with pulmonary nodular fibrosis in adult horses.

SYNONYM(S)

- EHV-1
  - Equine rhinopneumonitis
  - Viral abortion
  - Neurologic herpes
  - Equine herpesvirus myeloencephalopathy (EHM)
- EHV-3: Coital exanthema
- EHV-4: Equine rhinopneumonitis
- EHV-5: Pulmonary nodular fibrosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most adult horses have serologic evidence of exposure to EHVs.
- The neurologic form of disease appears to be more common in adult horses.

RISK FACTORS

- Areas of high comingling of horses: Racetracks, show grounds, veterinary hospitals
- Stress or immunosuppression: Transport, hospitalization, training, showing, weaning, high doses of corticosteroids

GEOGRAPHY AND SEASONALITY

- Worldwide
- Highest incidence of EHV-1 neurologic disease in late winter, spring, and early summer with concomitant outbreaks of respiratory disease or abortion.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Respiratory disease
  - Usually EHV-4, occasionally EHV-1
  - Typically causes a self-limiting upper respiratory disease
  - In neonates or immunocompromised young animals, may cause a severe viral pneumonitis with secondary bacterial pneumonia
- Abortion
  - Almost always EHV-1
  - EHV-4 with single cases rather than outbreaks (possibly indicating reactivation of latent infection)
- Neurologic disease: See "Myeloencephalitis, Equine Herpesvirus-1" in this section.
- Ocular disease
  - Recurrent conjunctivitis ± corneal ulceration may be caused by EHV-1 or EHV-2.
  - Uveitis has been described in association with EHV-1.
  - Keratitis has been described in association with EHV-2.
- Multinodular pulmonary fibrosis: EHV-5 has been associated with this disorder and may be a cofactor or primary etiologic agent.

HISTORY, CHIEF COMPLAINT

Horses may present with one or more of the following common complaints:

- Inappetence, fever, nasal discharge
- Mare in late gestation with sudden abortion or expulsion of placenta
- Multiple abortions on the premises
- Acute-onset neurologic deficits in one or more horses with some horses febrile
- Weak foal that is not thriving
- Persistent keratitis or keratoconjunctivitis
- Adult horse with weeks-long history of intermittent fever, weight loss, coughing, or tachypnea

PHYSICAL EXAM FINDINGS

- Respiratory disease
  - Depression, anorexia
  - Fever from 101° to 106° F that may be biphasic peaking at 24 to 48 hours after infection and again on days 6 to 7
  - Serous nasal discharge changing to mucopurulent
  - Conjunctivitis
  - Serous ocular discharge
  - Progressive lymphadenopathy of mandibular and retropharyngeal lymph nodes
  - Coughing may or may not be evident (less consistent than with equine influenza)
  - Occasional limb edema, diarrhea, colic
- Viral pneumonitis of neonates
  - Fever, marked depression
  - Tachypnea
  - Dyspnea, respiratory distress
  - Abnormal lung sounds
  - Petechia, icterus
- Abortion
  - Abortion in the last third of pregnancy; refractory to abortion if

ElibeVet.com

infected less than 120 days' gestation
  - After abortion, mare may be normal or have respiratory disease or neurologic signs before abortion
  - Typically no premonitory signs, with rapid expulsion of placenta
  - After abortion, mares generally breed successfully and foal normally.
  - May result in birth of stillborn or very weak foals that die shortly after birth
  - Stallions may develop scrotal edema, loss of libido, reduction in sperm quality, and shedding of infectious virus in semen.
  - Foals may be stillborn or born weak and die
- Neurologic disease: See "Myeloencephalitis, Equine Herpesvirus-1" in this section
- Infectious keratitis
  - Blepharospasm, serous epiphora
  - Chemosis, conjunctival hyperemia
  - Superficial punctuate or dendritic lesions
  - Recurrent cases may have corneal vascularization.
- Multinodular pulmonary fibrosis
  - Weight loss, poor body condition
  - Fever
  - Cough, nasal discharge
  - Tachypnea, respiratory disease

ETIOLOGY AND PATHOPHYSIOLOGY

- Principal reservoir of infection is latently infected horses.
  - An estimated 80% to 90% of horses are latently infected with EHV-1 or EHV-4 by 2 years of age.
  - Foals are exposed and may become latently infected as early as 1 to 2 weeks of age (from their dam or other adult horses).
  - Latently infected horses serve as a source of virus for spread to other foals.
  - Reactivation of latent virus may occur with any stressful situation, including transport, handling, rehousing, or weaning.
  - Reactivation of latent virus in adult horses often causes viral shedding without clinical signs.
- Environmental transmission is important during outbreaks and may occur by:
  - Aerosolization of virus in nasopharyngeal secretions of infected horses
  - Direct horse-to-horse contact
  - Exposure to aborted fetal and placental tissues and fluids
  - Exposure to fomites contaminated with respiratory or reproductive secretions
- For EHV-1 and EHV-4
  - The virus invades respiratory epithelium and incubates 1 to 10 days.
  - Onset of clinical signs (fever, nasal and ocular discharge) in 1 to 3 days
  - Shedding of virulent virus for 6 to 10 days after onset of fever.
  - Latent infection of virus in circulating CD8+ T lymphocytes, upper respiratory lymph nodes, and trigeminal ganglia (EHV-1 and EHV-4) or in lymphocytes and trigeminal ganglia (EHV-2 and EHV-5)
  - Reactivation of virus during periods of stress (eg, transport, hospitalization, illness) may result in symptomatic or asymptomatic nasal shedding of virus.
  - Natural infection of EHV-1 induces protective immunity for only a few weeks to a few months.
  - Abortion: EHV-1 infects endothelial cells in pregnant uterus to cause a vasculitis of small arteriolar branches in the glandular layer of endometrium at base of microcotyledons. Fetus may be aborted before transplacental spread of virus to fetus.
  - Neurologic disease: See "Myeloencephalitis, Equine Herpesvirus-1" in this section.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Respiratory disease
  - Equine influenza
  - Equine viral arteritis
  - Equine adenovirus
- Neurologic disease: See "Myeloencephalitis, Equine Herpesvirus-1" in this section.
- Abortion
  - Equine viral arteritis
  - Leptospirosis
  - Bacterial placentitis
  - Nocardioform abortion
  - *Neorickettsia risticii*
  - *Chlamydia* spp.
  - *Mycoplasma* spp.
  - Mare reproductive loss syndrome
- Viral pneumonitis
  - Equine viral arteritis
  - Equine adenovirus
  - Equine influenza
- Infectious keratitis
  - Opportunistic bacteria or fungi with trauma
  - Other respiratory viruses (adenovirus, influenza, Borna virus)
- Conjunctivitis
  - Equine adenovirus
  - Equine viral arteritis
  - Bacterial agents (*Streptococcus equi* subsp. *equi*, *Moraxella* spp., *Chlamydia* spp., *Mycoplasma* spp.)
  - *Histoplasma farciminosus*
  - *Aspergillus* spp.
  - *Rhinosporidium seeberi*
  - Blastomycosis
  - Parasitic (*Thelazia* spp., *Onchocerca* spp., *Habronema* spp., *Trypanosoma* spp.)
- Uveitis
  - Equine influenza
  - Equine viral arteritis
  - Equine infectious anemia
  - Bacterial agents
  - Parasitic agents
  - Equine recurrent uveitis

INITIAL DATABASE

- EHV-1 and EHV-4
  - Leukopenia (transient; first 7–10 days)
  - Lymphopenia
- Viral pneumonitis
  - Diffuse bronchointerstitial pattern on thoracic radiographs
  - Toxic, neutropenic, lymphopenic, leukopenia
- Infectious keratitis:
  - Superficial and punctate lesions identified with rose Bengal stain of cornea
- Multinodular pulmonary fibrosis
  - Neutrophilic leukocytosis with hyperfibrinogenemia
  - Severe nodular interstitial pattern on thoracic radiographs
  - Discrete nodular lesions (1–7 cm) on thoracic ultrasound

ADVANCED OR CONFIRMATORY TESTING

- EHV-1 and EHV-4
  - Virus isolation using whole blood (EDTA, heparin) or swabs of nasopharyngeal secretions collected using a 6-inch polyester or Dacron swab. Collect within the first 24 to 48 hours after clinical onset.
  - Serology using paired sera (acute and convalescent) collected 10 to 21 days apart
    - Most available tests cannot differentiate between EHV-1 and EHV-4.
    - EHV IgG enzyme-linked immunosorbent assay differentiates between EHV-1 and EHV-4.
  - Real-time polymerase chain reaction (PCR) on whole blood, nasal swabs
    - Test available to identify DNA mutation associated with "neuropathic" strains of EHV-1
  - Aborted fetus: Liver, lung, adrenal, and thymus samples are important.
    - Histopathology, immunohistochemistry, PCR, virus isolation
  - Cerebrospinal fluid
    - Xanthochromia, high protein (100–500 mg/dL), normal nucleated cell numbers.
  - Foals
    - Postmortem findings: Severe diffuse interstitial pneumonia, hepa-

ElibeVet.com

titis with viral inclusion bodies and bone marrow depletion
    - Histopathology, immunohistochemistry, PCR, virus isolation
- Coital exanthema: Virus isolation from lesions, inclusion bodies seen on histopathology, PCR
- Infectious keratitis
    - Corneal cytology
    - Culture and sensitivity
    - Histopathology
    - PCR for EHV-2 and EHV-5
- Multinodular pulmonary fibrosis
    - PCR assay for EHV-5
        - Bronchoalveolar lavage fluid
        - Lung biopsy sample
    - Transtracheal wash
        - Of the five reported cases, only one horse had *Enterobacter* spp. infection
        - Purulent inflammation with nondegenerate to degenerate neutrophils

TREATMENT

THERAPEUTIC GOAL(S)

- Provide symptomatic treatment.
- Establish biosecurity measures to minimize spread of infection, particularly with EHV-1 induced abortion and neurologic EHV-1.
- Confirm EHV-1 diagnosis with testing.

ACUTE GENERAL TREATMENT

- Respiratory disease
    - Nonsteroidal antiinflammatory drugs (NSAIDs) for high fever
    - Nursing care
    - Hydration and fluids if needed
    - Rest for at least 7 days after clinical signs
    - Maintain good air hygiene in stables with (minimal dust with low concentrations of allergens, bacteria, and irritants)
- Viral pneumonitis
    - Treatment for septic foal
        - Broad-spectrum antibiotics, IV plasma (see "Neonatal Sepsis" in this section)
        - NSAIDs
        - Nursing care
        - Nasal insufflation with O_2
    - Generally unrewarding because foals fail to survive
    - Consider antiviral therapy as described below
- Neurologic disease: See "Myeloencephalitis, Equine Herpesvirus-1" in this section.
- Infectious keratitis
    - Topical antivirals, four to 12 times per day for 3 to 5 days; then three to six times per day
        - Idoxuridine (0.1%)
        - Trifluridine (0.3%)
    - Topical NSAIDs
        - 0.03% flurbiprofen
        - 0.1% diclofenac
    - Avoid topical corticosteroids
    - Oral L-lysine 10 to 30 g q24h
- Multinodular pulmonary fibrosis
    - Supportive treatment (IV fluids, nasal O_2, nasogastric feeding)
    - Broad-spectrum antimicrobials
    - Corticosteroids
        - Dexamethasone: 0.037 mg/kg IV q24h for several weeks, tapering
        - Prednisolone: 1 mg/kg PO q24h
    - Antiviral medications
    - NSAIDs
    - For pulmonary hypertension
        - Sildenafil
        - Furosemide
    - Inhaled medications
        - Fluticasone (2200 µg q12h)
        - Albuterol
        - Nebulized antibiotics

POSSIBLE COMPLICATIONS

Bacterial pneumonia or pleuropneumonia

RECOMMENDED MONITORING

- Guidelines for management of infectious disease outbreaks are available at the website of the American Association of Equine Practitioners (AAEP) (see Recommended Reading below) and include the following:
    - Monitor horses twice daily for increased rectal temperature. Segregate horses with fever from the general horse population.
    - Quarantine of horses for 28 days after the last known clinical case.
    - Affected horses should be tested with nasopharyngeal swabs to make sure they are no longer contagious.
    - Proper disinfection of trailers, equipment, and so on
    - Use of separate equipment for each horse
    - Efficient and open communication among attending veterinarian, premises' owners, and other parties working with the affected premises

PROGNOSIS AND OUTCOME

- The majority of respiratory infections are inapparent and self-limiting with clinical signs lasting for 24 hours up to 3 days.
- Foals born with EHV-1 infection are weak and fail to thrive despite treatment. Foals that survive for more than 2 or 3 days develop secondary bacterial pneumonia, and may survive for 10 to 14 days, but eventually die from respiratory disease and a complex combination of other complications, including lymphoid depletion and profound leukopenia.
- Horses with neurologic disease manifest rapid progression of signs and then stabilize in a few days. Recumbency for more than 24 hours signifies a poor prognosis. Horses that remain standing usually improve and may recover completely within weeks to months. Control of urination returns typically before gait abnormalities (see "Myeloencephalitis, Equine Herpesvirus-1" in this section).
- Multinodular pulmonary fibrosis
    - Of the five horses reported, two horses survived and returned to previous level of activity after several months of therapy.
    - Horses that had evidence of pulmonary hypertension had a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

EHVs are endemic within the equine population. Control of EHV disease occurs by a combination of management and hygiene measures supplemented by vaccination.

PREVENTION

- Horses returning from areas of high exposure risk (eg, shows, breeding, hospitalization) should be housed separately from the general barn population for at least 21 days (ideally 28 days) and monitored for clinical signs.
- Mares that abort should be isolated for a minimum of 4 weeks and not mixed with pregnant mares for 56 days.
- Practice good hygiene measures and biosecurity on the farm.
    - Separate different age groups of horses; maintain small numbers of horses in each cohort.
    - Isolate pregnant mares from other horses.
    - Individually house mares in the last third of gestation.
    - Disinfect stalls, equipment, and so on before use by another horse.
    - Minimize visitor contact and traffic with animals.
    - Practice appropriate pest and vector control.
- Vaccination recommendations (see AAEP guidelines for vaccination)
    - Broodmares: Killed virus vaccines at 5, 7, and 9 months of gestation
    - Foals: Begin three-dose series of vaccinations at 4 to 6 months of age.
    - Young horses: Vaccinate against EHV-1 and EHV-4 to prevent respiratory disease.

ElibEVet.com

    - Booster for EHV-1 and EHV-4 every 6 months
  - In the face of a neurologic EHV-1 outbreak:
    - None of the current vaccines for EHV-1 have been labeled as protective against neurologic disease.
    - Horses showing clinical disease *should not* be vaccinated.
    - Exposed horses potentially harboring the virus should not be vaccinated.
    - Booster nonexposed horses at risk that must enter the premises if they have not been vaccinated within the previous 90 days.
- Further preventative measures
  - Immunomodulators: Zylexis (Parapox ovis) labeled for prevention of respiratory signs from EHV-1 and EHV-4
  - Antivirals: Prophylactic use may be beneficial to reduce viral replication, viremia, and shedding in the face of a disease outbreak (especially neurologic disease); these drugs are costly.

CLIENT EDUCATION

- Establish guidelines for general husbandry and preventative measures such as outlined in the US Department of Agriculture brochure *Biosecurity: The Key to Keeping your Horses Healthy* available at http://www.aphis.usda.gov/animal_health/animal_dis_spec/horses/.
- Establish a contingency plan in the case of abortion for the proper handling of biologic tissues and measures to isolate the aborting mare from the rest of the herd.

Histoplasmosis

BASIC INFORMATION

DEFINITION

- A systemic fungal infection of horses caused by the fungus *Histoplasma capsulatum* that may result in pulmonary disease, abdominal or gastrointestinal disease, placentitis and abortion, or disseminated disease

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No known age, sex, or breed predilection

RISK FACTORS

- Immune compromise
- Residing in or traveling through endemic areas.

CONTAGION AND ZOONOSIS

- People in endemic regions are at risk of exposure and disease.
- Concurrent common source infection of humans and animals has been observed.
- There is no evidence of direct transmission of histoplasmosis from animals to humans.

GEOGRAPHY AND SEASONALITY

- In the United States, histoplasmosis is endemic in the Mississippi, Missouri, and Ohio River valleys; southwestern and eastern Ontario to Montreal, Ottawa; and the St. Lawrence River valley.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Pulmonary disease is most common
- Abdominal or gastrointestinal disease
- Placentitis and abortion
- Disseminated disease

HISTORY, CHIEF COMPLAINT

- Weight loss
- Depression
- Dyspnea
- Edema
- Diarrhea
- Abortion, neonatal death

PHYSICAL EXAM FINDINGS

- Vary depending on the site of infection
- Fever, poor body condition, depression
- Dyspnea, increased respiratory rate, abnormal lung sounds
- Diarrhea, abdominal pain

ETIOLOGY AND PATHOPHYSIOLOGY

- In nature, *H. capsulatum*, a dimorphic ascomycete, exists as a filamentous fungus.
- At 37° C, microconidia germinate and form mycelia that are transformed into small, budding, oval yeasts.
- In nature, the organism is found in bat and bird guano, especially that of chickens and starlings.
- Infection occurs by inhalation of microconidia that germinate in vivo to the yeast form.
- Immune competent hosts can usually control the organism with a cell-mediated immune response.
- Many horses in endemic areas are seropositive with no evidence of disease.
- Exposure to a large inoculum may result in disease in immune competent hosts.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Varies depending on the site of infection

INITIAL DATABASE

- Usually evidence of chronic infection and inflammation
- With gastrointestinal disease, panhypoproteinemia is often observed.

ADVANCED OR CONFIRMATORY TESTING

- Observation of organism in tissue samples stained with Gömöri methenamine silver or periodic acid-Schiff.
- Culture of the organism remains the gold standard for diagnosis.
- Serology: Immunodiffusion and complement fixation test results are usually positive but do not provide a definitive diagnosis.
- Antigen detection in blood, urine, and other body fluids may provide a diagnosis.
- Intradermal testing with histoplasmin is not diagnostically useful because of the large number of false-positive reactions.

ElibeVet.com

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate infection.

ACUTE GENERAL TREATMENT

- Systemic antifungal therapy is recommended.
- Disease is rare, so there is minimal information on individual drug efficacy.
- Amphotericin B, itraconazole, or both may be used.
- Therapy may need to be continued for many weeks.

PROGNOSIS AND OUTCOME

Histoplasmosis is a rare disease in horses, and data are insufficient to draw conclusions about equine treatment. Treatment of affected horses has been infrequently attempted because of the severity of clinical signs, failure to make the diagnosis, expense of treatment, and concerns of a poor prognosis for recovery from fungal disease.

Hoary Alyssum Toxicosis

BASIC INFORMATION

DEFINITION

Characterized by limb edema and laminitis, hoary alyssum toxicity occurs primarily in horses grazing the plants in pastures or eating the plants when incorporated in hay.

SYNONYM(S)

Hoary alyssum (*Berteroa incana*), hoary false madwort

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses are the only domestic animals affected by hoary alyssum.

RISK FACTORS The plants are toxic when green and remain toxic for months when dried in hay. Overgrazing favors the invasiveness of this weed.

GEOGRAPHY AND SEASONALITY *B. incana*, a member of the Brassicaceae family, is an annual, biennial, or perennial introduced weed that has become naturalized in most areas of North America. Stems are gray-green, hairy (hoary), 1 to 3 feet tall, with many branches near the top. Leaves are gray-green, hairy, alternate, oblong, narrow, 0.5 to 3 inches long, with smooth edges. Flowers are white with four deeply divided petals. Seed pods are hairy and oblong with short beaks on the end (Figure 1).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Edematous swelling of the legs, lameness and, in severe cases, laminitis

PHYSICAL EXAM FINDINGS Lameness caused by distal limb edema and laminitis is a typical sign of hoary alyssum poisoning. Experimentally horses fed hay containing 30% hoary alyssum develop pyrexia, an increased digital pulse, and limb edema within 24 hours. Severe laminitis with rotation of the third phalanx may occur in severe cases. Red-colored urine (hemoglobinuria) as a result of red blood cell hemolysis and hemorrhagic diarrhea have been reported in pregnant mares fed alfalfa hay containing hoary alyssum. Late-term abortion is reported in pregnant mares. Death may occur in 1% to 2% of natural cases of hoary alyssum poisoning.

ETIOLOGY AND PATHOPHYSIOLOGY The toxin responsible for the limb edema and laminitis is not known.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Laminitis secondary to grain overload, fever, sustained trauma to the feet
- Black walnut intoxication
- Congestive heart failure with peripheral edema
- Edema of the legs secondary to photosensitization affecting the white-skinned areas

INITIAL DATABASE

- Complete blood count: Hemolytic anemia.
- Serum biochemical analysis: Serum bilirubin, urea nitrogen, and creatinine elevated
- Urine analysis: Hemoglobinuria, proteinuria

ADVANCED OR CONFIRMATORY TESTING

Radiography to assess the severity of laminitis

TREATMENT

THERAPEUTIC GOAL(S)

Remove the source of hoary alyssum

FIGURE 1 Hoary alyssum (*Berteroa incana*).

ACUTE GENERAL TREATMENT

- Antiinflammatory and analgesic therapy: Flunixin meglumine, or phenylbutazone
- Cold water hydrotherapy for the swollen legs
- Supportive therapy, including IV fluids and electrolytes is indicated in severe cases

CHRONIC TREATMENT

Appropriate hoof care to manage the chronic effects of laminitis

POSSIBLE COMPLICATIONS

- Rotation of the third phalanx in severely laminitic feet
- Abortion in late-term pregnant mares

ElibeVet.com

PROGNOSIS AND OUTCOME

Early recognition and removing the horses from hoary alyssum immediately favors a rapid recovery.

PEARLS & CONSIDERATIONS

COMMENTS

Hoary alyssum is an aggressive invasive weed of hay meadows and should not be allowed to become established.

PREVENTION

Feed weed-free hay whenever possible.

CLIENT EDUCATION

- Educate clients so they can recognize hoary alyssum in pastures and hay.
- Application of herbicides (2,4-dichlorophenoxyacetic acid) according to label directions before the plants bloom is effective in controlling hoary alyssum. Preventing the plant from producing seed will stop the spread of hoary alyssum.

SUGGESTED READING

AUTHOR: **ANTHONY P. KNIGHT**

EDITOR: **CYNTHIA L. GASKILL**

Hydronephrosis

BASIC INFORMATION

DEFINITION

Distension and dilation of the kidney and renal pelvis caused by obstruction of urine flow (Figure 1)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Males are predisposed to urolithiasis in general.
- Urolithiasis is typically seen in adult horses, with a mean age of 10 years.

RISK FACTORS

- Obstructive urinary tract disease of any cause
- Uroliths (calculi) are the most common cause of urinary tract obstruction, although neoplasia, trauma, or urinary tract displacement may also obstruct urine flow.

ASSOCIATED CONDITIONS AND DISORDERS

- Chronic renal failure
- Urolithiasis
- Neoplasia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Complete or incomplete obstruction may occur, and signs may be acute or chronic.

HISTORY, CHIEF COMPLAINT

- Complete obstruction typically results in moderate to severe abdominal pain (colic).
- Incomplete obstruction typically results in mild, intermittent abdominal pain or no clinical signs.
- Many horses present for signs consistent with chronic renal failure (anorexia, lethargy, weight loss).

PHYSICAL EXAM FINDINGS The physical examination may be unremarkable, consistent with signs of abdominal pain (eg, tachycardia, tachypnea), or consistent with signs of renal failure (eg, poor hair coat and body condition, excessive dental tartar).

ETIOLOGY AND PATHOPHYSIOLOGY

- Urinary flow is obstructed, primarily via nephroliths or ureteroliths.
- Outflow obstruction causes a backflow of urine and increased pressure in the kidney, resulting in renal distension and dilatation of the renal pelvis.
- Postrenal azotemia and chronic renal failure occurs with occlusion of urinary outflow, backpressure in the collecting system, and resultant decreased renal blood flow.
- A retrospective study reported uroliths in the kidneys (22%; 53% bilaterally) and ureters (3%; 50% bilaterally) of affected horses. Approximately 9% of horses had urolithiasis in more than one location.

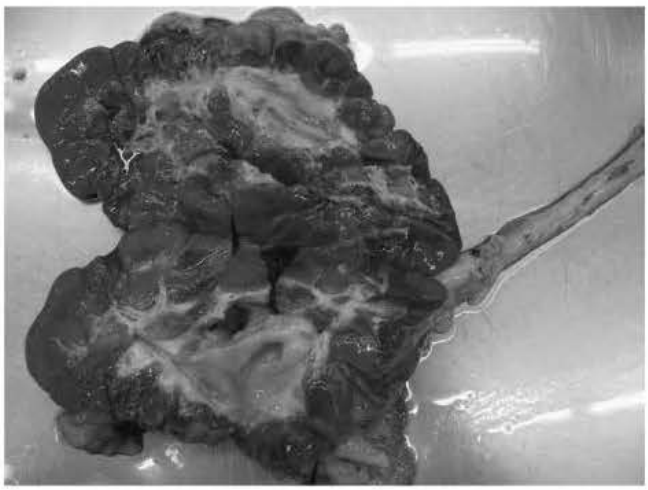

FIGURE 1 A left kidney with hydronephrosis and hydroureter. The ureter was obstructed with numerous small ureteroliths.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Any urinary tract obstruction (urolithiasis)
- Gastrointestinal disease (if showing signs of abdominal pain)
- Hepatic or renal disease (if vague signs consistent with renal failure)

INITIAL DATABASE

- Complete blood count: Typically unremarkable unless there is an infectious process present
- Serum chemistries: May have elevated blood urea nitrogen (BUN) and creatinine concentrations if the obstruction is bilateral or chronic and has

ElibeVet.com

FIGURE 2 Ultrasound image of the kidney in Figure 1. The renal pelvis is dilated.

resulted in renal compromise or failure.
- Renal ultrasonography: Dilated ureter or renal pelvis. The affected kidney will likely be enlarged and dilated. Calculi may be present within the renal pelvis or ureter. Lesions may be unilateral or bilateral (Figure 2).
- Rectal examination: May be able to palpate an enlarged, dilated kidney or ureter

ADVANCED OR CONFIRMATORY TESTING

- Cystoscopy: Able to evaluate urine flow from both ureters. May be able to perform ureteroscopy if the ureter is dilated on the side of the affected kidney. May also observe the presence of calculi in the bladder or urethra as well as neoplasia or other sources of urinary tract obstruction.
- Urine culture: May be useful if there is an infectious component to the obstructive disease.
- Urinalysis: May reveal hematuria, proteinuria, and pyuria, especially in horses that also have cystic or urethral calculi. There may also be evidence of bacteriuria.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove the source of obstruction.
- Prevent further obstruction.

ACUTE GENERAL TREATMENT

- Surgical removal of obstruction (typically nephrectomy): Nephrectomy should only be pursued if the disease is unilateral. Nephrostomy and ureterostomy have been rarely reported, with poor long-term outcomes. It is imperative that renal function is assessed before surgery because signs of chronic renal failure may not resolve after resolution of the obstruction.
- Medical treatment: Diuresis, antimicrobials, and dietary modification (low-calcium diet) have been used successfully in a few cases.

CHRONIC TREATMENT

- Attempt to prevent formation of additional uroliths that can cause urinary obstruction.
- Urinary acidification (efficacy is questionable in horses): Ammonium sulfate (175 mg/kg PO q12h), ammonium chloride (100 mg/kg PO q1–2h), or ascorbic acid (4 g PO q12h). Ascorbic acid has been reported to be more palatable.
- Increase water intake by adding salt to the diet (50–75 mg/day).
- Dietary modifications may be helpful, with the goal of reducing the intake of protein, calcium, phosphorous, and magnesium. This can be accomplished by feeding grass hay and avoiding legumes.

POSSIBLE COMPLICATIONS

Chronic renal failure is a common sequela to hydronephrosis.

RECOMMENDED MONITORING

Monitor BUN and creatinine concentrations as well as clinical condition.

PROGNOSIS AND OUTCOME

- Horses with signs of chronic renal failure have a poor prognosis.
- Nephrectomy has been associated with a good prognosis if the disease is unilateral and contralateral renal function is normal.
- Recurrence of urolithiasis is common in horses, so there remains a risk for future obstructive events.

PEARLS & CONSIDERATIONS

COMMENTS

The majority of hydronephrosis cases are diagnosed after the horse is already in chronic renal failure.

PREVENTION

Optimize renal health (judicious use of nephrotoxic drugs, maintenance of hydration) to minimize the risk of urolithiasis and obstructive urinary tract disease.

ElibVet.com

Hymen, Persistent

BASIC INFORMATION

DEFINITION

The hymen is a sheet of tissue separating the vagina and the vestibular vault, just cranial to the urethral meatus.

SYNONYM(S)

Imperforate hymen

EPIDEMIOLOGY

SPECIES, AGE, SEX It may be identified in the maiden mare during routine vaginal examination.

GENETICS AND BREED PREDISPOSITION Persistent hymen is one of the most common congenital reproductive anomalies seen in mares.

ASSOCIATED CONDITIONS AND DISORDERS Conditions related to chromosomal or genetic defects such as vaginal hypoplasia and aplasia.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- May manifest as a pink mass protruding from the vulva of a recumbent maiden female
- May manifest as infertility (failure of intrauterine semen deposition)

PHYSICAL EXAM FINDINGS Digital palpation of the persistent hymen (wrist deep in the vestibular vault)

ETIOLOGY AND PATHOPHYSIOLOGY A persistent or imperforate hymen results from the failure of this tissue to naturally break at the time of breeding or artificial insemination. Could also be considered a form of segmental aplasia as a result of an embryonic malunion of the paramesonephric (Müllerian) ducts and the ectodermal urogenital sinus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypoplasia of the tubular reproductive tract at the level of the vestibular vaginal junction
- Vaginal mural adhesions
- Vaginal septum: This is a band of tissue that may be found running from the dorsal to ventral vaginal surfaces. A vaginal septum results from failure of proper fusion of the paramesonephric ducts.

INITIAL DATABASE

Visualization of the persistent hymen by vaginoscopic examination (presence of a blind-ending short vagina with no visible cervix)

ADVANCED OR CONFIRMATORY TESTING

Transrectal ultrasound examination of the reproductive tract may show the cranial portion of the vagina filled with fluid as a result of mucus accumulation.

TREATMENT

THERAPEUTIC GOAL

Perforate the hymen to allow future successful breeding

ACUTE GENERAL TREATMENT

- When identified in maiden mares during routine examination, the hymen can be broken with firm steady pressure and digital dilatation.
- Sometimes the persistent hymen may be so tough that it may need to be ruptured with a guarded scalpel blade or scissors, then enlarged by using the fingers and hand.
- Laser ablation or electrocautery fulguration may be useful when available.

POSSIBLE COMPLICATIONS

It is very important to identify and isolate the location of the urethra as to avoid any damage to it, specifically the dorsal wall, while working to transect the hymen.

PROGNOSIS AND OUTCOME

This condition has no adverse effect on fertility once corrected.

PEARLS & CONSIDERATIONS

Twice daily application of a soft emollient cream (such as udder balm), phenylephrine ointment, topical antibiotics, and/or steroid-impregnated ointments can help prevent mural adhesions.

AUTHOR: **HERNÁN J. MONTILLA**

EDITOR: **JUAN C. SAMPER**

Hyperparathyroidism

BASIC INFORMATION

DEFINITION

A pathologic condition characterized by excessive secretion of parathyroid hormone (PTH) by the parathyroid glands, hypercalcemia, and bone loss. Hyperparathyroidism can be primary or secondary (nutritional).

SYNONYM(S)

Osteodystrophia fibrosa, equine osteoporosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Hyperparathyroidism has been reported in horses of all ages.
- Clinical signs of hyperparathyroidism secondary to nutritional imbalances are more evident in young, growing animals.
- In nutritional hyperparathyroidism, many horses can be affected in one farm, but only one horse is affected in primary hyperparathyroidism.

ElibeVet.com

GEOGRAPHY AND SEASONALITY

- There is no information on seasonality.
- There are no geographical differences for primary hyperparathyroidism.
- Nutritional secondary hyperparathyroidism remains a problem in developing countries, where appropriate nutritional management of horses is lacking.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hyperparathyroidism may be primary or secondary.
  - Primary hyperparathyroidism: An autonomous and excessive secretion of PTH from the parathyroid glands. The parathyroid glands in these horses are not responsive to calcium concentrations (refractory).
  - In secondary hyperparathyroidism, the inciting cause of excessive PTH secretion is not in the parathyroid gland but rather the result of unbalanced nutrition or renal disease.
  - Secondary hyperparathyroidism in horses is primarily nutritional (nutritional secondary hyperparathyroidism).
  - Renal secondary hyperparathyroidism has not been reported in horses.
- Another condition associated with abnormal calcium and phosphorus concentrations is humoral hypercalcemia of malignancy (HHM; pseudohyperparathyroidism).

HISTORY, CHIEF COMPLAINT

- Signs of hyperparathyroidism include weight loss, anorexia, soft tissue mineralization, lameness, angular deformities, pathological fractures, facial enlargement (osteodystrophia fibrosa), and polyuria and polydipsia.

PHYSICAL EXAM FINDINGS

- Horses with nutritional secondary hyperparathyroidism (also termed *big head, Miller's disease*) may have generalized swelling of the skull and narrowing of the nasal meatus, which may lead to upper airway stridor.
- Whereas facial changes or deformations are evident in young animals, lameness and decreased bone mass are the main findings in old horses.

ETIOLOGY AND PATHOPHYSIOLOGY

- Under physiological conditions, PTH is secreted by the chief cells of the parathyroid gland in response to hypocalcemia.
- PTH increases renal reabsorption of calcium, renal excretion of phosphorus, and bone resorption by osteoclasts.
- The cause of primary hyperparathyroidism in horses remains unknown because few cases have been documented.
- In nutritional secondary hyperparathyroidism, the parathyroid glands secrete PTH in response to excessive dietary phosphorus and oxalates or low dietary calcium.
- Dietary phosphate and oxalate bind calcium to decrease its absorption.
- Low calcium leads to hypocalcemia and PTH secretion.
- Excessive phosphorus in the diet also results in hyperphosphatemia, which stimulates PTH secretion. High phosphorus levels may precipitate calcium in the extracellular compartment, contributing to hypocalcemia and soft tissue mineralization.
- In renal hyperparathyroidism, hypovitaminosis D and hyperphosphatemia from renal dysfunction result in excessive PTH secretion. Unlike in small animals, renal secondary hyperparathyroidism has not been reported in horses.
- Of interest, horses with chronic renal disease also develop hypercalcemia, which is the result of decreased glomerular filtration and calcium retention (the equine kidney eliminates large amounts of calcium) because PTH concentrations in these horses are normal.
- In horses with pseudohyperparathyroidism (HHM) the clinical signs are the result of the malignancy rather than hypercalcemia. In HHM, there is excessive secretion of parathyroid hormone–related protein (PTHrP), which interacts with the PTH receptor to increase renal reabsorption of calcium and bone resorption, resulting in hypercalcemia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- HHM
- Chronic renal failure
- Equine systemic granulomatous disease
- Hypervitaminosis D (plants, iatrogenic)
- Malignancies that secrete vitamin D

INITIAL DATABASE

- Measurement of serum PTH, ionized calcium, phosphorus concentrations, and serum and urine chemistry; determination of the fractional excretion of calcium and phosphorus; radiography; and measurement of plasma PTHrP concentrations
- Horses with primary hyperparathyroidism have hypercalcemia, hypophosphatemia, hyperphosphaturia, and increased serum PTH concentrations.
- Horses with secondary hyperparathyroidism have normocalcemia or hypercalcemia, normophosphatemia or hyperphosphatemia, hyperphosphaturia, and increased PTH concentrations.
- Plasma PTHrP concentrations are normal in both conditions.
- Markers of bone resorption have been determined in horses with bone diseases, but their use remains impractical.
- Radiography may be helpful in assessing bone density; mineralization of soft tissues, tendons, and ligaments; and fractures.
- Scintigraphy has been proposed for the diagnosis of primary hyperparathyroidism.

TREATMENT

ACUTE GENERAL TREATMENT

- There is no specific treatment for primary hyperparathyroidism.
- Surgical excision of the affected parathyroid gland may be performed. However, the variable location of the parathyroid glands may require scintigraphy to localize them.
- The use of glucocorticoids to decrease intestinal calcium absorption and to increase renal calcium elimination has been proposed.

CHRONIC TREATMENT

- Restrict access to pastures rich in oxalates and diets high in phosphorus.
- Animals in pastures rich in oxalates may require calcium supplementation (calcium carbonate, dicalcium phosphate).

PROGNOSIS AND OUTCOME

- Depends on clinical signs
- Growing animals with nutritional hyperparathyroidism may improve (6 months), but facial deformation may remain.
- Animals with soft tissue mineralization, particularly of the internal organs, have a poor prognosis.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- The disease is incurable.
- Secondary infections are common.

SUGGESTED READING

Toribio RE: Disorders of calcium and phosphorus. In Reed SM, Bayly WM, Sellon DC, editors: *Equine internal medicine*, ed 3, St Louis, 2010, Saunders Elsevier, pp 1277–1291.

ElibeVet.com

Hyperthermia

BASIC INFORMATION

DEFINITION

An increase in body temperature without an alteration in the body temperature set point

EPIDEMIOLOGY

Caused by an increase in heat production, impaired heat loss, or absorption of heat beyond the ability of the body to compensate

GENETICS AND BREED PREDISPOSITION

- Quarter Horses are genetically prone to malignant hyperthermia (MH).
- Draft horses are predisposed to anhydrosis, which can induce hyperthermia.

GEOGRAPHY AND SEASONALITY Hot, humid weather may predispose to heat stroke as well as anhydrosis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Heat stroke (Figure 1)
- Exercise- or seizure-related hyperthermia
- Anhydrosis
- MH
- Drug or toxin reaction
- Central nervous system (CNS) disorders

HISTORY, CHIEF COMPLAINT

- Depression
- Excessive sweating or unusual lack thereof
- Increased respiratory rate
- Seizures
- Weakness or collapse

PHYSICAL EXAM FINDINGS

- Elevated rectal temperature (>106° F)
- Altered mentation

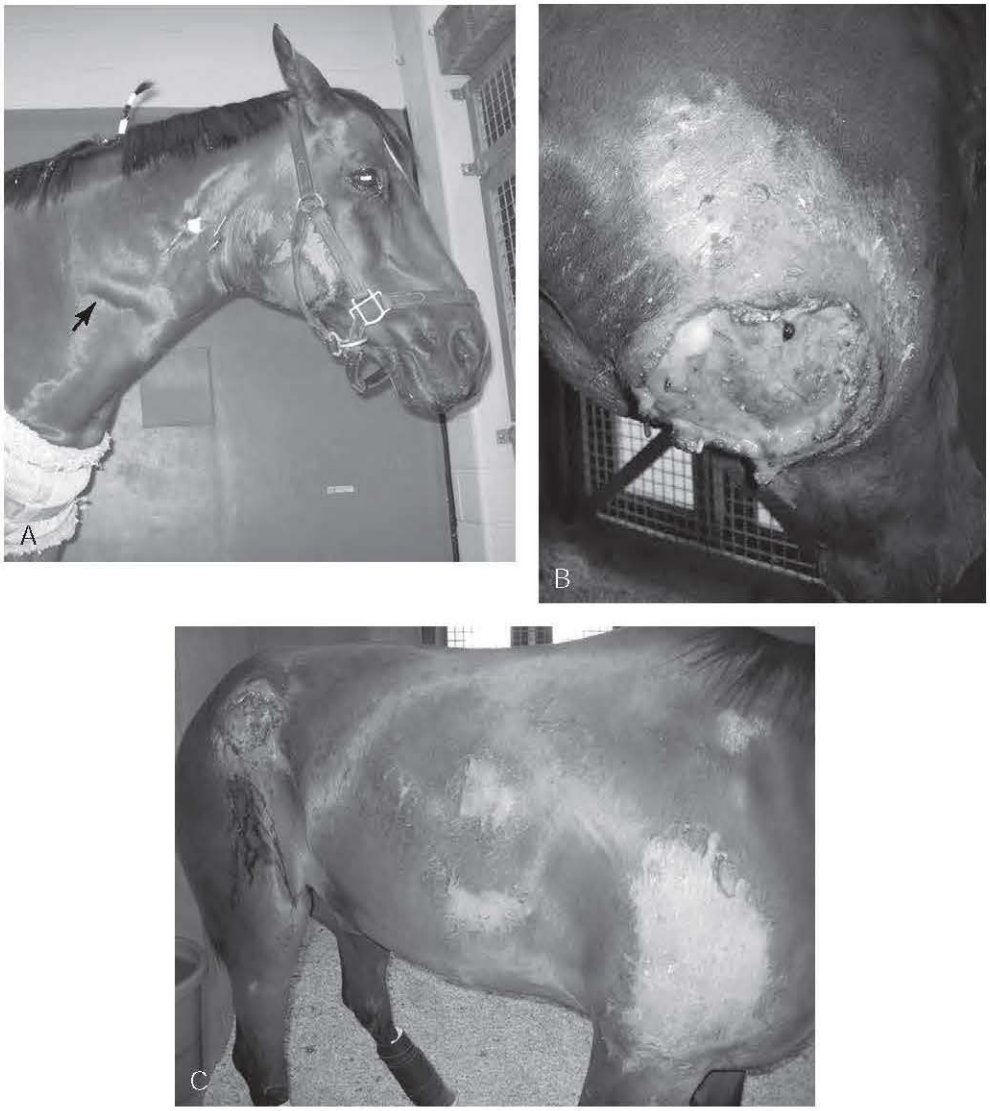

FIGURE 1 The consequences of heat stroke after becoming tangled in a fence in right lateral recumbency. **A** shows the acute edema of the neck (*arrow*) and localized swelling in the throatlatch. **B** (right mandible) and **C** (right flank) were taken 10 days later, where extensive tissue necrosis has occurred. Coagulation abnormalities were noted by increased bleeding times and right jugular thrombosis. Acute laminitis without rotation also developed.

ElibeVet.com

- Hyperemic mucous membranes ± a toxic line
- Tachycardia
- Tachypnea
- Petechiation
- Myopathy
- Synchronous diaphragmatic flutter

ETIOLOGY AND PATHOPHYSIOLOGY

Depends on the initiating cause of hyperthermia:

- Heat stroke occurs when environmental factors elevate the body temperature above 107° F (41.5° C).
  - Sweating and dehydration may increase the risk because of electrolyte imbalances.
  - Vasoconstriction, reduced cardiac output, and decreased blood pressure initiate circulatory shock and may lead to disseminated intravascular coagulation (DIC), multiorgan failure, and death.
- Anhydrosis is caused by the loss of the ability to sweat.
  - Unknown etiology
  - Draft foals may be susceptible
  - Hot, humid climates predispose
- MH is caused in Quarter Horses by a mutation in exon 46 of the skeletal muscle ryanodine receptor gene, which alters calcium metabolism. Muscle hypermetabolism is triggered by halogenated inhalation anesthetics, depolarizing skeletal muscle relaxants, and stress.
- The antibiotic erythromycin increases the risk of hyperthermia, which may be triggered by exposure to direct sunlight. The causative mechanism has not been determined.
- Any condition that affects the hypothalamus (eg, hemorrhage, neoplasia, abscess) may prevent sweating and promote an excessive response to external cooling.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Fever
  - An alteration in the body's hypothalamic set point for thermoregulation
  - Differentials include infectious, inflammatory, immunologic, and neoplastic diseases
  - All causes of fever induce a release of endogenous pyrogens, which stimulate the hypothalamus to increase heat production and conservation.

INITIAL DATABASE

- Physical examination
- Neurological examination
- Packed cell volume (PCV)
- Complete blood count
- Serum chemistry, including electrolytes
- Coagulation panel (activated partial thromboplastin time, prothrombin time, platelet count)
- Lactate
- Urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Ephedrine or terbutaline challenge test for anhydrosis
  - Affected horses do not sweat
    - 0.1 mL SC 1:1000 epinephrine
    - 0.5 mg intradermal terbutaline
- Genetic testing for MH

TREATMENT

THERAPEUTIC GOALS

- Lower the core body temperature to an acceptable range.
- Treat the primary disease process.
- Prevent or treat unwanted sequelae, including coagulation disorders and renal insufficiency.

ACUTE GENERAL TREATMENT

- For hyperthermia caused by heat stroke, overexertion, anhydrosis, medications, toxins, or CNS disorders:
  - Remove the animal from high ambient temperature (if an instigating cause).
  - Cool the animal internally and externally.
    - Initiate internal cooling with room temperature IV fluids. Correct electrolyte abnormalities.
    - External cooling (misting and fans) may augment temperature reduction.
      - Avoid ice and large volumes of cold water externally because vasoconstriction may hinder heat loss. Room temperature water is better.
      - Alcohol may be used sparingly if water is not available or in high humidity. Large volumes of external alcohol and its fumes can be fatal.
      - Stop cooling when temperature reaches 103° F to prevent hypothermia.
  - Administer flunixin meglumine (1.1 mg/kg q12h IV) for antipyretic and antiendotoxin effects.
  - Plasma may be administered for clotting factors and an antiendotoxin effect.
  - Cerebral edema may be treated with hypertonic saline or mannitol. Use only 3% hypertonic (half strength) in endurance horses because of extreme cellular swelling.
  - Seizures may be controlled with IV diazepam (adults, 0.05–0.44 mg/kg; foals, 0.1–0.2 mg/kg) or IV phenobarbital (5–15 mg/kg slowly).
- MH: Treatment is often ineffective, but external cooling, mechanical ventilation, and room temperature fluid resuscitation should be attempted.
- For mild exercise-induced hyperthermia, inactivity or rest typically reduces the temperature to an acceptable range.

CHRONIC TREATMENT

- Treat the primary disease process.
- Provide a more temperate climate or air conditioning for horses with anhydrosis.

POSSIBLE COMPLICATIONS

- Dissemintated intravascular coagulation
- Cerebral edema
- Renal failure with severe dehydration
- Laminitis may result from systemic inflammation

RECOMMENDED MONITORING

- PCV
- Total protein
- Coagulation profile
- Platelet count
- Renal parameters: Blood urea nitrogen and creatinine
- Muscle enzymes: Creatine kinase and aspartate aminotransferase

PROGNOSIS AND OUTCOME

- Depends on the severity of the systemic inflammatory response and the response to therapy
- The prognosis for MH is poor.

PEARLS & CONSIDERATIONS

PREVENTION

- Horses with the genetic potential for MH should not receive halogenated anesthetics.
- Prophylaxis: Dantrolene (a skeletal muscle relaxant; 4 mg/kg 30–60 minutes before anesthesia PO)
- Endurance horses and other high-level athletes should be closely monitored for signs of heat exhaustion and dehydration.

CLIENT EDUCATION

- Clients should be educated as to the genetic potential and clinical signs for progressive anhydrosis.
- The risks of MH caused by local and general anesthesia should always be presented to the client before the procedure.

Hyperthyroidism

BASIC INFORMATION

- The equine thyroid glands are two firm lobes located in the dorsolateral aspect of the third to sixth tracheal rings.
- In most healthy horses, the thyroid glands are not visible but are palpable.
- The follicular cells of the thyroid gland secrete two thyroid hormones (THs), thyroxine (T4) and triiodothyronine (T3).
- The synthesis and secretion of THs is regulated by a negative feedback system that includes the hypothalamus, pituitary gland, and thyroid gland (hypothalamus-pituitary-thyroid axis)
- Hypothalamic neurons release thyrotropin-releasing hormone (TRH), which stimulates thyrotropes in the pituitary gland to secrete thyroid-stimulating hormone (TSH, thyrotropin), which in turn increases the synthesis and secretion of THs by the follicular cells of the thyroid gland.
- Most of the THs released into circulation is T4, which is converted to active T3 by deiodinases.
- Circulating THs are T4, T3, and reverse T3 (rT3).
- Free T3 is the most active hormone.
- THs circulate free and bound to proteins.
- THs are important in cell growth, differentiation, and energy metabolism.
- An increase in THs leads to a hypermetabolic state; a decrease results in the opposite.

DEFINITION

Hyperthyroidism is defined as a hypermetabolic state, the result of high concentrations of free THs (T3, T4).

EPIDEMIOLOGY

SPECIES, AGE, SEX Most cases occur in performance horses and in horses older than 20 years.

GEOGRAPHY AND SEASONALITY No evidence that hyperthyroidism is associated with geography or season.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Horses with hyperthyroidism have a history of hyperexcitability, weight loss, polyphagia, and polydipsia.
- Thyroid gland enlargement may be present, although this rarely occurs.
- Anhidrosis and hyperhidrosis have been reported.
- Hyperthyroidism has not been documented in foals.
- In adult horses, there is a history of weight loss.
- There may be unilateral thyroid enlargement.
- Hyperexcitability, tachycardia, tachypnea, tremors, sweating, alopecia, polydipsia, anhidrosis, hyperhidrosis, enophthalmos, and weight loss have been described in horses suspected of hyperthyroidism.

ETIOLOGY AND PATHOPHYSIOLOGY

- There are few documented cases of equine hyperthyroidism.
- The disease can be spontaneous, associated with malignancies (thyroid adenocarcinoma), or iatrogenic from iodide-containing compounds (Jod-Basedow phenomenon) or administration of THs (thyrotoxicosis).
- Autoimmune hyperthyroidism has not been documented in horses.
- Clinical signs result from high TH concentrations.
- Most thyroid adenomas are nonfunctional tumors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Thyroid adenocarcinomas
- Unilateral nonfunctional adenomas are common and associated with aging.
- Parafollicular cell (C cell) adenomas, which in general are nonfunctional tumors
- Masses in the laryngeal area

INITIAL DATABASE

- Clinical history and clinical signs
- Biopsy
- Serum TH concentrations are elevated
- Important: Normal TH values depend on each laboratory
- TSH stimulation test
- T3 suppression test: T4 concentrations do not decrease after the administration T3 in hyperthyroid horses.
- TH concentrations in newborn foals are up to 10 times the values of adult horses, which may lead to misdiagnosis.

TREATMENT

ACUTE GENERAL TREATMENT

- Remove access to iodide-containing compounds.
- Thyroidectomy of affected gland
- Potassium iodide (1 g/d PO)
- Glucocorticoids in horses with severe clinical signs
- There is limited information on the use of the antithyroid drugs such as propylthiouracil and methimazole in horses with hyperthyroidism.
- Propylthiouracil (1–4 mg/kg/d PO) has been used in horses to decrease thyroid function.

PROGNOSIS AND OUTCOME

- Good
- Signs improve with surgical or medical treatment.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- The use of compounds containing iodide may lead to hyperthyroidism.

SUGGESTED READING

AUTHOR & EDITOR: **RAMIRO E. TORIBIO**

 ElibeVet.com

Hypogammaglobulinemia, Transient

BASIC INFORMATION

DEFINITION

A syndrome characterized by the delayed onset of immunoglobulin synthesis in newborn foals

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Has been described in Thoroughbred and Arabian foals but has not been proven to be genetic in origin

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Affected foals appear normal at birth but develop infections as maternal immunoglobulin levels decline.
- Recurrent opportunistic infections, especially diarrhea, arthritis, or respiratory disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- At birth, foals are protected by maternal antibodies acquired through colostrum. These antibodies provide effective protection for 1 to 3 months, although their levels decline gradually.
- As maternal antibodies decline, the foal begins to make its own immunoglobulins. Under normal circumstances, the decline of maternal antibodies occurs at the same time as autologous antibody production begins, so there is no gap in protection.
- In transient hypogammaglobulinemia, there is a delay in autologous immunoglobulin synthesis, leaving the foal temporarily unprotected and susceptible to opportunistic bacterial infections.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infections secondary to other primary immunodeficiencies such as severe combined immunodeficiency and agammaglobulinemia
- Failure of passive transfer

INITIAL DATABASE

- Complete blood count
- Serum chemistry profile
- Bacterial culture and sensitivity
- Serum immunoglobulin levels: At 2 to 4 months of age, all immunoglobulin classes and subclasses will be substantially below age-matched levels.

ADVANCED OR CONFIRMATORY TESTING

- Repeated serum immunoglobulin quantitation is required to document this condition and monitor the onset of immunoglobulin synthesis.
- Affected foals have normal blood lymphocytes, and T-cell function assays are normal.
- Lymphoid tissue structure is normal.

TREATMENT

THERAPEUTIC GOAL(S)

- Minimize opportunistic infections until the foal's immune system develops.
- Provide prompt immunologic treatment designed to remedy any immunologic deficit.
- Foals presenting with severe infections must be promptly addressed.

ACUTE GENERAL TREATMENT

- A total of 50 to 70 g of lyophilized equine immunoglobulin G (IgG) may be administered to increase serum IgG levels to greater than 400 mg/dL.
- If plasma transfusions are not given, then owners should be advised of the risks of infection and the foals maintained in an environment where exposure to potential pathogens is minimal.
- Frozen horse plasma is available commercially, although it may not contain antibodies against local pathogens.
- Plasma may be obtained from local donors. Blood should be collected aseptically with heparin or sodium citrate. The plasma is collected after the erythrocytes settle and is stored frozen until used. The plasma must be prechecked for antierythrocyte antibody and must be free of bacterial contamination. The transfusion should be given slowly while the foal is monitored for untoward reactions.
- All foals receiving plasma should have their IgG levels rechecked 12 to 24 hours later.
- Antibiotic treatment: A combination of a penicillin and an aminoglycoside is a good starting therapy. A suitable aminoglycoside, such as gentamicin (6.6–8.8 mg/kg IV or IM q24h) or amikacin (22–25 mg/kg IV or IM q24h), may be given.
- Other third-generation cephalosporins, such as cefotaxime (20–40 mg/kg IV or IM q6–8h), may also be used.
- Circulatory support: It is essential to maintain or restore effective circulating volume through aggressive IV fluid therapy. Administer fluids at the highest tolerated rate.
- Septicemic foals are hypoglycemic so dextrose should be provided.

CHRONIC TREATMENT

- Move the foal to as clean an environment as possible.
- Immunoglobulin preparations should be administered as required to maintain adequate blood levels.

RECOMMENDED MONITORING

Immunoglobulin levels must be monitored on a regular basis until they reach normal ranges.

PROGNOSIS AND OUTCOME

Prognosis is good provided bacterial and viral infections are well controlled.

PEARLS & CONSIDERATIONS

COMMENTS

The true prevalence of this disease is unclear. It may well be much more common than reported, and its severity and duration are highly variable.

PREVENTION

Because this disease is likely heritable, it is appropriate to discourage future breeding of the parent animals.

CLIENT EDUCATION

Provide advice on future breeding policies.

Hypoparathyroidism

BASIC INFORMATION

DEFINITION

Pathologic condition of the parathyroid glands characterized by low secretion of parathyroid hormone (PTH), hypocalcemia, and hyperphosphatemia. Hypoparathyroidism can be primary or secondary.

SYNONYM(S)

Parathyroid gland dysfunction

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hypoparathyroidism can be primary or secondary.
- Primary hypoparathyroidism: Few cases have been documented in horses. These horses have clinical signs consistent with hypocalcemia, including muscle tremors and fasciculations, synchronous diaphragmatic flutter (thumps), cardiac arrhythmias, hyperexcitability, seizures, ileus, and (in severe cases) death.
- In secondary hypoparathyroidism, parathyroid gland dysfunction is the consequence of a primary problem elsewhere, typically sepsis or hypomagnesemia.
- In sepsis, hypoparathyroidism may also be associated with high concentrations of inflammatory systemic mediators (interleukin-1 [IL-1]) that decrease parathyroid gland function in horses.
- In hypomagnesemia, hypoparathyroidism may be subclinical, and horses will not show improvement until magnesium is supplemented.

ETIOLOGY AND PATHOPHYSIOLOGY

- PTH is secreted by the chief cells of the parathyroid gland in response to hypocalcemia. PTH increases renal reabsorption of calcium and excretion of phosphorus. Thus, an appropriate response to hypocalcemia would be an increase in PTH concentrations.
- Horses with hypoparathyroidism have hypocalcemia and hyperphosphatemia and low or normal PTH concentrations. This is indicative of parathyroid gland dysfunction.
- The cause of primary hypoparathyroidism in horses remains unknown.
- Hypoparathyroidism secondary to sepsis occurs in horses.
- Inflammatory mediators such as IL-1 have been shown to decrease PTH secretion in horses.
- Hypomagnesemia is a frequent finding in critically ill horses.
- Magnesium is required for PTH secretion and PTH action.
- In hypomagnesemia, PTH concentrations are low until the magnesium status is restored.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute renal failure
- Hypoproteinemia (pseudohypocalcemia)

INITIAL DATABASE

- Sepsis
- Clinical findings
- Measurement of serum PTH, ionized calcium, ionized magnesium, and phosphorus concentrations, serum and urine chemistry, and determination of the fractional excretion of calcium and phosphorus
- Horses with hypoparathyroidism have hypocalcemia, hyperphosphatemia, hypophosphaturia, and low serum PTH concentrations.
- Horses with hypocalcemia from acute renal failure may have hyperphosphatemia and elevated PTH concentrations.

TREATMENT

ACUTE GENERAL TREATMENT

- There is no specific treatment for primary hypoparathyroidism.
- Parenteral administration of calcium gluconate is the treatment of choice.
- Calcium gluconate 23% solution in crystalloid fluids (lactated Ringer's solution, 0.9% sodium chloride) can be administered safely to horses.
- Typical calcium gluconate rates are 50 to 100 mL/5 L of crystalloids. Horses with normal renal function can tolerate calcium gluconate rates of 200 mL/hr with no problem. This rate is rarely required.
- Determining serum ionized calcium concentrations helps to calculate the dose.
- Vitamin D supplementation should be considered, keeping in mind that this treatment may result in soft tissue mineralization.

CHRONIC TREATMENT

- Horses with recurrent hypocalcemia can be supplemented orally with calcium carbonate (100–200 g/d PO) or dicalcium phosphate.
- A number of horses may require frequent IV administration of calcium. These animals have a poor prognosis.

PROGNOSIS AND OUTCOME

- The prognosis depends on the clinical signs.
- In general, prognosis is poor because some horses may show improvement with medical treatment, but signs reoccur soon after discontinuation of calcium supplementation.
- Long-term supplementation with calcium carbonate or dicalcium phosphate may be necessary.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

A number of horses may require frequent IV administration of calcium. These animals have a poor prognosis.

ElibeVet.com

Hypothyroidism

BASIC INFORMATION

- Thyroid hormones (THs) are important in cell growth, differentiation, and energy metabolism.
- Development of the skeletal, nervous, and respiratory systems are highly dependent on THs.
- Low concentrations of THs do not mean hypothyroidism.
- Nonthyroidal diseases decrease THs but do not mean the horse has hypothyroidism; the horse may actually have nonthyroidal illness syndrome (euthyroid sick syndrome).
- Functional tests are required to assess thyroid gland function.

DEFINITION

- Hypothyroidism is defined as a deficiency of THs or a disruption of the hypothalamus-pituitary-thyroid axis.
- Hypothyroidism can be primary when there is thyroid gland disease or secondary to hypothalamic or pituitary dysfunction.

SYNONYM(S)

Thyroprivia

EPIDEMIOLOGY

SPECIES, AGE, SEX Most cases occur in newborn foals; rarely occurs in adult horses

GEOGRAPHY AND SEASONALITY

- Prevalence can be higher in iodide deficient areas and in regions with high concentrations of nitrates in the water or pasture.
- Congenital hypothyroidism is endemic in areas of western Canada and the United States.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Foals: Prematurity, weakness, incoordination, hypothermia, poor suckle reflex, musculoskeletal abnormalities (physeal dysgenesis, defective ossification of carpal and tarsal bones, extensor tendon rupture, flexural deformities), prognathism, goiter, respiratory distress, failure to thrive, and death. Thyroid enlargement may be present at birth (congenital goiter).
- Adults: Hair coat abnormalities, poor performance, infertility, lethargy, obesity, laminitis

ETIOLOGY AND PATHOPHYSIOLOGY

- In general, the cause of the problem is not identified
- Foals:
  - In fetuses and newborn foals, THs are required for the development and differentiation of various body systems, including the nervous, musculoskeletal, and pulmonary systems.
  - Neuronal differentiation and myelin synthesis are highly dependent on THs.
  - Chondrocyte and osteoblast proliferation and differentiation depend on THs.
  - Pulmonary maturation, including surfactant production, requires THs.
  - Deficient or excessive iodide intake by the mare may lead to hypothyroidism in a newborn foal.
  - Endophyte (*Neotyphodium coenophialum*)–infected fescue plants may decrease thyroid gland function in pregnant mares and their foals.
  - Hypothyroidism is associated with abnormal development of the growth plates and the carpal and tarsal bones, angular and flexural deformities, weakness, maladjustment, and respiratory failure.
  - Recovery in these foals is unlikely because many critical developmental stages are passed at birth.
- Adults:
  - Inadequate or excessive ingestion of iodide in the diet or topical treatments with iodide-containing compounds may lead to hypothyroidism (Wolff-Chaikoff effect).
  - TH deficiency in adults is associated with a hypometabolic state that results in obesity, lethargy, poor appetite, poor performance, hypothermia, anhidrosis, anemia, laminitis, hair loss, and infertility.

DIAGNOSIS

- Measurement of baseline THs have limited value.
- Thyroid stimulation tests are more appropriate for the diagnosis of hypothyroidism
- Foals: Elevated serum concentrations of THs are normal in foals (serum triiodothyronine [T3] concentrations in newborn foals are ≤10% of adult values), which can lead to misdiagnosis.
- Adults
  - Measurement of T3 and thyroxine (T4) concentrations
  - Response to thyroid-stimulating hormone (TSH) or thyrotropin-releasing hormone (TRH) stimulation tests
- Animals with normal thyroid function should have a twofold increase in T3 at 2 hours and T4 at 4 hours after TSH or TRH administration.
- Factors affecting the diagnosis
  - Low TH concentrations have limited clinical value in horses because they can be decreased with various pathological conditions, but it does not imply hypothyroidism. This is known as the nonthyroidal illness syndrome (euthyroid sick syndrome).
  - Nutrition: Feed deprivation and anorexia decrease TH concentrations; high-carbohydrate and high-protein diets increase THs.
  - Stress decreases THs.
  - Exercise and cold weather increase THs.
  - Age: THs are several-fold higher in foals.
  - Drugs:
    - Dexamethasone: One dose can decrease THs for 5 days
    - Phenylbutazone: One dose can decrease THs for up to 10 days. This does not mean the horse has hypothyroidism.
  - These drugs are often used in equine practice; not knowing their effect on thyroid function can lead to misdiagnosis.

DIFFERENTIAL DIAGNOSIS

- Adults: Equine metabolic syndrome, Cushing's disease, obesity, laminitis, infertility
- Foals: Sudden death, prematurity or dysmaturity, developmental orthopedic diseases

TREATMENT

ACUTE GENERAL TREATMENT

- Adults
  - Iodinated casein: 5 g PO q24h
  - Levothyroxine sodium: 1 to 6 mg/100 kg PO q24h
  - T3: 1 mg/kg PO q24h
  - Thyroid extract: 2 mg/kg PO q24h
- Foals
  - Mares should have adequate access to iodide.
  - In endemic areas, mares should receive supplemental iodide.
  - The value of supplementing hypothyroid foals with THs is limited.

ElibeVet.com

PROGNOSIS AND OUTCOME

- Guarded in adults
- Poor in foals because many of the problems present are irreversible

PEARLS & CONSIDERATIONS

- In endemic areas, mares should receive supplemental iodide.
- Avoid excess or inadequate iodide in pregnant mares.
- Avoid nonthyroidal factors and consider supplementation.
- Remove access to goitrogenic plants such as *Brassica* spp. (turnips, cabbage, broccoli, cauliflower, kale, kohlrabi, black mustard), *Raphanus sativus* (radish), and *Thiaspi arvense* (stinkweed).

AUTHOR & EDITOR: **RAMIRO TORIBIO**

Hypotrichosis

BASIC INFORMATION

DEFINITION

Less than the normal amount or density of hair

SYNONYM(S)

Hair follicle dystrophy

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Arabians and Appaloosas are reportedly predisposed (the long hairs of the mane and tail are affected)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Thinning of the hair, mane, or tail

PHYSICAL EXAM FINDINGS Thinning or lack of hair, especially around eyes and muzzle, resulting in a scaly appearance of the skin; mane and tail density are decreased

ETIOLOGY AND PATHOPHYSIOLOGY Inherited

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Selenium poisoning
- Copper and iodine deficiency
- Chronic or recurring mild trauma (rubbing from equipment)

ADVANCED OR CONFIRMATORY TESTING

Histopathologic examination of skin biopsy shows a decrease in the number of hair follicles.

TREATMENT

No treatment is currently available.

AUTHOR: **JENNIFER TAINTOR**

EDITOR: **DAVID A. WILSON**

Hypoxemia

BASIC INFORMATION

DEFINITION

A reduction in the oxygen tension in arterial blood that may lead to a reduction in oxygen at the tissue level, referred to as hypoxia

SYNONYM(S)

- Low PaO_2 level
- Low dissolved oxygen level

EPIDEMIOLOGY

SPECIES, AGE, SEX Hypoxemia may affect any age or breed and both sexes and is related to any condition that prevents adequate levels of arterial oxygen.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Variable depending on the cause of hypoxemia

PHYSICAL EXAM FINDINGS

Variable depending on the cause of hypoxemia:

- Respiratory system: tachypnea, hypopnea, apnea, stridor, stertor, auscultation abnormalities
- Neurologic system: May note depression, ataxia, signs of central nervous system (CNS) involvement
- Musculoskeletal system: Muscle weakness, tremors, hyperreflexia, hyporeflexia
- Cardiovascular system: Tachycardia, murmur, poor peripheral pulses, increased capillary refill time

ETIOLOGY AND PATHOPHYSIOLOGY

Hypoxemia is the result of diseases or conditions that:

- Reduce the ability of oxygen to diffuse across the alveoli
- Reduce perfusion of ventilated alveoli
- Reduce the ventilation of perfused alveoli
- Reduce the oxygen tension of inspired air
- Reduce the volume of inspired air

ElibeVet.com

FIGURE 1 Hoisting a recumbent horse in a sling may help to improve oxygenation due to ventilation/perfusion mismatching caused by recumbency.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypoxia
  - Iatrogenic (reduced inspired oxygen content): Anesthetic circuit malfunction
  - Environmental: High altitude
- Hypoventilation (ventilation/perfusion [V/Q] ratio <1)
  - Neurogenic: Anesthesia, head trauma, CNS neoplasia, edema or infection
  - Musculoskeletal: Botulism, tetanus, paralytic medications
  - Pulmonary: Pneumothorax, pleural effusion, flail chest
  - Mechanical; Upper airway obstruction, laryngeal hemiplegia
  - Iatrogenic: Anesthetic circuit malfunction, anesthetic overdose
- Reduced diffusion
  - Pulmonary disease: Pneumonia, pulmonary edema or fibrosis, recurrent airway obstruction, acute respiratory distress syndrome, or acute lung injury
- V/Q mismatch (V/Q ratio >1) (Figure 1)
  - Positional: Prolonged recumbency
- Vascular shunt
  - Pulmonary: Atelectasis, pneumonia, pulmonary edema
  - Cardiovascular: Tetralogy of Fallot, patent foramen ovale, patent ductus arteriosus

INITIAL DATABASE

- Arterial blood gas (ABG) analysis to identify reduced PaO_2 level

ADVANCED OR CONFIRMATORY TESTING

- Dependant on physical examination findings and suspected cause of hypoxemia:
  - Complete blood count
  - Serum chemistry
  - Thoracic ultrasonography and radiography
  - Neurologic examination, skull radiography, computed tomography, cerebrospinal fluid analysis
  - Echocardiography
  - Assessment of anesthetic circuit

TREATMENT

THERAPEUTIC GOALS

- Restore PaO_2 to normal levels
  - Pressure greater than 80 mm Hg in adults; may be lower in normal neonates because of a physiologic shunt fraction
  - PaO_2 increases from 53.9 to 84.3 mm Hg in the first 4 days of life.

ACUTE GENERAL TREATMENT

- Oxygen therapy: For hypoxia, hypoventilation, reduced diffusion, and V/Q mismatch
- May require additional ventilatory stimulation or mechanical ventilation
- Oxygen is not effective for shunting.
- Treat the primary cause.

CHRONIC TREATMENT

Depends on the initiating cause of hypoxemia

POSSIBLE COMPLICATIONS

PaO_2 does not determine the oxygen content of the blood, only dissolved oxygen; therefore, hemoglobin concentration and cardiac output must be accounted for to determine true tissue oxygen delivery.

RECOMMENDED MONITORING

- Serial ABG analysis
- Lactate
- Central venous oxygen levels

PROGNOSIS AND OUTCOME

Depends on the initiating cause of hypoxemia

PEARLS & CONSIDERATIONS

COMMENTS

Prolonged hypercapnia may blunt the horse's ability to respond to increase CO_2. These horses rely on hypoxia for respiratory drive. Oxygen administration may adversely affect ventilation by reducing this stimulus and cause further hypoventilation.

PREVENTION

Horses with predisposing factors or diseases should be monitored by serial ABG analysis.

EDITORS: **R. REID HANSON** and **AMELIA MUNSTERMAN**

ElibeVet.com

Ileus

BASIC INFORMATION

DEFINITION

Functional obstruction of abnormal gastrointestinal (GI) transit

SYNONYM(S)

Postoperative ileus, paralytic ileus

EPIDEMIOLOGY

RISK FACTORS

- Intestinal surgery: Postoperative ileus occurs predominantly after surgical correction of lesions involving the small intestine. Postoperative ileus may also be seen after correction of ascending colon lesions, primarily large colon volvulus. Traumatic handling of the intestine, intestinal distension, resection and anastomosis, and intestinal ischemia may contribute to ileus in these cases.
- Other conditions that have been associated with ileus include:
  - Anterior enteritis
  - Peritonitis
  - Electrolyte imbalances
  - Endotoxemia
  - General anesthesia
- Risk factors for postoperative ileus identified in one equine retrospective study were age older than 10 years, Arabian breed, packed cell volume (PCV) above 45%, high serum concentrations of protein and albumin, anesthesia longer than 2.5 hours, surgery longer than 2 hours, resection and anastomosis, and lesions in the small intestine. Performing a pelvic flexure enterotomy decreased the risk of postoperative ileus in this study.
- In another report PCV above 48%, high heart rate, elevated serum glucose, small intestinal lesions, and ischemic small intestine were identified as risk factors. The incidence of postoperative ileus in horses undergoing surgical treatment of colic has been reported to be between 21% and 18.4%.

ASSOCIATED CONDITIONS AND DISORDERS

- Intestinal diseases and surgery

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The major signs associated with ileus are depression and anorexia.
- As the intestine distends, the horse demonstrates increasing signs of abdominal pain, such as pawing, flank watching, lying down, and rolling.

PHYSICAL EXAM FINDINGS

- Borborygmi are usually decreased or absent.
- The heart rate is elevated as a result of pain associated with the intestinal distension and hypovolemia.
- The mucous membranes become discolored, and capillary refill time is prolonged.
- Fecal production stops.

ETIOLOGY AND PATHOPHYSIOLOGY

- The muscle layers in the intestinal tract responsible for gross motility are contained in the muscularis externa layer, which is divided into an inner circular muscle and an outer longitudinal muscle and separated by the myenteric plexus. Coordination of activity of both of these muscle layers is necessary for normal progressive motility. Coordination of smooth muscle cell activity occurs at four levels:
  - GI smooth muscle cells demonstrate continual oscillations in membrane potential that initiate contractile activity.
  - Interstitial cells of Cajal are highly branched cells located in the myenteric and submucosal plexuses of the enteric nervous system (ENS) and are involved in the coordination of muscle activity.
  - The third level of control is the ENS. The ENS has been described as the third division of the autonomic nervous system (ANS) with the parasympathetic and sympathetic systems comprising the other two divisions. The cell bodies of neurons in the ENS are located within walls of the GI tract either in the myenteric or submucosal ganglia.
  - The next level of control is through extrinsic neural input from the sympathetic and parasympathetic divisions of the ANS.
- The precise cause of ileus is unknown, although evidence suggests that inflammation may play a central role.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other types of colic
- Mechanical intestinal obstruction (including impaction at the anastomosis after small intestinal resection)
- Peritonitis
- Equine grass sickness

INITIAL DATABASE

- Hemoconcentration is reflected by increases in the PCV and total protein.
- Decreases in plasma chloride and potassium are the most common electrolyte abnormalities seen, although sodium and chloride may also be low.
- As the severity of the intestinal distension increases, abdominal distension may become grossly visible.
- Rectal examination and ultrasonography aid in determining if the small or large intestine is involved.
- In foals, both abdominal radiography and ultrasonography can be helpful in assessing distension.
- Nasogastric decompression often retrieves 3 to 10 L of fluid.
- After nasogastric decompression, the horse usually shows some clinical improvement, such as decreased pain and decreased heart rate.
- Uses of intestinal obstruction

ADVANCED OR CONFIRMATORY TESTING

Confirmation of the presence of ileus and differentiation from other mechanical causes of intestinal distension can only be achieved by exploratory celiotomy.

TREATMENT

THERAPEUTIC GOAL(S)

- Maintain circulating blood volume and normal electrolyte balance.
- Stimulate return of normal intestinal motility.
- Relieve gastric distension to reduce the risk of gastric rupture.

ACUTE GENERAL TREATMENT

- Supportive therapy: Fluid, acid-base, and electrolyte therapy
- Antibiotics are indicated if there is compromised intestine or the possibility of bacterial contamination of the abdomen.
- Nasogastric intubation and decompression remains the primary method of treating postoperative ileus in horses. This may be achieved by repeated nasogastric intubation every 3 to 4 hours (or more frequently if indicated) or leaving an indwelling nasogastric tube in place.
- Management of pain and inflammation are also important. Phenylbutazone and flunixin meglumine have been shown to significantly attenuate the disruption of gastric, small intestine, and large colon motility associated with endotoxemia.
- Food and water should not be offered until intestinal motility has returned.

ElibeVet.com

CHRONIC TREATMENT

- Pharmacologic modulation of intestinal motility is directed at either increasing excitatory cholinergic activity with the administration of the parasympathomimetic agents such as bethanechol or neostigmine or blocking inhibitory sympathetic hyperactivity with α-adrenergic blockers such as yohimbine and acepromazine.
  - Bethanechol: Bethanechol chloride is a muscarinic cholinergic agonist that stimulates acetylcholine receptors (M2 receptors) on GI smooth muscle, causing them to contract. It has been used in the treatment of certain GI motility dysfunctions such as postoperative ileus, gastric impactions, and cecal impactions. The recommended dosage is 0.025 mg/kg IV or SC q4–6h. The most common side effect of the drug is salivation, with abdominal cramping and diarrhea occurring less frequently.
  - Neostigmine: Neostigmine methylsulfate is a cholinesterase inhibitor that prolongs the activity of acetylcholine at the synaptic junction. In studies on normal horses, the effects of neostigmine (0.022 mg/kg IV) vary depending on the location of the GI tract examined. These results suggest that the drug would not be appropriate for gastric and small intestinal problems but may be beneficial for large intestine motility dysfunction. The dosage used clinically is 0.0044 mg/kg (2 mg per adult horse) SC or IM repeated in 20 to 60 minutes. If there is no response and the horse is not exhibiting any side effects, the dose can be increased by 2-mg increments to a total of 10 mg per treatment. The most common side effect is abdominal pain.
  - Acepromazine and yohimbine: Both of these drugs are α-adrenergic antagonists. Acepromazine administered at 0.01 mg/kg IM q4h is thought to reduce the severity of postoperative ileus in horses with small intestinal lesions. However, it may produce hypotension, so the horse should be well hydrated before the drug is administered. Yohimbine hydrochloride should not produce the hypotensive response seen with acepromazine.
  - Metoclopramide: Metoclopramide is a substituted benzamide whose primary prokinetic activity is through dopamine receptor antagonism with additional prokinetic activity through augmentation of acetylcholine release from intrinsic cholinergic nerves. In horses, the drug is commonly administered at a dose of 0.25 mg/kg diluted in 500 mL of saline infused over 30 to 60 minutes. Metoclopramide may cause extrapyramidal side effects such as excitement, restlessness, and sweating, as well as abdominal cramping.
  - Cisapride: Cisapride is a substituted benzamide that functions as an indirect cholinergic stimulant by selectively enhancing the release of acetylcholine from postganglionic neurons in the myenteric plexus. There have been conflicting reports on its efficacy for correcting motility dysfunction caused by endotoxins. Unfortunately, cisapride is now difficult to obtain because of its cardiotoxic effects.
  - Erythromycin: Erythromycin is a macrolide antibiotic that influences motility by acting on motilin receptors on GI smooth muscles. The recommended dosage is 2.2 mg/kg diluted in 1 L of saline and infused over 60 minutes q6h. A recent study suggested that a lower dose of 1.0 mg/kg is effective in stimulating both cecal and small intestinal propulsive activity. Alternatively, it may be administered as a continuous rate infusion of 0.1 mg/kg/h. There is evidence that erythromycin can downregulate motilin receptors, which may explain why the prokinetic effect can diminish with repeated treatments. There have been a few reports of severe colitis associated with its use, making some clinicians reluctant to use it.
  - Lidocaine: Lidocaine hydrochloride may act by (1) reducing the concentration of circulating catecholamines by suppressing the sympathoadrenal response, (2) suppressing the activity of the primary afferent neurons involved in reflex inhibition of gut motility, (3) stimulating smooth muscle directly, and (4) decreasing the inflammation in the bowel wall. The recommended protocol includes an initial loading bolus of 1.3 mg/kg IV administered slowly over 5 minutes followed by 0.05 mg/kg/min in saline or lactated Ringer's solution q24h. Side effects include muscle fasciculations, trembling, and ataxia.
  - Repeat celiotomy is advocated by some surgeons after 48 to 72 hours if intestinal motility has not returned. This allows decompression of the distended small intestine as well as checking the intestine for mechanical obstruction (eg, impaction at an anastomosis) or secondary ischemia.

POSSIBLE COMPLICATIONS

- Gastric rupture
- Endotoxemia
- Hypovolemia and dehydration

RECOMMENDED MONITORING

- During treatment, horses should be monitored for signs of dehydration, acid-base derangements, and electrolyte abnormalities.
- Heart rate, mucous membrane color, and signs of pain are monitored.
- Intestinal motility can be assessed by abdominal auscultation and abdominal ultrasonography.
- The volume of gastric reflux should be recorded.

PROGNOSIS AND OUTCOME

The prognosis is guarded. The chance of a good prognosis declines with the length of time that the ileus persists

PEARLS & CONSIDERATIONS

Postoperative ileus is a major postoperative complication after emergency celiotomy for the treatment of small intestinal obstruction.

AUTHOR: **TIM MAIR**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

ElibEVet.com

Immunodeficiency, Agammaglobulinemia

BASIC INFORMATION

DEFINITION

A rare primary immunodeficiency disease characterized by a lack of B cells and thus a failure to make any immunoglobulins

EPIDEMIOLOGY

- Observed only in males, so it may be an X-linked disorder
- Described in Thoroughbreds, Quarter horses, and Standardbreds

CLINICAL PRESENTATION

- Recurrent opportunistic bacterial infections, especially arthritis or respiratory disease
- Bacterial dermatitis and enteritis also reported
- Affected foals appear normal at birth but fail to thrive.
- Infections develop at 2 to 32 weeks of age as maternal immunity wanes.
- The foals become extremely anemic.
- Death occurs 4 to 8 weeks after maternal immunity wanes.

ETIOLOGY AND PATHOPHYSIOLOGY

- Foals remain healthy as long as they have protective levels of maternal antibodies.
- Infections develop as maternal antibodies wane and are not replaced by autologous antibodies.
- Although total lymphocyte numbers remain within the normal range, B cells are absent.
- The molecular basis of this disease is unknown but appears to be the result of a stem cell defect that results in a failure to produce any functional B cells.
- There may be a persistent low level of immunoglobulin production suggesting that a few B cells may develop.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Severe combined immunodeficiency
- Other primary immunodeficiencies
- Transient hypogammaglobulinemia
- Failure of passive transfer
- Upper respiratory tract infections
- Chronic diarrhea
- Sepsis
- Bacteremia

INITIAL DATABASE

- Complete blood count
- Serum chemistry profile
- Bacterial culture and sensitivity

ADVANCED OR CONFIRMATORY TESTING

- Serum protein electrophoresis to evaluate immunoglobulin concentrations
- Repeated serum immunoglobulin quantitation to provide assurance that the animal is persistently agammaglobulinemic and that the hypogammaglobulinemia is not transient
- T-cell numbers are normal, but B cells are undetectable.

TREATMENT

THERAPEUTIC GOAL(S)

- Supportive care to control opportunistic infections is entirely appropriate until it is determined whether the agammaglobulinemia is persistent.
- Euthanasia is commonly the most humane option if persistent agammaglobulinemia is diagnosed

ACUTE GENERAL TREATMENT

- Immunologic support to minimize recurrence risks
- Immediate control and elimination of infection
- Circulatory support to correct any deficits in intravascular volume and to maintain organ perfusion
- If the foal is determined to lack immunoglobulins before the development of infections, then prompt immunologic treatment should be instituted designed to remedy any immunologic deficit. If, however, the foal presents with severe infections, then they must be promptly controlled.
- A total of 50 to 70 g of lyophilized equine immunoglobulin G (IgG) may be administered to increase serum IgG levels to greater than 800 mg/dL.
- If plasma transfusions are not given, then owners should be advised of the risks of infection and the foals maintained in an environment where exposure to potential pathogens is minimal.
- Ideally, the dose to be used can be calculated in order to attain an IgG level of at least 800 mg/dL.
- Frozen horse plasma is available commercially, although it may not contain antibodies against local pathogens.
- Plasma may be obtained from local donors. Blood should be collected aseptically with heparin or sodium citrate. The plasma is collected after the erythrocytes settle and is stored frozen until used. The plasma must be checked for antierythrocyte antibody and must be free of bacterial contamination. The transfusion should be given slowly while the foal is monitored for untoward reactions.
- All foals receiving supplemental plasma should have their IgG levels rechecked 12 to 24 hours later.
- Antibiotic treatment: A combination of a penicillin and an aminoglycoside is a good starting therapy. A suitable aminoglycoside such as gentamicin (6.6–8.8 mg/kg IV or IM q24h) or amikacin (22–25 mg/kg IV or IM q24h) may be given.
- Other third-generation cephalosporins such as cefotaxime (20–40 mg/kg IV or IM q6–8h) may be used.
- Circulatory support: It is essential to maintain or restore effective circulating volume by aggressive IV fluid therapy. Administer fluids at the highest tolerated rate.
- Septicemic foals are hypoglycemic so dextrose should be provided.

POSSIBLE COMPLICATIONS

Complications of sepsis include disseminated intravascular coagulation, acute renal failure, pulmonary thromboembolism, acute respiratory distress syndrome, and intractable hypotension and cardiac arrest.

RECOMMENDED MONITORING

- Heart rate and pulse
- Respiratory rate, mentation, blood pressure as dictated by the case
- CBC, hematocrit, total protein and electrolytes, urine output
- During long-term aminoglycoside therapy, dehydration must be prevented and urinalysis and serum creatinine monitored once weekly.

PROGNOSIS AND OUTCOME

This disease is uniformly fatal but animals may survive for as long as 1 to 2 years. Given that these recurrent infections are usually bacterial in origin and may be controlled for a time by aggressive antibiotic therapy, prolonging their lives may be achievable but may not be the most appropriate course.

PEARLS & CONSIDERATIONS

COMMENTS

This is a rare disease with a poor prognosis.

ElibVet.com

PREVENTION

This is an inherited disease. The parents of affected foals may be considered to carry the relevant genes, so they should be excluded from breeding programs.

CLIENT EDUCATION

It is important to explain to the client that this is an inherited disease and that other foals from these parents may also be affected.

Immunodeficiency, Common Variable

BASIC INFORMATION

DEFINITION

A heterogeneous group of immunodeficiency diseases characterized by a failure of B cells to make antibodies. The B-cell deficiency is secondary to a defect in helper T cells.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Sporadic in occurrence and severity
- Usually in animals older than 3 years of age and hence distinctly different from the inherited primary immunodeficiencies

CLINICAL PRESENTATION

- Recurrent infections that are not responsive to medical treatment
- Bacterial meningitis may be a consistent feature.
- Severe liver disease may also be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Absence of B cells in lymphoid organs, blood, or bone marrow
- The underlying defect is only expressed when the immune system is stressed by infection.
- Also associated with a selective immunoglobulin M (IgM) deficiency
- Many develop a concurrent lymphosarcoma

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Naturally occurring bacterial meningitis or other infections
- Infections occurring after secondary immunodeficiencies induced by stresses such as transportation, malnutrition, or excessive work or exercise

INITIAL DATABASE

- Complete blood count (CBC), serum chemistry profile with culture and sensitivity, urinalysis, fibrinogen
- Serum protein electrophoresis to evaluate immunoglobulin concentrations
- Serum immunoglobulin quantitation is highly variable. Usually, however, one or more of the IgG subclasses is severely reduced. Some cases, for example, contain only trace levels of IgG and IgM, no detectable IgG3, and very low IgA levels.
- Sometimes individual IgG subclasses are deficient but IgA levels are normal.
- T-cell numbers are normal, but B cells are undetectable.
- Neutrophil function assays are normal.

ADVANCED OR CONFIRMATORY TESTING

Peripheral blood lymphocytes show depressed responses to mitogens compared with age-matched control horses.

TREATMENT

Because of the great variability in severity of this syndrome, treatment success and prognosis are unpredictable. Some animals may require minimal support. Others may require euthanasia.

THERAPEUTIC GOAL(S)

Reduce suffering and maintain quality of life by controlling opportunistic infections until the animal regains immune function or the immunodeficiency is considered irreversible.

ACUTE GENERAL TREATMENT

- A total of 50 to 70 g of lyophilized equine IgG may be administered to increase serum IgG levels to greater than 400 mg/dL.
- Frozen horse plasma is available commercially, although it may not contain antibodies against local pathogens.
- Plasma may be obtained from local donors. Blood should be collected aseptically with heparin or sodium citrate. The plasma is collected after the erythrocytes settle and is stored frozen until used. The plasma must be prechecked for antierythrocyte antibody and must be free of bacterial contamination. The transfusion should be given slowly while the horse is monitored for untoward reactions.
- Animals receiving plasma should have their IgG levels rechecked 12 to 24 hours later.
- Antibiotic treatment: A combination of a penicillin and an aminoglycoside is a good starting therapy. A suitable aminoglycoside such as gentamicin (6.6–8.8 mg/kg IV or IM q24h) or amikacin (22–25 mg/kg IV or IM q24h) may be used.
- Other third-generation cephalosporins such as cefotaxime (20–40 mg/kg IV or IM q6–8h) may be used
- Circulatory support: It is essential to maintain or restore effective circulating volume by aggressive IV fluid therapy. Administer fluids at the highest tolerated rate.
- Septicemic horses are hypoglycemic, so dextrose should be provided.
- Appropriate antifungal therapy should be provided.

CHRONIC TREATMENT

- Nonspecific supportive therapy
- Frequent monitoring with aggressive antimicrobial therapy when warranted

POSSIBLE COMPLICATIONS

- Overwhelming sepsis
- Recurrent, antibiotic resistant infections

 ElibeVet.com

RECOMMENDED MONITORING

- Appetite, activity level, temperature, and CBCs may permit early detection of infections.
- During long-term aminoglycoside therapy, dehydration must be prevented and urinalysis and serum creatinine monitored once weekly.

PROGNOSIS AND OUTCOME

As with all immunodeficiency diseases, the prognosis is guarded. However, common variable immunodeficiency (CVID), as its name suggests, is of variable severity. Some horses succumb rapidly. Some with mild disease may well survive in apparent health, especially if recurrent infections are promptly and aggressively treated.

PEARLS & CONSIDERATIONS

COMMENTS

Possibly much more common than realized. Consider CVID in all meningitis cases.

PREVENTION

Because this condition may be heritable, consider reviewing the horse's pedigree and altering breeding strategies to minimize the chance of other animals developing the disease.

CLIENT EDUCATION

Be cautious to pessimistic in the prognosis. Consider alterations in breeding strategies.

Immunodeficiency, Fell Pony Syndrome

BASIC INFORMATION

DEFINITION

An autosomal recessive syndrome consisting of anemia, peripheral, ganglionopathy, and immunodeficiency occurring in foals of the Fell Pony breed

EPIDEMIOLOGY

SPECIES, AGE, SEX Restricted to Fell Ponies, so it is assumed to be of genetic origin. It occurs in animals of both sexes and is believed to be autosomal in nature.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Recurrent opportunistic infections, especially diarrhea or respiratory disease
- Affected foals appear normal at birth but fail to thrive.
- Decreased suckling, cough
- Chewing motions
- Infections develop at 2 to 32 weeks of age as maternal immunity wanes.
- The foals become extremely anemic.
- Death usually occurs 4 to 8 weeks after maternal immunity wanes.

ETIOLOGY AND PATHOPHYSIOLOGY

- Foals develop severe normochromic to macrocytic anemia as a result of a failure to develop bone marrow erythroid stem cells.
- Affected animals lack germinal centers and plasma cells, suggesting a B-cell deficiency. B-cell numbers in affected foals are less than 10% of normal.
- CD4 and CD8 T-cell numbers are within the normal range but show reduced major histocompatibility class II expression.
- Immunoglobulin levels are relatively normal, but any immunoglobulin deficiency may be masked by maternal antibodies.
- Neutrophil counts are normal.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Failure of passive transfer
- Other primary immunodeficiency syndromes
- Upper respiratory tract infections
- Chronic diarrhea
- Sepsis
- Bacteremia

INITIAL DATABASE

- Complete blood count (CBC) showing severe erythroid hypoplasia
- White blood cell counts: Normal or reflecting infection status
- Lymphopenia: Inconsistent
- Thrombocytopenia has been described.
- Blood immunoglobulin levels: Severely depressed
- Serum chemistry profile
- Blood culture and sensitivity, urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Bone marrow aspirate to characterize the anemia
- Serum protein electrophoresis to evaluate immunoglobulin concentrations
- Serum immunoglobulin quantitation
- Flow cytometry shows that T-cell numbers are normal, but B cells are undetectable.
- Mitogenic responses to phytohemagglutinin and concanavalin A are normal.
- Mitogenic responses to bacterial lipopolysaccharide, a B-cell mitogen, are severely depressed.

TREATMENT

THERAPEUTIC GOAL(S)

Supportive care to treat opportunistic infections. Euthanasia is commonly the most humane option.

ACUTE GENERAL TREATMENT

- Immunologic support to minimize recurrence risks
- Immediate control and elimination of infection
- Circulatory support to correct any deficits in intravascular volume and to maintain organ perfusion
- If the foal lacks immunoglobulins before the development of sepsis or pneumonia, then prompt immunologic treatment should be instituted to address the immunologic deficit. If, however, the foal presents with severe infections, then these must be promptly controlled.
- A total of 50 to 70 g of lyophilized equine immunoglobulin G (IgG) may be administered to increase serum IgG levels to greater than 800 mg/dL.

ElibVet.com

- If plasma transfusions are not given, then owners should be advised of the risks of infection and the foals maintained in an environment where exposure to potential pathogens is minimal.
- Ideally, the dose to be used can be calculated to attain an IgG level of at least 800 mg/dL.
- Frozen horse plasma is available commercially, although it may not contain antibodies against local pathogens.
- Plasma may be obtained from local donors. Blood should be collected aseptically with heparin or sodium citrate. The plasma is collected after the erythrocytes settle and is stored frozen until used. The plasma must be checked for antierythrocyte antibody and must be free of bacterial contamination. The transfusion should be given slowly while the foal is monitored for untoward reactions.
- All foals receiving supplemental plasma should have their IgG levels rechecked 12 to 24 hours later.
- Antibiotic treatment: A combination of penicillin and an aminoglycoside is a good starting therapy. A suitable aminoglycoside such as gentamicin (6.6–8.8 mg/kg IV or IM q24h) or amikacin (22–25 mg/kg IV or IM q24h) may be used.
- Other third-generation cephalosporins such as cefotaxime (20–40 mg/kg IV or IM q6–8h) may be given.
- Circulatory support: It is essential to maintain or restore effective circulating volume with aggressive IV fluid therapy. Administer fluids at the highest tolerated rate.
- Septicemic foals are hypoglycemic, so dextrose should be provided.

CHRONIC TREATMENT

Inappropriate because of the poor prognosis

POSSIBLE COMPLICATIONS

- Sepsis and recurring infections
- Complications of sepsis include disseminated intravascular coagulation, multiorgan dysfunction syndrome, acute renal failure, pulmonary thromboembolism, acute respiratory distress syndrome, intractable hypotension, and cardiac arrest.

RECOMMENDED MONITORING

- Heart rate and pulse
- Respiratory rate, mentation, blood pressure as dictated by the case
- CBC, hematocrit, total protein and electrolytes, urine output
- During long-term aminoglycoside therapy, dehydration must be prevented and urinalysis and serum creatinine monitored once weekly.

PROGNOSIS AND OUTCOME

This disease is uniformly fatal. The foals usually die or are euthanized by 3 months of age as a result of infections with *Cryptosporidium* spp. or adenoviruses.

PEARLS & CONSIDERATIONS

COMMENTS

This is a rare disease with a poor prognosis.

PREVENTION

Given that this disease appears to affect only the Fell Pony breed, appropriate screening of potential breeding pairs and of pairs that have produced affected foals should be done.

CLIENT EDUCATION

It is important to explain to the client that this is an inherited disease and that other foals from these parents may also be affected. Advice should be provided on appropriate selection of breeding animals.

AUTHOR & EDITOR: **IAN TIZARD**

Immunodeficiency, Selective Immunoglobulin M

BASIC INFORMATION

DEFINITION

An immunodeficiency syndrome characterized by low or absent serum immunoglobulin M (IgM) with normal or elevated levels of other immunoglobulin classes

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Probably of genetic origin and hence a primary immunodeficiency, but breeding studies have yielded inconclusive results
- Most often reported in Arabians and Quarter Horses but other breeds also affected

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Recurrent severe infections, especially diarrhea, arthritis, or respiratory disease leading to death before age 10 months
- Foals with a history of repeated infections that usually respond to aggressive antibiotic treatment. Infections recur after treatment has stopped. These foals do poorly and show stunted growth but may survive for several years.

ETIOLOGY AND PATHOPHYSIOLOGY

- Foals have unusually low levels of IgM. This may be because of decreased production or increased catabolism or because of excessive regulatory T-cell activity.
- Lymphocyte counts are usually within normal ranges, so there is no gross B- or T-cell deficit.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other primary immunodeficiencies
- Failure of passive transfer
- Delayed immunoglobulin synthesis
- Infections not associated with immunodeficiency, upper respiratory tract infections, chronic diarrhea, sepsis, arthritis, bacteremia

ElibVet.com

INITIAL DATABASE

- Complete blood count (CBC) and serum chemistry profile may reflect the ongoing infection and inflammation
- Bacterial culture and sensitivity

ADVANCED OR CONFIRMATORY TESTING

- Serum protein electrophoresis to evaluate immunoglobulin concentrations.
- Serum immunoglobulin quantitation.
- Serum IgM levels are more than two standard deviations below the age-specific normal IgM levels.
- Multiple IgM assays must be performed to confirm that the levels are persistently depressed.
- Other immunoglobulin classes are within normal limits or elevated for age.
- On necropsy lymphoid tissues are apparently normal. Evidence of bacterial infection, pneumonia, sepsis, and arthritis is present.

TREATMENT

THERAPEUTIC GOAL(S)

- Supportive care to treat opportunistic infections and to maintain quality of life until a definitive diagnosis is obtained. After it has been confirmed, euthanasia is commonly the most humane option.
- Immunologic support to minimize recurrence risks
- Immediate control and elimination of infection
- Circulatory support to correct any deficits in intravascular volume and to maintain organ perfusion
- If the foal is identified as lacking IgM before the development of sepsis or pneumonia, then prompt immunologic treatment should be instituted to address the immunologic deficit. If, however, the foal presents with severe infections, then these must be promptly controlled.
- A total of 50 to 70 g of lyophilized equine IgG may be administered to increase serum IgG levels to greater than 800 mg/dL.
- If plasma transfusions are not given, then owners should be advised of the risks of infection and the foals maintained in an environment where exposure to potential pathogens is minimal.
- Ideally, the dose to be used can be calculated to attain an IgG level of at least 800 mg/dL.
- Frozen horse plasma is available commercially, although it may not contain antibodies against local pathogens.
- Plasma may be obtained from local donors. Blood should be collected aseptically with heparin or sodium citrate. The plasma is collected after the erythrocytes settle and is stored frozen until used. The plasma must be checked for antierythrocyte antibody and must be free of bacterial contamination. The transfusion should be given slowly while the foal is monitored for untoward reactions.
- All foals receiving supplemental plasma should have their IgG levels rechecked 12 to 24 hours later.
- Antibiotic treatment: A combination of a penicillin and an aminoglycoside is a good starting therapy. A suitable aminoglycoside such as gentamicin (6.6–8.8 mg/kg IV or IM q24h) or amikacin (22–25 mg/kg IV or IM q24h) may be used.
- Other third-generation cephalosporins such as cefotaxime (20–40 mg/kg IV or IM q6–8h) may be given.
- Circulatory support: It is essential to maintain or restore effective circulating volume by aggressive IV fluid therapy. Administer fluids at the highest tolerated rate.
- Septicemic foals are hypoglycemic, so dextrose should be provided.

POSSIBLE COMPLICATIONS

Complications of sepsis include disseminated intravascular coagulation, acute renal failure, pulmonary thromboembolism, acute respiratory distress syndrome, intractable hypotension, and cardiac arrest.

RECOMMENDED MONITORING

- Heart rate and pulse
- Respiratory rate, mentation, blood pressure as dictated by the case
- CBC, hematocrit, total protein and electrolytes, urine output
- During long-term aminoglycoside therapy, dehydration must be prevented and urinalysis and serum creatinine monitored once weekly.

PROGNOSIS AND OUTCOME

Very poor to fatal

PEARLS & CONSIDERATIONS

COMMENTS

This is a rare disease with a poor prognosis.

PREVENTION

Given that this disease may be genetic in origin, appropriate screening of potential breeding pairs and of pairs that have produced affected foals should be considered seriously.

CLIENT EDUCATION

It is important to explain to the client that this is an inherited disease and that other foals from these parents may also be affected.

AUTHOR & EDITOR: **IAN TIZARD**

ElibeVet.com

Immunodeficiency, Severe Combined

BASIC INFORMATION

DEFINITION

A genetic disorder resulting in absence of mature functional B and T lymphocytes

SYNONYM(S)

Combined immunodeficiency

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Arabian foals and part-Arabian foals, but sporadic cases have been reported in breeds other than Arabians.
- Age at presentation is typically 1 to 2 months.

GENETICS AND BREED PREDISPOSITION

- Autosomal recessive inheritance in Arabians
- Only homozygous animals affected

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Recurrent infection in foals ages 1 to 4 months
- Opportunistic infectious agents commonly isolated

PHYSICAL EXAM FINDINGS

- Clinical examination findings vary with the type of infection.
- Bronchopneumonia and diarrhea are common.

ETIOLOGY AND PATHOPHYSIOLOGY

- The severe combined immunodeficiency (SCID) trait results from a 5-base pair deletion.
- Affected foals are born without functional B and T lymphocytes, rendering them unable to produce either antibody-mediated or cell-mediated immune responses.
- Acquisition of maternal antibodies through colostrum ingestion provides initial immunity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Because SCID results in chronic infection, primary infectious disease is a differential.

INITIAL DATABASE

Complete blood count: Persistent and severe lymphopenia (<1000 lymphocytes/μL)

ADVANCED OR CONFIRMATORY TESTING

Genetic testing (performed by VetGen, Ann Arbor, Mich.)

TREATMENT

THERAPEUTIC GOAL(S)

Treatment of causative agent of disease is recommended until a diagnosis of SCID is confirmed with genetic testing.

ACUTE GENERAL TREATMENT

- No treatment exists for SCID foals. Most do not survive beyond 5 months of age.
- Respiratory infections with adenovirus, *Rhodococcus equi*, or *Pneumocystis carinii* are common. Treatment for infectious disease should be initiated until results of genetic testing are available.

RECOMMENDED MONITORING

Lymphocyte count: Persistent lymphopenia is suggestive of SCID in Arabian foals.

PROGNOSIS AND OUTCOME

Grave; most foals do not survive beyond 5 months of age.

PEARLS & CONSIDERATIONS

COMMENTS

Persistent lymphopenia in an Arabian foal warrants genetic testing for SCID even if the foal appears healthy.

PREVENTION

Responsible breeding practices involve testing of both mares and stallions for the SCID gene and elimination of carriers from breeding programs.

SUGGESTED READING

Lunn P, Horohov D: Primary immunodeficiencies. In Reed S, Bayly W, Sellon D, editors: *Equine internal medicine*, ed 3, St Louis, 2010, Saunders Elsevier, pp 37–38.

AUTHOR: **PHOEBE A. SMITH**

EDITORS: **PHOEBE A. SMITH** and **ELIZABETH M. SANTSCHI**

Infertility, Chromosomal or Genetic

BASIC INFORMATION

DEFINITION

- The horse (*Equus caballus*) has 64 chromosomes—62 autosomal chromosomes and two sex chromosomes (XX-female and XY-male). Horses of all domestic breeds have the same number, size, and shape of chromosomes.
- Horses are affected by chromosomal abnormalities that cause congenital abnormalities, embryonic loss and infertility. Most chromosomal abnormalities reported in horses are associated with the sex chromosomes. However, abnormalities in autosomal chromosomes have also been reported.
- Common abnormalities include deletion or translocation of specific genes (testicular feminization, XTfmY; sex reversal, XXSxr or XYSxr), absence of a sex chromosome (Turner's syndrome, 63, X or 63, XO), and an extra copy of the X chromosome in males (XXY syndrome, 65,XXY). Moreover, some horses carry normal cells and cells with chromosome abnormalities, such as sex chromosome mosaics (63, X/64,XX).

SYNONYM(S)

Gonadal dysgenesis, Turner's syndrome, sex reversal, testicular feminization, trisomies, Klinefelter's syndrome, sex chromosome aneuploidy, sex chromosome mosaics

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Chromosome abnormalities affect stallions primarily as sex chromosome

 ElibeVet.com

mosaicism or sex-reversal syndromes. In mares, the most common form of chromosome abnormality is 63,X (Turner's syndrome).

- Most abnormalities occur during gametogenesis, embryogenesis, or both. However, the majority of cases are only diagnosed later in life, usually after puberty when infertility is evident.
- A recent study conducted in Poland with 500 randomly selected mares and stallions of several breeds found that 2% of the overall population had a chromosome abnormality, and 3.7% of mares (n = 272) had chromosome abnormalities. A similar study conducted in the United States with 204 broodmares of different breeds found that fewer than 3% of animals had chromosome abnormalities.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Gonadal dysgenesis: This condition is usually caused by absence of an X chromosome (63,X). However, mares affected with partial deletions of an X chromosome or mosaicism may also present with vestigial gonads. Affected mares are presented with chronic primary infertility, failure to cycle regularly or at all, small ovaries, and an underdeveloped reproductive tract. Usually, animals are small in size relative to the breed and may present angular limb deformities and poor overall conformation.
- Sex reversal: This condition is the result of a translocation of the SRY region from the Y chromosome into the X chromosome. Two main types of this condition are recognized: (1) animals with a mare-like phenotype and a male genotype (64, XYSry–), and (2) animals with a stallion-like phenotype and a female genotype (64, XXSry+). Sex-reversal horses have also been reported with karyotype of 64, XX and SRY negative; the etiology of this particular type of abnormality is unknown.
- Testicular feminization (XTfmY) or androgen insensitivity syndrome: This condition is caused by a mutation in the androgen receptor encoded by a gene in the X chromosome. XTfmY animals have the phenotype of females, with testes usually located in the abdomen or both testes and ovaries and absence of tubular genitalia (cervix and uterus). The vagina may end in a blind pocket. These animals are SRY positive, have stallion-like behavior, and have high levels of testosterone in the circulation.
- Trisomies of the sex chromosomes or Klinefelter syndrome (XXY): Affected animals are phenotypically males and may present with normal sexual behavior; small, soft, or normal testes; azoospermia; and a small or normal penis.
- Autosomal chromosome disorders: There have been few reports of horse autosomal chromosome abnormalities; the abnormalities can be classified as deletions, translocations, and autosomal trisomies. Only four horses have been reported with autosomal deletions. Seven cases of autosomal trisomy have been reported in horses, all involving smaller chromosomes. It has been suggested that trisomy of larger chromosomes may be involved in early embryonic loss. Animals with abnormalities in autosomal chromosomes are presented with a history of subfertility. The diagnosis of autosomal translocations is rare in horses, probably because most horses have a normal phenotype and the subfertility may not be attributed to chromosomal abnormalities.

HISTORY, CHIEF COMPLAINT

- Animals are usually presented with a history of subfertility or infertility or abnormal sexual behavior (eg, stallion-like behavior in a mare). Mares are presented with a history of chronic infertility, anestrous, failure to cycle regularly, and sometimes persistent estrus, and some mares are reported to be small in size for their age and breed and have poor body conformation. Intersex animals are often presented for their ambiguous external genitalia.

PHYSICAL EXAM FINDINGS

- The clinical signs vary according to the chromosome abnormality. Reproductive examination often reveals small, inactive ovaries and a flaccid, small uterus and cervix. The external genitalia are feminine, but the vulva may be smaller than normal, and there is no clitoral hypertrophy. A sex-reversed animal may have ambiguous external genitalia and retained testicles.
- Findings in genital examinations of intersex animals include enlargement of the clitoris; increased anogenital distance; incomplete vaginal and or scrotal development; presence of subcutaneous, inguinal, or abdominal testes; and a small penis and prepuce, which are often associated with hypospadias. Internally, the gonadic structures vary from inactive testicular tissues to ovotestes.

ETIOLOGY AND PATHOPHYSIOLOGY Chromosomal sex (either XX or XY) is determined at the time of fertilization, depending on whether the male gamete that fertilizes the X-bearing female gamete contains an X or a Y chromosome. During normal early embryonic development, the chromosomal sex of the zygote determines the eventual gonadal sex. The presence of genetic information borne on the SRY region of the Y chromosome directs the XY embryo to become a male. In the presence of the SRY region, the indifferent gonad will develop into testicles: Leydig cells secrete testosterone, and Sertoli cells secrete anti-Müllerian hormone (AMH). As a result, the Müllerian (paramesonephric) ducts regress, the Wolffian (mesonephric) ducts form vasa deferentia and epididymides, and masculinization of the external genitalia occurs. In the absence of the Y chromosome (or SRY region), the indifferent gonad will develop into ovaries. The absence of testosterone results in regression of the Wolffian ducts, and the absence of AMH results in development of the Müllerian ducts into oviducts, a uterus, and a cervix. Thus female physical development is not attributable to the presence and influence of estrogens but to the absence or ineffectiveness of androgens. The inherent trend is for any fetus to develop female external genitals and general body form in the absence of the masculinizing effects of male hormones.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Subnutrition
- Acyclic or anestrous
- Senility
- Retarded puberty

INITIAL DATABASE

- A cytogenetic analysis (karyotype) is the most useful tool to diagnose chromosome abnormalities.
- Blood samples must be collected into acid citrate dextrose or heparin and sent by overnight shipping to a laboratory specializing in animal karyotyping.
- An examination of peripheral blood smears for sex chromosome appendages, or drumsticks, on polymorphonuclear neutrophils (PMNs) may be used as a screening procedure to detect a reduced number of chromosomes. Drumsticks appear as lobes on the nucleus of PMNs and are present in approximately 10% of PMNs from normal mares but are absent in stallions and geldings. An examination of peripheral blood smears reveals an absence of drumsticks in XO mares.

ADVANCED OR CONFIRMATORY TESTING

Fluorescence in situ hybridization test

 ElibeVet.com

TREATMENT

THERAPEUTIC GOALS

- Eliminate stallion-like behavior.
- Remove intraabdominal testis or testes, which are prone to become neoplastic.

ACUTE GENERAL TREATMENT

Elective castration and removal of the testicle(s)

RECOMMENDED MONITORING

Animals presenting any of the signs described above should undergo a cytogenetic evaluation to determine if chromosomal abnormalities are present.

PROGNOSIS AND OUTCOME

- Favorable for life
- Reserved to poor for reproduction

PEARLS & CONSIDERATIONS

Recently, new laboratory techniques in cell culture, chromosome visualization, and chromosome banding have helped to improve our diagnostic capabilities for the different types of genetic infertilities. However, an accurate clinical examination constitutes the basis for deciding which animals need to be tested to avoid extra expenses to the breeders as well as achieve a precise diagnosis.

Inflammatory Airway Disease

BASIC INFORMATION

DEFINITION

- Inflammatory airway disease (IAD) is a respiratory disease of adult horses that is characterized by noninfectious inflammation of the small airways accompanied by airway hyperreactivity.
- It is not yet clear whether IAD is entirely a particulate-induced inflammation or if there is an allergic component to this disease.

SYNONYM(S)

- Small airway inflammatory disease
- Small airway disease
- Allergic airway disease

EPIDEMIOLOGY

SPECIES, AGE, SEX Equine adults

RISK FACTORS Stabling, a dusty environment, poor ventilation, high ambient endotoxin levels, high particulates of any kind

GEOGRAPHY AND SEASONALITY Seen more frequently in areas where horses are kept stabled and during months when horses are stabled

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Older horses may present with a more advanced form of disease that is more easily recognized as arising from the respiratory system.
- Younger horses may have much milder disease without distinct respiratory signs.

HISTORY, CHIEF COMPLAINT

- Horses may present with variable cough, nasal discharge, exercise intolerance, poor recovery from work, and mild tachypnea.
- Dressage horses may be reluctant to come onto the bit. Racehorses may have no specific airway signs but may exhibit poor performance.

PHYSICAL EXAM FINDINGS

- Affected animals are usually in good flesh.
- There is no evidence of increased respiratory effort at rest. The horse may have a mildly elevated respiratory rate, serous to mucoid nasal discharge, and cough or may have no distinct respiratory signs. Loud bronchovesicular sounds or mild wheezes and crackles on auscultation of the chest and mild fluid noises on auscultation of the trachea may be heard.
- Horses are afebrile.

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of IAD has not been fully elucidated. However, contributing factors include high environmental particulate and endotoxin levels and high levels of noxious gases, such as ammonia. It is unclear whether there is an allergic component to IAD.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Noninfectious respiratory diseases such as recurrent airway obstruction, various forms of pulmonary fibrosis (eg, silicosis or equine multinodular pulmonary fibrosis), toxicosis from inhaled gases, perilla mint
- Infectious lung disease such as septic bronchitis, bronchopneumonia, or viral pneumonia
- Exercise-induced pulmonary hemorrhage
- Toxicoses, including inhaled toxins (silicosis, various gases) as well as systemically ingested substances such as perilla mint
- Neoplastic disease, including primary tumors of the respiratory tract, or more commonly, distant metastases
- Static or dynamic upper airway obstructions

INITIAL DATABASE

- Complete blood count and serum chemistry profile show no abnormalities.
- Auscultation after using a rebreathing bag may show no abnormalities, or the horse may cough or have mild wheezes or crackles.
- Palpation of the larynx or trachea may elicit a cough.
- Arterial blood gas analysis is within normal limits at rest; however, horses have an early onset of hypoxemia and hypocapnia during exercise.
- Bronchoalveolar lavage is the preferred method of sampling and shows elevated levels of neutrophils (>5%), mast cells (>2%), or eosinophils (>0.1%) or a combination, along with variable amounts of mucus, without evidence of infection.

ElibEVet.com

ADVANCED OR CONFIRMATORY TESTING

- Lung function testing is extremely helpful in characterizing the disease. Measures of airway resistance are often normal at baseline, but histamine bronchoprovocation reveals airway hyperreactivity ("twitchy airways").
- Endoscopy may or may not show excessive amounts of tracheal mucus.
- Radiography is not helpful in characterizing the disease but may show nonspecific mild interstitial or bronchial pattern.
- Ultrasonography is not helpful.

TREATMENT

THERAPEUTIC GOAL(S)

- Immediate goals involve dilating the small airways to achieve improved exercise tolerance.
- Longer term goals involve reduction of inflammation and control of contributing environmental factors.

ACUTE GENERAL TREATMENT

- Inhaled albuterol (metered dose inhaler [MDI]) using a spacer device (450–900 µg). Ipratropium via MDI may be used in addition for a more sustained effect.
- Treatment with corticosteroids (prednisolone 0.8 mg/kg PO q12h, tapering over a 4-week period).
- Environmental control to minimize dust and noxious gases is extremely important.

CHRONIC TREATMENT

Environmental control is critical to successful long-term treatment. Horses may require long-term treatment with inhaled corticosteroids such as fluticasone propionate or beclomethasone. Mast cell stabilizers such as sodium cromoglycate may be helpful with mast cell–mediated disease.

RECOMMENDED MONITORING

Patients should undergo radiographic (or less ideally, sonographic) monitoring until the disease is resolved.

PROGNOSIS AND OUTCOME

Prognosis for neutrophil-mediated IAD is good, provided environmental remediation takes place. Horses with mast cell–mediated IAD may be less responsive.

AUTHOR & EDITOR: **MELISSA R. MAZAN**

Inflammatory Bowel Disease

BASIC INFORMATION

DEFINITION

Primary inflammatory disease of immune-mediated or idiopathic etiology affecting focal or diffuse portions of the small (and sometimes large) intestine and resulting in intestinal malabsorption

EPIDEMIOLOGY

SPECIES, AGE, SEX No age or sex predisposition, although most cases occur in adult horses

GENETICS AND BREED PREDISPOSITION

- Some studies report increased incidence in Standardbreds and Thoroughbreds, although this may represent regional equine populations rather than true breed predispositions.
- Granulomatous enteritis has been described in some related horses, suggesting a potential genetic predisposition, although this has not been definitively documented.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Inflammatory bowel disease (IBD) is characterized histopathologically by the predominant cell type in the inflammatory infiltrate.

- Granulomatous enteritis
- Lymphocytic-plasmacytic enteritis
- Multisystemic eosinophilic epitheliotropic disease (MEED)
- Eosinophilic enterocolitis
- Focal eosinophilic enteritis (see "Enteritis, Focal Eosinophilic" in this section)

HISTORY, CHIEF COMPLAINT

- Weight loss (usually with a good appetite) and intermittent, mild colic signs are the most common presentations.
- ± Skin lesions or diarrhea (most common in MEED or eosinophilic enterocolitis)

PHYSICAL EXAM FINDINGS

- Thin body condition
- Temperature, pulse, and respiratory rate are usually within normal limits.
- Ventral edema (caused by hypoproteinemia) is frequently present.
- A generalized, exudative, crusting dermatitis and ulcerative lesions on the coronary bands are often present in horses with MEED.
- Rectal examination
  - May be within normal limits, although focally or diffusely thickened small intestine is often appreciated
  - Colonic and rectal mural thickening may also be evident with diffuse disease.
- In contrast, initial evaluation of horses with focal eosinophilic enteritis is identical to horses presenting for other causes of nonstrangulating small intestinal obstruction (see "Enteritis, Focal Eosinophilic" in this section).

ETIOLOGY AND PATHOPHYSIOLOGY

- The specific etiology of all types of IBD is unknown. Infectious, toxic, allergic, or autoimmune mechanisms have been postulated to play a role. IBD has been reported in horses after *Salmonella* or parasitic infections and in horses that may have ingested feed contaminated with aluminium.
- In most cases, though, by the time clinical signs are evident, the primary pathology appears to be immune mediated in nature, even though an initial toxic, dietary, or infectious insult may have initiated the pathology.
- In some cases, IBD may represent a chronic hypersensitivity reaction to unknown (likely dietary) antigens.
- Regardless of the inciting cause, intestinal inflammation results in dysfunction of the intestinal villous epithelial cells, resulting in malabsorption and maldigestion of nutrients and causing weight loss and hypoproteinemia.

ElibEVet.com

With severe inflammation involving the submucosal vasculature, plasma protein is also lost.
- Partial intermittent small intestinal obstruction with hay and fibrous feed caused by small intestinal thickening is likely the cause of intermittent colic in IBD.
- In most cases of IBD, the predominant inflammatory infiltrates are found in the small intestine, although colonic involvement does occur, and some lesser degree of inflammation is usually evident on histopathologic evaluation of the entire intestinal tract in most affected horses.
- In MEED, inflammatory infiltrates are found in the skin, liver, pancreas, and large intestine in addition to the small intestine. The reason these locations are targeted is not known.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Intestinal lymphosarcoma
- *Rhodococcus equi* enterocolitis or proliferative enteropathy (in foals and weanlings)

INITIAL DATABASE

- Complete blood count
  - Variable
  - Mild to moderate anemia is frequently observed.
  - Leukocytosis and hyperfibrinogenemia associated with chronic inflammation may be present but are not consistently seen.
  - Thrombocytopenia (caused by concurrent disseminated intravascular coagulation) is rarely reported.
- Serum biochemistry profile
  - Hypoproteinemia and hypoalbuminemia are frequently seen.
  - Globulin concentrations may be low, normal, or increased.
  - Liver function should be assessed by measuring serum hepatocellular enzyme activity and serum bile acid concentration to ensure that hypoproteinemia is not associated with liver failure.
- Transabdominal ultrasonography
  - Diffusely or focally increased small intestinal mural thickness (>5 mm) is usually but not always appreciated.
  - Concurrent colonic mural thickening (>5 mm) may also be appreciated.
- Peritoneal fluid analysis: Variable. In most cases, the peritoneal fluid is normal or has a mildly increased nucleated cell count and total protein concentration.
- Urinalysis should be performed to rule out renal protein loss.
- Fecal flotation for parasites should also be performed because intestinal inflammation may occur secondary to chronic parasite infestation.

ADVANCED OR CONFIRMATORY TESTING

- The D-glucose or D-xylose absorption test can confirm the presence of small intestinal malabsorptive disease but does not help differentiate between IBD and other intestinal infiltrative diseases such as lymphosarcoma.
- Rectal mucosal biopsy: In some cases of inflammatory or infiltrative intestinal disease, a diagnosis can be obtained via rectal mucosal biopsy. However, a normal rectal biopsy does not rule out inflammatory intestinal disease confined to the more proximal intestinal tract. In addition, many causes of intestinal inflammation result in nonspecific inflammation on rectal mucosal biopsy.
- Gastroduodenoscopy
  - Concurrent gastroesophageal ulceration is common in IBD.
  - Gastric and duodenal mucosal biopsies may be obtained endoscopically, although these are not always diagnostic for IBD because a full-thickness sample cannot be obtained.
- Exploratory celiotomy and intestinal biopsy
  - Intestinal biopsies may be obtained via laparotomy or laparoscopically from some locations.
  - Several sites (grossly normal and abnormal) should be biopsied, and samples should be evaluated histopathologically.

TREATMENT

THERAPEUTIC GOAL(S)

Immunosuppressive or antiinflammatory therapy

ACUTE GENERAL TREATMENT

- Immunosuppressive therapy
  - The mainstay of treatment for IBD
  - Corticosteroids are used most frequently and may include:
    - Dexamethasone: 0.1 mg/kg IV, IM, or PO q24h
    - Prednisolone: 1 to 2 mg/kg PO q24h
- In general, parenteral therapy is preferred initially in severe cases because of limited intestinal absorption.
- If a good response to the above therapy is observed, with improvement in serum protein levels and weight gain, steroid therapy may be tapered slowly over 6 to 12 weeks, with a goal of reaching the lowest possible dosage that controls the horse's signs.
- Gastric ulcer prophylaxis with omeprazole: 1 to 2 mg/kg PO q24h
  - If corticosteroids are ineffective, azathioprine (2–3 mg/kg PO q24h) alone or in combination with corticosteroids may be effective, although this has not been well studied in horses.
  - Occasionally, horses respond well to immunosuppressive therapy and remain in remission after discontinuation of treatment. Most horses, though, either do not respond sufficiently or require lifelong immunosuppressive therapy.
- Dietary management
  - Hay and fibrous feed is poorly tolerated in most horses with IBD.
  - Maintenance on good-quality, short, clipped pasture and a well-balanced complete pelleted feed is ideal.
  - In other species, allergy testing and exclusion diets can be helpful in determining the role dietary antigens may play in IBD. In horses, designing an effective yet nutritionally balanced exclusion dietary regimen for horses is quite difficult and requires the input of a veterinary nutritionist and great motivation and expense on the part of the owner.
- Euthanasia is warranted in horses with severe disease that fail to respond to immunosuppressive and dietary therapy.

PROGNOSIS AND OUTCOME

Guarded to poor

PEARLS & CONSIDERATIONS

Intestinal biopsy of the affected intestinal segment is required to make a definitive diagnosis of IBD. Laparotomy allows the most thorough diagnostic evaluation of the intestinal tract, but it is associated with the greatest expense and morbidity.

ElibeVet.com

Influenza

BASIC INFORMATION

DEFINITION

Influenza virus A-Eq2 (H3N8) is an orthomyxovirus that is an important worldwide respiratory pathogen of horses.

SYNONYM(S)

Flu

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common in younger horses (yearlings, ages 2–3 years)
- Rare in foals; however, 11 foals during a recent outbreak in Australia died of severe bronchointerstitial pneumonia as a result of equine influenza infection.

GENETICS AND BREED PREDISPOSITION Affects all breeds. Disease may be more severe in donkeys and mules.

RISK FACTORS

- Areas of high comingling of horses (eg, racetracks, show grounds, veterinary hospitals)
- Immunosuppression (eg, traveling, hospitalization, training, showing)

CONTAGION AND ZOONOSIS

- Eurasian and American lineage strains of equine influenza virus (H3N8) have been isolated.
- There is no known zoonosis.
- Equine influenza A(H3N8) strains were found to be the causative agent of pathogenic respiratory disease outbreaks in dogs in 2004.

GEOGRAPHY AND SEASONALITY

- Not seen in New Zealand and Iceland.
- Australia had been influenza free until an outbreak in 2007. Strict quarantine and massive surveillance measures resulted in declaration of Australia as free of Equine influenza in December 2007.
- Most common in fall and winter.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Anorexia
- Fever that may be biphasic (48–96 hours after infection and at 7 days)
- Depression, lethargy, inappetence
- Nasal discharge
- Coughing

PHYSICAL EXAM FINDINGS

- High fever (≤106° F)
- Mild depression, inappetence
- Distal limb edema
- Serous nasal discharge becoming mucopurulent after 72 to 96 hours
- Slightly enlarged retropharyngeal lymph nodes
- Coughing (dry) that may persist for up to 21 days
- Tachypnea
- Arrhythmia (rare) cause of cardiomyopathy
- Muscle soreness
- Weight loss

ETIOLOGY AND PATHOPHYSIOLOGY

- Highly infectious virus transmission through aerosolized droplets
- Transmission through fomites probably also occurs.
- The virus is inhaled and attaches and multiplies in the respiratory epithelium with a short incubation period of 1 to 3 days.
- The virus causes epithelial cell death and desquamation, with predominant damage in the trachea and bronchial tree, resulting in disruption of mucociliary clearance critical for preventing secondary bacterial infection.
- A high concentration of virus is shed through nasal secretions.
- Fever and virus shedding 48 hours after exposure; shedding for 6 to 7 days
- Subclinical infection with shedding is possible.
- The virus survives on wet surfaces for 72 hours and dry surfaces for 48 hours.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine herpesviruses 1 and 4
- Equine viral arteritis
- Equine rhinoviruses
- Bacterial pneumonia or pleuropneumonia
- Other respiratory pathogens

INITIAL DATABASE

- Complete blood count may reveal leukopenia caused by lymphopenia

ADVANCED OR CONFIRMATORY TESTING

- Virus isolation from nasopharyngeal secretions collected from the nasal passage using a 6-inch polyester or Dacron swab. Samples should be collected within first 24 to 48 hours after clinical onset.
- Serology using paired sera (acute and convalescent) collected 10 to 21 days apart. Common tests include hemagglutination inhibition, single radial hemolysis, fluorescent antibody, and enzyme-linked immunosorbent assay (ELISA).
- ELISA (eg, Directogen test, Becton Dickinson, Franklin Lakes, NJ) to detect viral antigen in nasopharyngeal secretions can be done stall side using a nasal swab sample.
- Reverse transcriptase polymerase chain reaction may be used to detect viral RNA in clinical samples.

TREATMENT

THERAPEUTIC GOALS

- Provide supportive and symptomatic treatment.
- Establish biosecurity measures to minimize the spread of infection.

ACUTE GENERAL TREATMENT

- Rest with minimal stress is the most important component of therapy. Damaged respiratory epithelium takes a minimum of 3 weeks to regenerate.
- Antipyretics (nonsteroidal antiinflammatory drugs [NSAIDs]) for high fever or significant myalgia
- Hydration and fluids if needed
- Nursing care
- Antiviral medication has not been evaluated in horses, but there have been some suggestions that amantadine at 10 mg/kg IV q8h or 5 mg/kg q4h (avoid in renal patients because central nervous system effects have been reported) or rimantadine at 30 mg/kg PO q12h may reduce the severity and duration of infection in horses.

POSSIBLE COMPLICATIONS

- Secondary bacterial infections
- Pleuropneumonia
- Reactive airway obstruction
- Myocarditis, myositis

RECOMMENDED MONITORING

- Monitor horses twice daily for increased rectal temperature. Segregate horses with fever from the general horse population.
- Monitor hydration status, especially if treating with NSAIDs.
- Quarantine horses for 21 days after the last known clinical signs resolve.

PROGNOSIS AND OUTCOME

- The majority of infections are self-limiting with clinical signs lasting for 24 hours to 3 days.
- High morbidity (60%–90%); less than 1% mortality rate

ElibeVet.com

PEARLS & CONSIDERATIONS

COMMENTS

- Common cause of self-limiting respiratory disease in young horses
- Confirming the diagnosis with virus isolation is important for monitoring viral antigenic variation.
- Serologic confirmation of the diagnosis is most accurate if several sick and in-contact horses are simultaneously tested.
- It is important to use vaccines produced from current and clinically relevant strains of equine influenza.

PREVENTION

- Horses returning from areas of high exposure risk (eg, shows, breeding, hospitalization) should be housed apart from the general barn population for at least 14 days and monitored for clinical signs.
- Vaccines for Equine influenza that are currently available in the United States include
  - Inactivated virus intramuscular vaccines
  - A recombinant canarypox vector intramuscular vaccine
  - A modified-live virus (MLV) cold adapted intranasal equine influenza vaccine
- The American Association of Equine Practitioners recommends that mature performance, show, or pleasure horses at regular risk of exposure be revaccinated at 6-month intervals. Other adult horses could be vaccinated as infrequently as once a year.
- Pregnant mares that have been previously vaccinated should be vaccinated with an intramuscular product 30 days before foaling.
- Foals from vaccinated mares should be vaccinated once with the MLV intranasal vaccine or a primary series of three doses of IM vaccine beginning at 6 months of age. There should be 4 to 6 weeks between the first and second dose of IM vaccine; the third dose should be administered at 10 to 12 months of age.
- Vaccination of clinically normal horses in an outbreak situation may be beneficial. Horses with no known history of vaccination may benefit from a modified intranasal vaccine in which onset of protective immunity is within 7 days with a single dose.

CLIENT EDUCATION

- Emphasize the importance of rest for minimum of 3 weeks for affected horses (1 week of rest for every day of fever).
- Training and stress may increase the risk of secondary infections.

EDITORS: **DEBRA C. SELLON** and **MAUREEN T. LONG**

Insect Hypersensitivity

BASIC INFORMATION

DEFINITION

A hypersensitivity reaction to bites by various insects

SYNONYM(S)

Summer itch, summer "fungus," sweet itch, lichen tropicus, Queensland itch (Australia), Sommerekzem (Germany), Manochsvankorv (Sweden), Kasen (Japan)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in horses but may also be seen in other Equidae
- Signs may start at any age but more commonly start between 2 and 4 years of age and often become more severe as the horse ages.

GENETICS AND BREED PREDISPOSITION

- Several horse breeds appear to have a hereditary predisposition, including Icelandic, German Shire, Arabian, Connemara, Swiss Warmblood, Quarter Horse, and ponies.
- A genetic influence in the frequency of the disease has been found in Swiss Warmbloods.
- Breeding of affected horses is not recommended.

GEOGRAPHY AND SEASONALITY Insect hypersensitivity in horses has a worldwide distribution. The disease is prevalent during the warm weather season or year round in more tropical regions.

ASSOCIATED CONDITIONS AND DISORDERS Insect hypersensitivity is commonly seen in conjunction with atopic dermatitis (environmental allergies).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Owners frequently notice increasing self-trauma (scratching, biting, and rubbing of the skin; hair loss; and loss of the mane and tail hair; excoriations) during insect season. Other horses on the same premises may be unaffected. The history often reveals similar problems in previous years at similar times of year.

PHYSICAL EXAM FINDINGS

- Skin lesions vary from mild with areas of broken-off hair only, papules, and crusts to complete alopecia and severe excoriation.
- The distribution of the lesions depends on where the involved insects are feeding and can affect any combination of locations, including the face, mane, ventrum, dorsal back, legs, and tail.
- "Classic" lesions of *Culicoides* hypersensitivity include "buzzed-off manes" and "rat tails."
- Chronic lesions may include lichenification and hyperpigmentation and skin fold development (rugae) at the base of mane and tail.
- Some severely affected horses may also show behavioral changes (restlessness and irritability) and even weight loss, making the horse unsuitable for riding in some cases.
- Affected horses may also develop secondary bacterial infection of the skin (folliculitis). Signs of this complication

ElibeVet.com

range from erected hairs over small papules with or without crusts to deeper lesions with nodules and draining tracts in rare cases.
- Urticaria is an uncommon manifestation of insect hypersensitivity in horses.

ETIOLOGY AND PATHOPHYSIOLOGY
- Type I (immunoglobulin E–mediated) hypersensitivity reaction to saliva from various biting insects ± type IV (delayed or cell-mediated) hypersensitivity reaction.
- Insects found most commonly to be involved are *Culicoides* spp. (biting midges, "no-see-ums") but also by mosquitoes, black flies, horse flies, horn flies, stable flies, sand flies and, less commonly ants, wasps, and bees.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Sarcoptic mange affecting the head, especially the ears, that has progressed to the whole body.
- Psoroptic mange affecting the mane, forelock, and tail.
- Chorioptic mange affecting the (lower) legs.
- Straw itch mites affecting areas on the horse that are exposed to hay and straw.
- Trombiculiasis (chiggers, harvest mites, red bugs), which is most common in the late summer and fall and affects mostly the legs and face.
- Migrating microfilarial stage *Onchocerca cervicalis* may cause similar lesions anywhere on the body but have been mostly eliminated since the introduction of ivermectin.
- Habronemiasis (summer sores) may cause a hypersensitivity reaction to aberrant intradermal migration of the larvae of the horses stomach worms.
- Lice infestation usually affects the neck and mane but may also affect the head, dorsum, flanks, fetlock, and tail or may be generalized in chronic cases.

INITIAL DATABASE
- Take a detailed history.
- Take skin scrapings of the lesions.
- Ivermectin trial (treatment every 2 weeks at least three times) of the affected horse and all in-contact horses.

ADVANCED OR CONFIRMATORY TESTING
- Intradermal testing for insect and environmental allergens (preferred over enzyme-linked immunosorbent assay [ELISA] testing).
- ELISA testing for insect and environmental allergens if skin testing is not available.
- Food trial (if symptoms are year round): Stop all supplements and grains and try to find a hay to which the horse has not been previously exposed.
- Complete blood count and serum chemistry profile: Usually normal (rarely shows eosinophilia).
- Skin biopsies for histopathology reveal a perivascular eosinophilic and lymphocytic dermatitis (this will only rule allergic dermatitis in or out, but not the type of hypersensitivity, ie, insect versus food versus environmental allergies).

TREATMENT

THERAPEUTIC GOALS
- It may not be possible to avoid insect bites completely, but clinical sign usually improve with treatment that lowers the exposure to insect bites and reduces the hypersensitivity reaction.
- An allergic reaction is only triggered if a certain threshold of allergen exposure is exceeded. This threshold varies for each individual animal.

ACUTE GENERAL TREATMENT
- Permethrin sprays (ideally 2% or higher in concentration applied q12–24h), spot-on products (at 45% applied once weekly), or both
- For pruritus: Prednisolone tablets mixed in the grain at 1 mg/kg q24h or dexamethasone liquid injectable given PO 0.05 to 0.1 mg/kg q24h
- Fly sheets (with or without permethrin impregnation) covering the affected areas of the horse

CHRONIC TREATMENT
- Elimination of standing water (including frequent dumping and cleaning of water buckets and troughs) to reduce breeding grounds for mosquitoes, *Culicoides* spp., and black flies.
- Stabling of the horse during peak feeding times:
  - *Culicoides* spp. and mosquitoes are active predominantly at dusk and dawn and in warm, humid weather.
  - Black flies, horse flies, stable flies, and horn flies are more active during the daylight.
- Use of mosquito dunks containing a bacterium that kills mosquito and black fly larvae in water sources.
- Installing large strong box fans in the barn and stall front because *Culicoides* spp. are weak fliers.
- Frequent manure removal or dragging pastures to break up manure pile because most flies use manure as breeding grounds.
- Use of feed-through fly control products containing insect growth regulators or chitin synthesis inhibitors to prevent larvae development in the manure pile.
- Allergen-specific immunotherapy, especially when environmental allergies are concurrently present.

PROGNOSIS AND OUTCOME

As with most allergic diseases, treatment is usually lifelong, and no cure should be expected. With the above treatments, regular use of the horse should be possible, and a good quality of life can be expected.

PEARLS & CONSIDERATIONS

COMMENTS
Treating horses with insect hypersensitivity usually requires a combination of the above treatments. One treatment alone will not likely resolve the clinical signs. Treatment protocols need to be tailored to the client's abilities.

PREVENTION
Strict insect control

CLIENT EDUCATION
The client needs be aware that long-term cure is unlikely, but the disease can be managed with a multimodal approach. This includes a combination of daily application of a high-percentage permethrin spray, fly sheets, elimination of standing water, use of fans, and so on. For most cases of equine insect hypersensitivity, these measures reduce the insect exposure enough to gain clinical control.

ElibeVet.com

Insulin Resistance

BASIC INFORMATION

- Insulin is the primary hormone that controls energy metabolism.
- The pancreatic β cells secrete insulin in response to glucose and glucagon.
- Insulin secretion is also regulated by sympathetic and parasympathetic systems: epinephrine (stress) inhibits and acetylcholine (food intake) stimulates insulin secretion.
- Somatostatin inhibits insulin secretion.
- Insulin regulates three major fuels: carbohydrates, proteins, and fats.
- The liver, skeletal muscle, and adipose tissue are the major targets for insulin.
  - Liver: Insulin decreases glycogen, gluconeogenesis, and ketogenesis, and stimulates glycogen and fatty acid synthesis.
  - Adipose tissue: Insulin decreases lipolysis and stimulates fatty acid uptake, synthesis, and esterification.
  - Skeletal muscle: Insulin decreases proteolysis and amino acid output and increases glucose and amino acid uptake, protein synthesis, and glycogen synthesis.
- Understanding insulin physiology is central to understanding the pathogenesis of equine pathological conditions such as hyperlipemia, pituitary pars intermedia dysfunction (Cushing's disease), equine metabolic syndrome (EMS), and polysaccharide storage myopathy.

DEFINITION

Insulin resistance (IR) is defined as a decreased response to endogenous or exogenous insulin

EPIDEMIOLOGY

SPECIES, AGE, SEX IR is more commonly reported in horses older than 7 years (metabolic syndrome, Cushing's disease), but it may be present in ponies at any age.

GENETICS AND BREED PREDISPOSITION

- There is a genetic predisposition: Saddlebreds, Morgans, Tennessee Walking Horses, Paso Finos, and Quarter Horses are predisposed to IR.
- IR is a common finding in ponies (genetics).

GEOGRAPHY AND SEASONALITY

- There is no evidence that IR is associated with geography or season per se.
- The condition is more often reported in developed countries, likely associated with the feeding habits of horses because IR in general is a condition of obese horses.

ASSOCIATED CONDITIONS AND DISORDERS

- See "Equine Metabolic Syndrome" in this section.
- Diabetes mellitus is a rare condition in horses.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- IR has been reported in horses and ponies with pars intermedia dysfunction (Cushing's disease), EMS, obesity, hyperlipemia, diabetes mellitus, laminitis, granulosa cell tumors, and endotoxemia.
- Laminitis is a consistent clinical finding of IR.
- Often these horses are obese, although horses with poor body condition (Cushing's disease) can have IR.
- A "cresty neck" or "stallion-like" appearance in mares is suggestive of IR (see "Metabolic Syndrome" in this section).

PHYSICAL EXAM FINDINGS

- Obesity, fat redistribution (tailhead, prepuce, mammary gland, supraorbital fat pads, shoulder area) and laminitis in EMS
- Laminitis, delayed haircoat shedding, hirsutism, weight loss, and polyuria and polydipsia in horses with Cushing's disease
- Anorexia, diarrhea, arrhythmias, and icterus in ponies with hyperlipemia
- Infertility

ETIOLOGY AND PATHOPHYSIOLOGY

- Decreased number of insulin receptors or lack of receptor response upon insulin stimulation (nonfunctional receptors).
- This leads to insulin insensitivity or resistance.
- This results in hyperinsulinemia with normoglycemia (compensated IR) or with hyperglycemia (noncompensated IR).
- Glucocorticoids stimulate glycogen formation, gluconeogenesis, and proteolysis; induce IR; and increase glycemia.
- Glucocorticoids induce IR by decreasing the receptor response to insulin.
- Increased glucocorticoid concentrations are present in conditions such as metabolic syndrome, hyperlipemia, and Cushing's disease.
- Carbohydrate feeding to horses increases glucocorticoid release and has been associated with IR.
- Dexamethasone administration to healthy horses decreases insulin sensitivity.
- Growth hormone also induces IR in horses.

DIAGNOSIS

- Tests to diagnose IR include baseline glucose and insulin concentrations, the glucose tolerance test (GTT), the insulin tolerance test, the combined glucose/insulin test (CGIT), the euglycemic-hyperinsulinemic clamp (EHC), and the minimal model analysis of a frequently sampled IV glucose tolerance test (FSIGT).
- Baseline insulin concentrations should be less than 20 μU/mL.
- Insulin concentration above 30 μU/mL suggests IR.
- Whereas hyperglycemia with hyperinsulinemia suggests IR, hyperglycemia with hypoinsulinemia indicates insulin-dependent diabetes mellitus.
- Contrary to IR, there are few cases of diabetes mellitus documented in horses

DIFFERENTIAL DIAGNOSIS

- IR is an endocrine abnormality present in various pathological conditions.
- IR is present in horses with obesity, hypothyroidism, Cushing's disease, metabolic syndrome, and hyperlipemia.
- IR is the hallmark of EMS.
- Consider IR in horses with laminitis.
- Hyperglycemia may be the result of diabetes mellitus (rare in horses).

TREATMENT

ACUTE GENERAL TREATMENT

- Address the primary problem.
- Start a weight loss plan.
- Increase physical activity.
- Consider levothyroxine sodium (1–6 mg/100 kg PO q24h)
- Levothyroxine is used to induce a hypermetabolic state, not because these horses have hypothyroidism.
- Do not feed carbohydrate-rich diets, except in ponies with hyperlipemia.

ElibEVet.com

PROGNOSIS AND OUTCOME

Guarded to poor depending on disease

PEARLS & CONSIDERATIONS

- The excessive feeding of carbohydrate-rich diets and obesity may lead to IR and laminitis.
- A good management plan (deworming, vaccination) should be used in ponies to avoid hyperlipemia.
- Obese horses and ponies are prone to IR.

Intracarotid Injection

BASIC INFORMATION

DEFINITION

Introduction of venous medications into the arterial system

EPIDEMIOLOGY

SPECIES, AGE, SEX Common in equine patients because of the high prevalence of IV medications administered

RISK FACTORS Reactions may occur with a number of medications, including sedatives, anesthetic agents, electrolyte solutions, and antibiotics.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT History of recent IV injection followed by immediate clinical abnormalities (within 10 seconds of injection)

PHYSICAL EXAM FINDINGS

Neurologic deficits are common:

- Excitement
- Seizures
- Central blindness (lack of menace, normal pupillary light reflex)
- Abnormal postural reactions
- Lethargy
- Circling
- Collapse
- Coma
- Death

ETIOLOGY AND PATHOPHYSIOLOGY

- Introduction of a medication intended for IV use only into the carotid artery may result in ischemic cerebral necrosis.
- The forebrain (prosencephalon, including the thalamus, hypothalamus, and cerebrum) is most commonly affected because of delivery of the medication from the external carotid to the circle of Willis, resulting in infarction and cavitation.
- Damage occurs, from most to least severe, in the thalamus, midbrain, cerebral cortices, hippocampus, corpus striatum, and cerebellum. However, the dose and type of medication injected may cause even more widespread cerebral damage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Drug reaction
- Head trauma
- Neoplasia
- Encephalitis
- Endotoxic shock

INITIAL DATABASE

- History
- Neurologic examination

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid analysis if neurologic disease is suspected
- Computed tomography or magnetic resonance imaging may show cavitary lesions in the prosencephalon.

TREATMENT

THERAPEUTIC GOALS

- Treat seizures.
- Provide cardiopulmonary support.
- Prevent or treat secondary trauma to the horse caused by seizures and loss of consciousness.
- Reduce cerebral edema and inflammation.

ACUTE GENERAL TREATMENT

- Sedation may be required to control the patient for therapy, but ensure that it is a venous injection.
- Anticonvulsants
  - Diazepam: Adults, 0.05 to 0.44 mg/kg IV; foals, 0.1 to 0.2 mg/kg IV
  - Phenobarbital: 5 to 15 mg/kg IV slowly
- Cardiovascular resuscitation
  - See "Shock Dose Fluid Administration" in Section II.
  - Mechanical ventilation
- Antiinflammatory medications
  - Flunixin meglumine (1.1 mg/kg q12h IV) for antiinflammatory and antiendotoxin effects
  - Hypertonic saline (adults, ≤4 mL/kg IV) for cerebral edema and shock
  - Mannitol (0.25–2.0 g/kg, infused over 30–45 min IV) for cerebral edema
  - Dimethylsulfoxide (0.5–1.0 g/kg in a 20% solution q8–12h IV) for edema and inflammation
- General wound and orthopedic trauma management; radiography when indicated

CHRONIC TREATMENT

May require continued seizure management

RECOMMENDED MONITORING

Repeated neurologic examinations are recommended to monitor recovery.

PROGNOSIS AND OUTCOME

- The severity of the reaction depends on the medication injected.
- Horses exhibit a wide range of individual variation in drug reaction and recovery.
- Most horses recover within hours to 1 week of injection.
- Neurologic deficits may be permanent.

ElibeVet.com

PEARLS & CONSIDERATIONS

PREVENTION

- To administer an IV medication, place the needle in the vessel with the syringe unattached.
- An 18-gauge needle or larger is recommended. The pulsations or flow of arterial blood can be seen.
- The tip of the needle can also be palpated in the vein to confirm placement. If unsure of placement, a test dose of the medication may be administered.
- The horse should be monitored for immediate reaction.
- The safest method to prevent intracarotid injection is through a catheter or IM injection.

CLIENT EDUCATION

Any IV medication administered by a needle should be performed by a veterinarian to reduce the risk of intracarotid injection.

EDITORS: **R. REID HANSON** and **AMELIA MUNSTERMAN**

Ionophore Toxicosis

BASIC INFORMATION

DEFINITION

Ionophore toxicosis is caused by the feed additives lasalocid, monensin, narasin, salinomycin, or other ionophores.

SYNONYM(S)

Ionophore antibiotics

EPIDEMIOLOGY

RISK FACTORS Exposure to premixes or feeds designed for other species such as swine, cattle, or chickens

ASSOCIATED CONDITIONS AND DISORDERS Chronic heart damage resulting in congestive heart failure or cardiomyopathy

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute toxicosis
- Delayed heart failure

HISTORY, CHIEF COMPLAINT

- Acute: Horses with ionophore toxicosis may have clinical signs of anorexia, diarrhea, depression, dyspnea, weakness, ataxia, hypermetria, paresis, colic, sweating, groaning, recumbency, paddling, and death.
- Delayed signs: Horses that recover from acute intoxication may develop signs consistent with heart failure. Signs include chronic unthriftiness, poor performance, poor exercise tolerance, cardiac arrhythmias, and sudden death.

PHYSICAL EXAM FINDINGS

- Acute: Elevated heart rate, congested mucous membranes, tachypnea, cardiac arrhythmias, and myoglobinuria
- Chronic: Cardiac arrhythmias, edema, weight loss, exercise intolerance

ETIOLOGY AND PATHOPHYSIOLOGY Ionophores enhance movement of ions through membranes. Increased intracellular calcium is associated with degeneration and necrosis of skeletal and cardiac muscle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Any myopathy, exertional myopathies, pasture myopathy, injection reactions, white snakeroot, rayless goldenrod, coffee senna, blister beetles, other causes of colic.

INITIAL DATABASE

- Myoglobinuria
- Elevated muscle enzymes
- Hyperglycemia

ADVANCED OR CONFIRMATORY TESTING

- Elevated serum cardiac troponin: Best to measure at 24 to 48 hours after exposure
- Analysis for ionophores in feeds or stomach contents
- Echocardiography and electrocardiography findings suggestive of cardiac abnormalities
- Histopathologic findings: Petechiation and pale skeletal or cardiac muscle; degeneration and necrosis of skeletal or cardiac muscle or both; and loss of striation and fiber swelling. Cardiac muscle lesions are generally more prominent than skeletal muscle lesions in horses.
- Animals that die peracutely may not have any histopathologic lesions evident.

TREATMENT

THERAPEUTIC GOALS

- Decontamination if possible
- Symptomatic treatment

ACUTE GENERAL TREATMENT

- Decontamination can be attempted soon after exposure. The efficacy of activated charcoal or mineral oil has not been specifically demonstrated for ionophore toxicosis in horses; however, these agents are generally not contraindicated and are commonly given within hours of exposure.
- Treatment of clinical signs is symptomatic and supportive. There is no antidote available for ionophore intoxication.
- Vitamin E therapy is often given to horses with ionophore toxicosis, although prevention of further muscle degeneration has not been demonstrated.

CHRONIC TREATMENT

Rest

DRUG INTERACTIONS

Some antibiotics can potentiate ionophore toxicity.

POSSIBLE COMPLICATIONS

Cardiac fibrosis resulting in congestive heart failure or cardiac arrhythmias

RECOMMENDED MONITORING

- Serum muscle enzymes
- Serum cardiac troponin
- Electrocardiology
- Cardiac ejection volume, cardiopulmonary flow index

PROGNOSIS AND OUTCOME

Prognosis varies depending on the dosage and treatment. Some horses die acutely with no chance of treatment. Other horses return to former performance after weeks to months of recovery. Some horses develop cardiac

ElibEVet.com

fibrosis and congestive heart failure that can hinder future performance and rarely results in sudden death months after initial exposure.

PEARLS & CONSIDERATIONS

COMMENTS

- For horses, the lowest reported toxic dosage of monensin incorporated into feed is 2 mg/kg of body weight and for lasalocid is 15 mg/kg of body weight.
- The presence of an ionophore in horse feed is not proof of toxicosis. Safety studies of horses consuming cattle feeds that contained the maximum approved concentration of monensin (33 ppm) showed that this did not cause clinical signs of intoxication in horses.
- Ionophore toxicosis most commonly occurs when premixes or feed intended for poultry, swine, or cattle are ingested by horses from feed mixing errors or inadvertent carryover.
- Occasionally, carryover of ionophore-containing feeds in mills or bulk delivery trucks may occur.
- Exercise stress tests, echocardiography, and electrocardiography may be used to determine if an exposed horse can return to athletic use.

PREVENTION

Flush feed bins and trucks used to make or haul ionophore-containing feeds with other untreated grain before loading horse feed.

CLIENT EDUCATION

Do not feed horses premixes or feeds intended for other species.

SUGGESTED READING

Novilla MN: Ionophores. In Gupta RC, editor: *Veterinary toxicology*, New York, 2007, Elsevier, pp 1021–1036.

AUTHOR: **MIKE MURPHY**

EDITOR: **CYNTHIA L. GASKILL**

Ischemia-Reperfusion Injury

BASIC INFORMATION

DEFINITION

- Ischemia is the deficiency of blood flow to tissues or organs.
- Reperfusion is the restoration of blood flow of blood to a previously ischemic tissue or organ.

EPIDEMIOLOGY

SPECIES, AGE, SEX All equine species are affected, but the underlying causes of intestinal injury vary among different age groups.

ASSOCIATED CONDITIONS AND DISORDERS

- Intestinal injury: Strangulating lesions of both small and large intestines, ileus
- Shock: Hypovolemic or endotoxic
- Dehydration

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Severe colic unresponsive to medical management
- Abdominal distension

PHYSICAL EXAM FINDINGS

- Tachycardia (>60 beats/min)
- Tachypnea (>40 beats/min)
- Prolonged capillary refill time (2–3 sec)
- Mucous membranes bright red to purple and tacky to the touch; a toxic line may be present
- Dehydration (enophthalmos, skin tenting)

ETIOLOGY AND PATHOPHYSIOLOGY

- Decreased blood flow to an area minimizes available oxygen for tissues.
- Decreased energy production in endothelial cells leads to cellular degeneration.
- Endothelial cell mitochondrial damage leads to production of cytokines that alert other cells (primarily neutrophils) to migrate to the affected area when perfusion is reestablished.
- The neutrophils that migrate from capillary beds cause the most prominent damage because of their inflammatory response (release of elastase, oxygen radicals, and proteases that attack collagen, ground substance, and cellular membranes).
- Because of the overwhelming inflammatory response during reperfusion, there may be a delayed onset or inhibition of the healing process.
- Areas that have been damaged by reperfusion can expand through inflammation from the initial injury site to surrounding viable tissue and cause irreversible damage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Continued ischemia

INITIAL DATABASE

- Complete blood cell count: Depends on the underlying cause of intestinal issue
- Packed cell volume (PCV) and total protein (TP): Elevation of a PCV (>45%) as well as total protein (>7.5–8.0 g/dL) are indicative of hypovolemia as well as systemic compromise.
- Serum chemistry, including lactate: Electrolyte abnormalities may be appreciated along with elevation in serum lactate resulting from tissue ischemia causing acidosis.
- Abdominal ultrasonography
  - Multiple loops of distended, nonmotile small intestine (5–7 cm in diameter)
  - Edema present within the walls of the small or large intestine.
- Abdominocentesis: Elevation in white blood cell count (>10,000 cells/dL), elevation in protein (>2 g/dL)
- Rectal examination
  - Palpable loops of distended small intestine
  - Large colon displacement with gas distension

ADVANCED OR CONFIRMATORY TESTING

- Coagulation profiles to identify underlying disseminated intravascular coagulation (DIC)

TREATMENT

THERAPEUTIC GOALS

- Correct underlying surgical lesion
- Restore circulating blood volume to ensure appropriate perfusion to tissues

ACUTE GENERAL TREATMENT

- IV fluid therapy (See "Shock Dose Fluid Administration" in Section II)
- Antiinflammatory drugs: Flunixin meglumine, dimethylsulfoxide
- Systemic antibiotics
- Antiendotoxin therapy

POSSIBLE COMPLICATIONS

- Loss of gastrointestinal integrity with absorption of bacteria and bacterial toxins
- Loss of vascular tone

ElibeVet.com

- DIC
- Sepsis
- Death

PROGNOSIS AND OUTCOME

Prognosis and outcome are case dependent based on the underlying lesion.

PEARLS & CONSIDERATIONS

Healing of the affected area has been correlated with the resolution of colic, obstruction, or strangulation. However, fibrosis and residual mucosal inflammation may increase the risk of future colic episodes.

SUGGESTED READING

White NA: Intestinal injury and healing in the horse. In Smith BP, editor: *Large animal internal medicine*, ed 4, St Louis, 2008, Elsevier, pp 702–711.

AUTHOR: **HEATHER DAVIS**

EDITORS: **R. REID HANSON** and **AMELIA MUNSTERMAN**

Ivermectin and Moxidectin Toxicosis

BASIC INFORMATION

DEFINITION

The macrocyclic lactones ivermectin and moxidectin are widely used parasiticides in equine medicine. Although they have a large margin of safety when used as directed, overdose causes central nervous system (CNS) toxicity that can be fatal.

EPIDEMIOLOGY

SPECIES, AGE, SEX Neonates, miniature donkeys, miniature horses, and underweight adult horses are at higher risk of overdose.

RISK FACTORS

- Drug administered: Toxicity is more frequent from the administration of moxidectin than ivermectin.
- Owner administration: Owners frequently do not follow the label directions, and the equine paste and gel formulations are easily overdosed in foals, miniature donkeys, miniature horses, and debilitated adult horses.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Oral overdose of ivermectin at 10 times the label dose or at three times the label dose for moxidectin
- IV administration of bovine formulations
- Onset of CNS signs is immediate after IV injection and within 8 to 12 hours of PO administration.
- Presence of clinical signs as described below if exposure is unknown

PHYSICAL EXAM FINDINGS

- Depression, ataxia, stupor, coma, mydriasis, blindness, tremors, hypersalivation, decreased respiratory rate, and drooping lower lip. In foals, the clinical signs are similar, but in addition, include a protruding tongue, vacant stare, and recumbency.
- Because ivermectin and moxidectin are γ-aminobutyric acid (GABA) agonists, seizures are not seen with toxicity.

ETIOLOGY AND PATHOPHYSIOLOGY

- Equine formulations of moxidectin and ivermectin are dosed at 0.4 mg/kg body weight and 0.2 mg/kg body weight, respectively. Moxidectin is not labeled for use in foals younger than 4 months.
  - Over-the-counter pastes and gels contain enough drug to treat 520 to 600 kg of body weight, and owners frequently administer the entire syringe regardless of the horse's actual weight.
  - At label dosing, the peak plasma concentrations of moxidectin are approximately twice the concentrations of ivermectin.
- Moxidectin is 100 times more lipid soluble than ivermectin, so it distributes to a greater degree in fat and has a much longer plasma elimination half-life (23 days for moxidectin; 4 days for ivermectin).
  - In animals with low fat stores, such as debilitated adults and neonates, plasma concentrations of moxidectin are higher, so the neurotoxic dose is lower.
  - Because neonates have a less developed blood-brain barrier, they appear to be more sensitive to toxicosis.
- Toxicity results from the potentiation of GABA, an inhibitory neurotransmitter.
  - Ivermectin and moxidectin stimulate synaptic secretion of GABA and enhance postsynaptic GABA binding to its receptor site, resulting in open chloride channels and membrane hyperpolarization.
  - P-glycoprotein is the transporter protein of the blood-brain barrier that effluxes these drugs out of the brain, protecting it from GABAergic neurotoxicity.
  - Moxidectin has less affinity than ivermectin for P-glycoprotein, which allows it to penetrate the brain more easily to cause neurotoxicity than ivermectin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- CNS trauma or neoplasia
- Idiopathic Arabian epilepsy (postictal presentation only)
- Viral encephalitides
- Hepatic encephalopathy
- Locoweed toxicity
- Fluphenazine toxicity

INITIAL DATABASE

Routine complete blood count and serum chemistries are typically within normal limits.

ADVANCED OR CONFIRMATORY TESTING

- High-pressure liquid chromatography or enzyme-linked immunosorbent assays can be performed on the liver, brain, fat, gastrointestinal contents, and feces to confirm exposure.
- No specific gross or histopathologic lesions are associated with ivermectin or moxidectin toxicity in horses.

TREATMENT

THERAPEUTIC GOAL(S)

Most affected foals and horses recover with intensive supportive therapy.

ACUTE GENERAL TREATMENT

- Good nursing care and fluid therapy are usually sufficient therapy. Fluid therapy is supportive because macrocyclic lactones are predominantly excreted through bile into the feces, so diuresis does not facilitate elimination.

 ElibeVet.com

- Repeated doses of activated charcoal may limit further intestinal absorption and enhance elimination.
- If the horse is fractious, sedate with IV propofol by continuous rate infusion at the lowest dose that controls clinical signs without causing respiratory and cardiovascular depression.
- Sarmazenil (0.04 mg/kg IV q2h) is a competitive antagonist at the benzodiazepine binding site of the GABA receptor in the CNS. Administration may hasten clinical recovery.
- Physostigmine and picrotoxin have been used for transient relief of ivermectin intoxication symptoms in dogs.
  - Physostigmine is a cholinesterase inhibitor that causes neuronal hypopolarization by increasing postsynaptic sodium conduction. It may cause severe bradycardia, so pretreatment with glycopyrrolate should be considered.
  - Picrotoxin is a chloride channel blocking drug that blocks GABA-mediated postsynaptic hyperpolarization. It has a very narrow safety margin.

DRUG INTERACTIONS

- Do not treat affected foals or horses with benzodiazepines (eg, diazepam) or barbiturates because these drugs potentiate the toxicity of ivermectin and moxidectin and prolong the duration of neurotoxicity. Benzodiazepines increase the frequency of chloride channel opening in the presence of GABA, further hyperpolarizing membranes. Barbiturates increase the duration of GABA-mediated chloride channel opening.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Bladder rupture
- Death

PROGNOSIS AND OUTCOME

With good supportive care, most foals and horses recover within days and are clinically normal. Because of slower elimination, moxidectin toxicity lasts longer than ivermectin toxicity.

PEARLS & CONSIDERATIONS

COMMENTS

IV lipid solution is used in the management of toxicoses in humans from a variety of lipophilic compounds. It has recently been successfully used in the treatment of moxidectin toxicity in dogs. It is thought that the lipid compartment formed in the blood acts as a sink for lipophilic drugs, preventing them from acting on their target receptors.

PREVENTION

When used according to label directions and dosed according to accurate body weight, ivermectin and moxidectin are very safe products for horses.

CLIENT EDUCATION

Owners should carefully dose ivermectin and moxidectin according to actual body weight using a scale or calibrated weight tape. Deworming of neonatal foals is not recommended.

EDITOR: **CYNTHIA L. GASKILL**

Keratitis, Infectious

BASIC INFORMATION

DEFINITION

- Acute or chronic corneal ulcer with associated bacterial, fungal, or viral infection

SYNONYM(S)

- Infected corneal ulcers
- Fungal keratitis
- Bacterial keratitis

EPIDEMIOLOGY

RISK FACTORS

- Any type of ocular trauma
- Feeding hay from hay bags, nets, or balls

GEOGRAPHY AND SEASONALITY

- Infectious keratitis is more common in warm, humid environments.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Bacterial keratitis (Figure 1)
- Fungal (mycotic) keratitis (Figure 2)
- Viral keratitis
- Other infectious keratopathies (parasitic)

HISTORY, CHIEF COMPLAINT

- Corneal ulceration with white to yellow cellular infiltrate, melting corneal ulceration, secondary uveitis

PHYSICAL EXAM FINDINGS

- A corneal ulcer is present when there is a break in the corneal epithelium. Clinically, this results in lacrimation, blepharospasm, photophobia, conjunctival hyperemia, corneal edema, and possibly miosis and aqueous flare. The diagnosis of a corneal ulcer is made based on these clinical signs and fluorescein staining of the cornea. Fluorescein stain will be retained by the underlying stroma and appear green in color.
- A corneal ulcer should be characterized regarding its size, depth, and the presence or absence of cellular infiltration. In addition, the anterior chamber is examined for anterior uveitis. It is essential with all corneal ulcers to attempt to establish the cause of the ulceration and eliminate it.
- The palpebral conjunctiva and bulbar surface of the nictitans are examined for the presence of a foreign body, the blink response and tear film are evaluated, and a complete history is obtained regarding trauma and previous medication. A history of previous topical corticosteroid therapy increases the likelihood of infectious, especially fungal, keratitis.

ETIOLOGY AND PATHOPHYSIOLOGY After a break of the corneal epithelium, opportunistic microorganisms, such as bacteria or fungi, invade the corneal stroma. Cellular infiltrate occurs, and there is release of enzymes, resulting in destruction of the corneal stroma.

ElibeVet.com

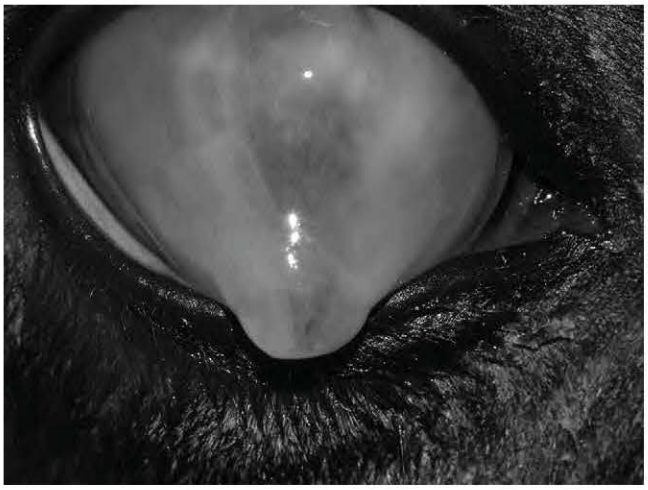

FIGURE 1 Bacterial corneal ulcer in a horse. These are typically called *melting corneal ulcers*.

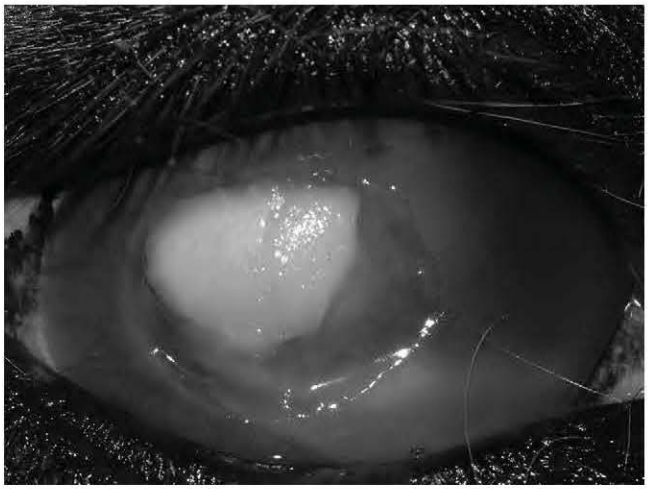

FIGURE 2 Mycotic corneal ulcer in a horse. The white plaque is typical of fungal keratitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of corneal ulceration should be ruled out before a diagnosis is made.

- Foreign body: Burdock bristles
- Ectopic cilia, distichiasis
- Infectious keratitis
- Viral keratitis
- Lagophthalmos (eg, facial nerve paralysis)
- Neurotrophic keratitis (lack of cranial nerve V innervation)
- Chronic trauma

INITIAL DATABASE

- A bacterial and fungal culture should be submitted from all corneal ulcers in the horse. Cultures should be obtained from the margin of the ulcer itself before instilling any therapeutic or diagnostic agents in the eye.
- After a culture has been obtained and the cornea has been fluorescein stained, topical anesthetic is applied, and a scraping is obtained from the ulcer for cytologic examination. The cells are placed on a glass slide and stained to examine for bacteria, fungal hyphae, and cell type. Gram, Giemsa, and Diff-Quik stains work well for examination.
- The presence of gram-negative rods indicates the possibility of an infection with *Pseudomonas* spp. The presence of fungal hyphae is pathognomonic for mycotic keratitis, with *Aspergillus* spp. being the most frequent corneal pathogen. Mixed bacterial and fungal infections are common.

ADVANCED OR CONFIRMATORY TESTING

- Cytologic evidence or isolation by culture of the microorganism is typically confirmatory of infectious keratitis.
- Polymerase chain reaction testing may be more sensitive and specific but is not widely available.

TREATMENT

THERAPEUTIC GOAL(S)

Treatment of infected corneal ulcers in horses is directed at eliminating the causative organism, minimizing corneal enzymatic destruction, and suppressing secondary uveitis.

ACUTE GENERAL TREATMENT

Treatment options reported in horses include:

- Medical therapy
  - Topical broad-spectrum antimicrobials (aggressive; every 2 hours)
  - Topical and systemic antifungals when indicated
  - Systemic nonsteroidal antiinflammatory drugs to control secondary uveitis
- Surgical therapy (if nonresponsive to medical therapy or pending perforation)
  - Conjunctival pedicle graft
  - Corneal and conjunctival graft

CHRONIC TREATMENT

If the lesions persists or if there is pending perforation (ie, depth of corneal ulcer >50% of the cornea), then surgical repair followed by antimicrobial treatment and treatment of secondary uveitis

POSSIBLE COMPLICATIONS

The most common complication is corneal perforation, leading to endophthalmitis, and possibly loss of the eye.

RECOMMENDED MONITORING

Examine daily until the cornea has healed.

PROGNOSIS AND OUTCOME

The prognosis for saving the eye is guarded.

PEARLS & CONSIDERATIONS

COMMENTS

- Infected corneal ulcers are very common in horses.
- They are frustrating to treat and generally take up to 4 to 6 weeks to heal.
- It is essential to have definitive culture and cytology results to specifically direct the antimicrobial therapy.

PREVENTION

- Minimizing ocular and corneal trauma may help prevent the development of infected corneal ulcers.
- Use of a quality fly mask is recommended.
- Feeding hay on the ground is recommended to minimize ocular trauma.

CLIENT EDUCATION

Client communication is essential so that expectations are not too high for quick healing of the corneal ulcer.

SUGGESTED READING

Andrew S, Willis M: Diseases of the cornea and sclera. In Gilger BC, editor: *Equine ophthalmology*, St Louis, 2005, Elsevier, pp 157–251.

AUTHOR & EDITOR: **BRIAN C. GILGER**

ElibeVet.com

Keratitis, Noninfectious

BASIC INFORMATION

DEFINITION

Immune-mediated keratitis (IMMK) is one of the most common noninfectious corneal diseases in horses.

SYNONYM(S)

Chronic equine keratitis

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION None known, although suspected in IMMK

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Clinical features of IMMK are based on the depth of the corneal lesion, and four distinct levels have been described. These include epithelial, superficial stromal (45% of cases) (Figure 1), midstromal (27% of cases), and endothelial (23% of cases). With endothelial IMMK, there is commonly focal or diffuse corneal edema and pigment deposition on or at the endothelial surface. Unilateral presentation of IMMK is most common (85%).

HISTORY, CHIEF COMPLAINT Chronic corneal opacities with mild to moderate cellular infiltrate and vascularization without secondary uveitis or severe ocular discomfort and not associated with infectious agents have been described as IMMK.

PHYSICAL EXAM FINDINGS

- Diagnosis of IMMK is made if there is a progressive or chronic (>3 mo in duration), nonulcerative, recurrent corneal opacity with or without mild signs of keratitis with cellular infiltrate, corneal vascularization, and ocular discomfort (ie, mild epiphora, slight blepharospasm). Other characteristic features include a lack of secondary uveitis or severe discomfort, a lack of microorganisms, and clinical improvement with antiinflammatory medications.
- Superficial stromal keratitis appears as a diffuse, mild to moderate, yellow to white, cellular infiltrate with diffuse superficial vascularization. Mid or deep stromal cellular infiltrate is less common and appears as diffuse, yellow to white, cellular infiltrate with mild surrounding corneal edema and vascularization. Endotheliitis appears as cellular infiltrate at the endothelium with associated diffuse corneal edema.

ETIOLOGY AND PATHOPHYSIOLOGY The possible pathogenesis of IMMK in horses is that the immune system has recognized a self-antigen in the cornea (ie, molecular mimicry) or a foreign protein or organism antigen within the cornea. An underlying infectious agent may be either the inciting or perpetuating cause (or both) in many horses with IMMK. The microorganism may be directly inciting active inflammation or may have induced immunologic cross-reaction with self-antigen in the cornea. Immunologic cross-reaction with self-antigens has been well documented with leptospiral organisms or their DNA in the equine cornea. Further study is warranted to define the pathogenesis of IMMK.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious keratitis (corneal abscessation)
- Keratouveitis
- Corneal squamous cell carcinoma
- Eosinophilic keratitis
- Glaucoma

INITIAL DATABASE

- In cases of epithelial, superficial, or midstromal IMMK (see description below), ocular cytology and culture collection should be attempted to rule out infectious causes of the lesions.
- Complete ophthalmic examination
- Ocular ultraonsonography results should be normal.
- Intraocular pressure (tonometry)

ADVANCED OR CONFIRMATORY TESTING

If the diagnosis is still in doubt, a superficial keratectomy or biopsy should be considered.

TREATMENT

THERAPEUTIC GOAL(S)

Treatment for IMMK depends on the clinical characteristics and type of IMMK that is present. The goals are to control the immune response characteristic of the disease.

ACUTE GENERAL TREATMENT

- Epithelial, superficial stromal, and midstromal IMMK are initially treated with topical neomycin, polymyxin, and dexamethasone (q6h; Alcon Laboratories, Houston, TX) or topical neomycin, bacitracin, and polymyxin (q6h; Bausch & Lomb, Rochester, NY) (eg, after creation of an epithelial defect during diagnostic corneal scraping) with 0.2% cyclosporine topically (q12h; Merck, Whitehouse Station, NJ).
- Topical neomycin, polymyxin, and dexamethasone HCl (q6h) is added after reepithelialization of the corneal wound.
- After the lesion has resolved, neomycin, polymyxin, and dexamethasone are tapered and discontinued, and the topical cyclosporine is maintained at q24h.

CHRONIC TREATMENT

- If the lesions persist, then a superficial keratectomy with or without a conjunctival graft is recommended.
- Several horses have been tapered off all medications after corneal healing with a keratectomy and conjunctival graft.
- The deeper the lesion, the more slowly and incompletely one would expect resolution of the lesions with therapy.

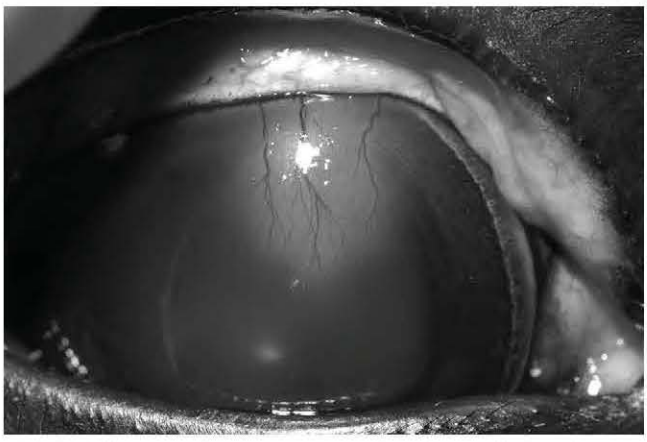

FIGURE 1 Superficial immune-mediated keratitis in a horse.

ElibVet.com

POSSIBLE COMPLICATIONS

The most common complication is the formation of infectious keratitis secondary to chronic topical steroid use.

RECOMMENDED MONITORING

Reexamine monthly until the disease is under control; then every 3 months.

PROGNOSIS AND OUTCOME

Prognosis is good for superficial lesions but poor for endothelial lesions.

PEARLS & CONSIDERATIONS

COMMENTS

- IMMK should be considered in horses with chronic, minimally painful corneal cloudiness.
- Infectious keratitis is more common, so be careful with use of topical corticosteroids, which will worsen infectious keratitis.

PREVENTION

Minimizing ocular and corneal trauma may help prevent the development of IMMK. Use of a quality fly mask is recommended.

CLIENT EDUCATION

IMMK can be controlled in most horses but not cured. The owner must be informed that persistent treatment to keep the eye clear may be required.

Lameness of the Carpus

BASIC INFORMATION

DEFINITION

The equine carpus, often referred to as the "knee," consists of three main joints. The most proximal joint, the radiocarpal (antebrachial) joint, is composed of the radius proximally and the proximal row of carpal bones distally. The middle carpal joint is located between the proximal and distal row of carpal bones. In 50% of horses, the first carpal bone is present in the distal row and is located medial and palmar to the second carpal bone. The fifth carpal bone is rare but can occasionally be found lateral to the fourth carpal bone. The carpometacarpal joint is composed of the distal row of carpal bones proximally and the second, third, and fourth metacarpal bones distally. The radiocarpal and middle carpal joints are high-motion joints and never communicate. The middle carpal joint and carpometacarpal joints always communicate, and the radiocarpal joint occasionally communicates with the carpal sheath.

SYNONYM(S)

Lameness of the knee

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Injury to the carpus can occur at any age. Thoroughbred and Quarter Horse racehorses are predisposed to some of the injuries mentioned below, but they can happen to any breed.
- Angular limb deformity (ALD) is primarily seen in young foals and is associated with developmental orthopedic disease. It can be the result of asymmetric growth of the distal radial metaphysis or distal radial epiphysis, incomplete development of the cuboidal bones or proximal second and fourth metacarpal bones, or joint laxity. If left untreated, ALDs can result in permanent deformity and chronic, progressive lameness because of osteoarthritis (OA). ALDs can occasionally be seen in adult horses, but they are usually related to traumatic injury to the carpus.

RISK FACTORS Any athlete that undergoes highly repetitive loading, such as a racehorse, is predisposed to injury to the carpus.

ASSOCIATED CONDITIONS AND DISORDERS OA may be a primary issue or may be secondary to intracapsular conditions of the carpus.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most commonly, horses present with a history of front limb lameness. Occasionally, the chief complaint is carpal joint effusion or the horse is "moving wide," and the owner may not appreciate a noticeable lameness.
- Horses with ALDs, whether they are foals or adult horses, present with a history of abnormal angulation to the front limbs. The angulation originates from the carpus. With traumatic injuries in the adult horse, lameness is often associated with the ALD. Lameness may not be appreciated in foals.

PHYSICAL EXAM FINDINGS

- On palpation, joint effusion in the radiocarpal joint or middle carpal joint may be evident. Effusion can be identified with the horse standing and is typically a reliable indicator of carpal synovitis. Pain is often elicited by pressing upward on the carpal bones during flexion in horses with chip or slab fractures of the carpal bones.
- Decreased range of motion of the carpus may be noted.
- A positive response to flexion of the carpus during a lameness examination also indicates that the carpus or the soft tissues around the carpus is the source of lameness. When asked to trot, the horse may try to minimize carpal flexion and will thus trot with the forelimbs abducted.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Carpal bone fracture
- Carpal bone chip (osteochondral) fragment
- OA of the radiocarpal joint or middle carpal joint
- Subchondral bone sclerosis
- ALD
- Injury to intercarpal ligaments

INITIAL DATABASE

- The initial evaluation should include a thorough lameness evaluation, including flexion tests. If the carpus is suspected as the source of lameness, then a full series of carpal radiographs should be obtained. A minimum of six radiographic views should be obtained, including the dorsopalmar, lateromedial, dorsolateral-palmaromedial oblique, dorsomedial-palmarolat-

ElibeVet.com

eral oblique views, skyline view (dorsoproximal-dorsodistal) of distal row of carpal bones, and a flexed lateromedial view. If the concern is in the proximal row of carpal bones, a skyline view of the proximal row of carpal bones should be taken.
- Intraarticular anesthesia is often the definitive diagnosis for localizing the carpus as the source of lameness.

ADVANCED OR CONFIRMATORY TESTING

- Nuclear scintigraphy can be used to further localize carpal injury when radiograph results are negative or equivocal for any abnormalities. The sensitivity is high, but the specificity is low, so specific localization is unlikely. Nuclear scintigraphy can be useful to diagnose early stress-related subchondral bone injury or to quantify the importance of a lesion visualized with radiography.
- Arthroscopy can further qualify the source of lameness in the carpus. Arthroscopy may be a treatment option as well as a diagnostic tool. The degree of OA can be quantified by visualizing cartilage erosions or proliferative synovium. Tearing of an intercarpal ligament can be identified, and osteophytes can be localized and removed. Arthroscopy can be used to remove chip fragments or to aid in lag screw placement for slab fractures.

TREATMENT

THERAPEUTIC GOAL(S)

- Stabilize fractures
- Remove fragments
- Stimulate healing (microfractures)
- Assess the full extent of injury with arthroscopy
- Control synovitis

ACUTE GENERAL TREATMENT

Very rarely do injuries to the carpus require immediate treatment. Situations that require immediate treatment are often related to traumatic fractures that result in severe instability of the carpus. Most injuries to the carpus are subtle and may be present for a length of time before a diagnosis is made. After a definitive diagnosis has been made, treatment may revolve around removing the inciting cause, stabilization of fractures, or control of synovitis.

CHRONIC TREATMENT

- Synovitis related to OA can often be controlled with intraarticular medications such as hyaluronic acid and corticosteroids, autologous conditioned serum (ACS) or interleukin-1 receptor antagonist protein (IRAP) or polysulfated glycosaminoglycans. To obtain the full effect of intraarticular medications, it is important to first address the inciting cause of OA (ie, removal of osteochondral [chip] fragments). Treatment with extracorporeal shockwave therapy has also been useful for treatment of lameness related to the carpus.
- Often rest and nonsteroidal antiinflammatory drug therapy are the most important aspects of a treatment regimen for horses with carpal injuries. Racehorses with subchondral bone sclerosis and osteophyte formation benefit from extended rest of 3 to 4 months.

PROGNOSIS AND OUTCOME

- Prognosis for injury to the carpus depends on a number of factors, including but not limited to the severity of clinical signs, severity of cartilage damage, duration of lameness, and level of competition.
- Horses in the early stages of mild to moderate disease can often be managed with a favorable prognosis.
- Advanced OA or severe disease warrants a guarded prognosis.

Lameness of the Elbow and Shoulder

BASIC INFORMATION

DEFINITION

Injuries and lameness associated with the upper forelimb, cubital joint, or scapulohumeral joint

EPIDEMIOLOGY

SPECIES, AGE, SEX Young horses are predisposed to osteochondrosis and cystlike lesions. Osteoarthritis is usually found in mature horses. Traumatic injuries may occur in any age group.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute, severe lameness of the elbow or shoulder region may be associated with a fall or crashing into a solid object. The horse will shift weight to the opposite limb and will often stand with the carpus slightly flexed.
- In motion, the horse may have a shortened anterior phase to the stride, especially if the biceps tendon or bicipital bursa is affected.
- Upper forelimb fractures usually result in non–weight-bearing lameness. If nerve injury has occurred, the primary complaint may be muscle atrophy over the shoulder, abduction of the shoulder during weight bearing, or dropped elbow.

PHYSICAL EXAM FINDINGS

- Mild upper forelimb lameness may be difficult to localize. Horses with fractures and luxations will not bear weight on the affected limb, will have localized swelling, and often stand with the carpus partially flexed. If the olecranon is displaced or the radial nerve is damaged, the horse will have a dropped elbow.
- Manipulation of the fracture will cause significant pain and may have auscultable and palpable crepitus.
- Stress fractures or enostoses may have no outward signs whatsoever except for acute lameness.
- Soft tissue injuries may have only a shortened anterior phase to the stride because swelling of the affected tissue is often not observed.
- Nerve injuries may result in abaxial displacement of the shoulder at the walk ("Sweeney shoulder"), dropped

ElibeVet.com

elbow, or muscle atrophy. Horses with septic arthritis will usually not bear weight on the affected limb.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Osteoarthritis: Usually a mild but progressive lameness that is relieved with intraarticular anesthesia
- Fractures: Olecranon, proximal radius, humerus, scapula
- Luxations: Elbow luxations are usually associated with proximal fractures of the radius; shoulder luxations are very rare
- Osteochondrosis: Very uncommon in the elbow but is recognized infrequently in the shoulder, particularly the glenoid fossa
- Osseous cyst: May be found in the proximal radius and rarely in the distal humerus
- Stress fracture: Common in racehorses and may be found in the proximal caudal, distal cranial, or caudal aspects of the humerus
- Enostosis (stress reaction, bone islands): Usually only recognized after scintigraphy and high-detail radiography
- Collateral ligament desmitis of the elbow: Usually associated with trauma
- Bicipital bursitis: May be caused by blunt force trauma or strain of the overlying tendon
- Biceps tendinitis
- Nerve injury to the suprascapular nerve, brachial plexus, or radial nerve
- Septic arthritis

INITIAL DATABASE

- Lameness evaluation with complete palpation of the upper limb. Comparative palpation of the contralateral limb often provides a baseline to determine the significance of findings. Manipulative tests of the upper limb often do not assist localization.
- Diagnostic anesthesia should be used to rule out the lower limb and then intraarticular anesthesia of the upper limb synovial structures should be done to localize the lameness.
- Radiography of the affected area should always be performed.

ADVANCED OR CONFIRMATORY TESTING

- Nuclear scintigraphy should be performed if diagnostic anesthesia does not help localize the lameness and evaluation of radiographs does not lead to a diagnosis.
- Ultrasonography helps determine if soft tissue injury is a component of the lameness.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce inflammation to reduce pain.
- Identify and stabilize recognized fractures.
- Provide appropriate rest and rehabilitative exercise

ACUTE GENERAL TREATMENT

- Osteoarthritis: Nonsteroidal antiinflammatory drugs (NSAIDs), oral joint support such as glucosamine/chondroitin, injectable systemic joint support such as polysulfated glycosaminoglycans or hyaluronan, and intraarticular injection with hyaluronan and corticosteroids. If the patient is not responsive to the aforementioned treatments, injection with autologous conditioned plasma should be considered.
- Fractures: Displaced fractures should be repaired and stabilized. Horses with incomplete or some nondisplaced fractures may respond favorably to stall confinement. In many cases, the horse must be prevented from lying down by using a "high line." On a high line, the horse is attached by a short rope from the halter to a carabiner clipped to a wire that runs over the top of the stall. The wire usually is placed from one corner diagonally to the other well above the horse's head. The horse is tied short enough to prevent lying down but long enough to allow reaching strategically placed water, hay, and feed.
- Luxations: Acute displacements without attendant fractures may be reduced under general anesthesia. The horse must have an assisted recovery and should often be put on a high line.
- Osteochondrosis: Usually requires arthroscopic evaluation and debridement
- Osseous cyst: If accessible from the joint, it may be debrided under arthroscopic control. A periarticular approach under radiographic control for debridement or injection of corticosteroid should be done if not accessible arthroscopically. IV tiludronate has also been used to successfully treat bone cysts.
- Stress fracture: Stall rest and handwalking over approximately 3 months. Gradual return to work using a controlled exercise program after that time. Recurrence is unusual.
- Enostosis: As for stress fracture
- Collateral ligament desmitis of the elbow: Rest for 4 to 9 months with restriction of free exercise and progressively increasing controlled exercise. Consider facilitating healing by injection of platelet-rich plasma, stem cells, or both.
- Bicipital bursitis: Injection with hyaluronan and corticosteroids
- Biceps tendinitis: As for collateral ligament desmitis
- Nerve injury: Suprascapular nerve entrapment or injury may be treated with surgery to notch the cranial aspect of the scapula and allow decompression of the nerve. Excessive notching may predispose the scapula to fracture. Radial nerve paresis without attendant fracture and trauma to the brachial plexus usually resolves with rest, NSAIDs, and parenteral corticosteroids alone or in combination. In acute nerve injury, dimethyl sulfoxide may be administered IV to reduce inflammation and swelling.
- Septic arthritis: Joint lavage, intraarticular and parenteral antibiotics, and NSAIDs

CHRONIC TREATMENT

Horses with osteoarthritis may require long-term supportive care as described for acute treatment.

POSSIBLE COMPLICATIONS

Any injuries involving the articular surfaces may result in osteoarthritis.

PROGNOSIS AND OUTCOME

- Osteoarthritis: The prognosis depends on the horse's response to treatment. This condition usually requires long-term management.
- Fractures: Horses with nondisplaced fractures without an articular component have a good prognosis for soundness. Horses with displaced fractures that require fixation usually have a guarded prognosis because of the difficulty in maintaining the stability of the fracture during healing, the possibility of infection, and the potential for laminitis in the contralateral limb.
- Luxations: Always a guarded prognosis and dependent on the ultimate level of joint stability and degree of osteoarthritis
- Osteochondrosis: Guarded prognosis for athletic soundness, particularly for large glenoid fossa lesions
- Osseous cyst: Often a guarded prognosis, even with surgical debridement
- Stress fracture: Good prognosis for full athletic use
- Enostosis: Usually a good prognosis for athletic function
- Collateral ligament desmitis of the elbow: Guarded prognosis for athletic

 ElibeVet.com

soundness, often complicated by osteoarthritis
- Bicipital bursitis: Often a favorable prognosis but may depend on response of concurrent tendinitis
- Biceps tendinitis: Favorable prognosis for acute injuries; poor for chronic injuries
- Nerve injury: Usually a slow, months-long convalescence that may result in complete recovery if the injury is mild
- Septic arthritis: Prognosis is favorable if treated aggressively early after occurrence

AUTHOR & EDITOR: **ANDRIS J. KANEPS**

Lameness of the Heel Region

BASIC INFORMATION

DEFINITION

Lameness caused by soreness originating at the palmar or plantar aspect of the foot

SYNONYM(S)

Palmar heel pain, navicular syndrome, heel soreness

EPIDEMIOLOGY

SPECIES, AGE, SEX
- Quarter Horse, Thoroughbred, and Warmblood breeds are most commonly affected.
- The average age at onset is 9 years (range, 3–18 years), but the average for Warmbloods is 7 years.

GENETICS AND BREED PREDISPOSITION Horses with small feet and a large body size are predisposed.

RISK FACTORS
- Predisposing factors include a long toe or an underrun heel; a long, sloping pastern; and small feet with a large body mass.
- Horses used for jumping or used frequently on hard footing are also predisposed.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- There are numerous causes of pain in the palmar aspect of the foot. These causes can be arbitrarily divided into conditions of the hoof wall and horn-producing tissues, conditions of the third phalanx, and conditions of the navicular region. Hoof problems include hoof wall defects, contusions of the hoof causing bruising or corn formation, abscess formation, and thrush or canker. Third phalanx lamenesses blocked out by palmar digital anesthesia include wing fractures, marginal fractures, solar fractures of the distal phalanx, and deep digital flexor insertional tenopathy.
- Conditions of the navicular region include distal interphalangeal synovitis, deep digital flexor tendinitis, desmitis of the impar (distal navicular) ligament or collateral sesamoidean ligaments, navicular osteitis or osteopathy, and vascular disease.

HISTORY, CHIEF COMPLAINT Chronic, recurring forelimb lameness that is most evident on hard ground or when the horse is worked in circles

PHYSICAL EXAM FINDINGS The lameness is usually mild to moderate but may be intermittently severe. It usually affects the front feet and is bilateral in most cases. The onset is chronic and insidious, yet owners frequently complain of sudden onset of lameness. The gait is often short and choppy at a trot, and lameness is exacerbated in a circle.

ETIOLOGY AND PATHOPHYSIOLOGY Excessive stress on the structures of the heel results in wear and tear of the flexor surface of the navicular bone and associated soft tissue structures.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Heel pain not associated with the navicular structures
- Bruising of the sole
- Fractures of the palmar aspect of the distal phalanx or the navicular bone
- Coffin joint arthrosis
- Pedal osteitis
- Digital sheath synovitis
- Tendinitis of the distal deep digital flexor tendon, superficial digital flexor tendon, or distal ligaments of the proximal sesamoid bones

INITIAL DATABASE

- Lameness examination
- Diagnostic local anesthesia (palmar digital nerve block)
- Contrast-enhanced computed tomography
- Radiography

ADVANCED OR CONFIRMATORY TESTING

- Intraarticular diagnostic anesthesia of the distal interphalangeal joint or navicular bursa
- Nuclear scintigraphy
- Magnetic resonance imaging
- Ultrasonography

TREATMENT

THERAPEUTIC GOAL(S)

- Correct hoof imbalance and provide corrective shoeing.
- Provide antiinflammatory treatment.
- Follow up to judge the effect of treatments.

ACUTE GENERAL TREATMENT

- Adjust hoof angles to reduce stress on heel structures (usually by raising the heels).
- Correct lateral-to-medial hoof imbalance.
- Ease breakover with rolled toe and shoe set back from the natural toe.
- Provide concussion protection with a full pad or rim pad.
- Administer nonsteroidal antiinflammatory drugs (NSAIDs) for 3 to 4 weeks.
- If lameness is severe, consider navicular bursa or distal interphalangeal joint injection with hyaluronan and corticosteroids.

CHRONIC TREATMENT

- Horses with navicular bone pain may be treated with the bisphosphonate drug tiludronate (Tildren; CEVA Sante Animal, Libourne, France). This medication is not currently approved by the Food and Drug Administration.
- If the horse has a limited response to initial therapy, consider advanced imaging with computed tomography or magnetic resonance to identify more clearly the specific cause of the pain.
- If the horse has a limited response to shoeing and NSAIDs, consider palmar digital neurectomy.

ElibVet.com

RECOMMENDED MONITORING

- Reevaluate hoof angles and shoeing 3 to 6 months after making the initial changes.
- Monitor the level of lameness as needed.

PROGNOSIS AND OUTCOME

- Shoeing alone is a very effective method for treating horses with heel pain and navicular syndrome.
- When lameness is not resolved, consider reevaluation of the shoeing protocol, direct medication of the navicular bursa, and advanced imaging.

PEARLS & CONSIDERATIONS

Maintaining good hoof balance is the most important preventive step.

AUTHOR & EDITOR: **ANDRIS J. KANEPS**

Lameness of the Hip and Pelvis

BASIC INFORMATION

DEFINITION

Lameness that originates in the hip and pelvis is uncommon in most horses.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute non–weight-bearing lameness or finding a horse down and unable to rise may indicate a fracture of the pelvis or proximal femur or coxofemoral luxation.
- Acute, severe lameness that resolves substantially with rest may indicate an ileal stress fracture or fracture of the tuber coxae.
- Progressive lameness that initially responds to nonsteroidal antiinflammatory drugs (NSAIDs) may be associated with osteoarthritis.

PHYSICAL EXAM FINDINGS

- Horses with coxofemoral luxation, fracture of the tuber coxa, and long-standing lameness have observable physical abnormalities such as a leg length discrepancy, displaced tuber coxa, and gluteal muscle atrophy, respectively. With most pelvic fractures, the horse will have no outward signs apart from severe lameness.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Osteoarthritis of the coxofemoral joint
- Fractures: Proximal femur, capital femoral fracture (Salter-Harris type 1 fracture), ileal shaft, ileal wing, acetabulum, tuber ischium, tuber coxa ("knocked-down" hip)
- Stress fracture of the ileal wing: Commonly found in young racing Thoroughbreds but difficult to identify without scintigraphy
- Coxofemoral luxation: With or without fractures of the proximal femur or acetabulum
- Sacroiliac injuries (see "Sacroiliac Joint Disorders" in this section)
- Muscle injuries or myositis (see "Back Pain," "Nutritional Myopathy," "Polysaccharide Storage Myopathy," and "Rhabdomyolysis" in this section)

INITIAL DATABASE

- The complete lameness evaluation should include palpation and visualization of the pelvic musculature. Severe lameness of chronic duration will result in atrophy of the gluteal muscles on the affected side.
- Manipulation of the hind limbs to stress the hip joint (adduction of each hindlimb) may help localize the soreness.
- A rectal examination should be done if a pelvic fracture is suspected.
- The pelvis or hind limb should be manipulated and the horse walked during the rectal exam to determine if instability is palpable. Some pelvic fractures cannot be detected on rectal palpation.
- Radiography and ultrasonography should be done when appropriate. High-quality radiography of the pelvis and hip of adult horses is only possible under general anesthesia. Induction and recovery from anesthesia may displace pelvic fractures that could lacerate the internal pudendal vessels, resulting in fatal hemorrhage. Ultrasonography may be done externally and per rectum to determine the continuity of the pelvic bones and sacrum and to evaluate the hip.

ADVANCED OR CONFIRMATORY TESTING

Nuclear scintigraphy of the lower back, pelvis, and upper hind limbs is often the best means to anatomically localize injuries in this area. This technique is done with the horse standing to minimize the risk to the horse from laceration of the pelvic vessels by fracture fragments.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce inflammation to reduce pain.
- Provide appropriate rest and rehabilitative exercise.

ACUTE GENERAL TREATMENT

- Osteoarthritis of the coxofemoral joint: The most immediate treatment is with NSAIDs. Injection of the coxofemoral joint is not easily accomplished, but intraarticular hyaluronan and corticosteroids may be administered.
- Fractures: Most fractures of the proximal femur and pelvis cannot readily be reduced and stabilized. Treatment for most fractures consists of stall rest for 3 to 6 months. A high line to prevent the horse from lying down may be useful for many pelvic fractures in which displacement may result in fatal hemorrhage.
- Stress fracture of the ileal wing: Rest and rehabilitative exercise often result in a return to work.
- Coxofemoral luxation: Usually not treated because of the grave prognosis for even pasture comfort.

ElibVet.com

CHRONIC TREATMENT

Osteoarthritis often requires long-term management with NSAIDs, oral or injectable joint support medications, and repeated intraarticular injections.

POSSIBLE COMPLICATIONS

Pelvic fractures of the ileal body or acetabulum may displace and lacerate the major vessels within the pelvis, resulting in fatal hemorrhage.

RECOMMENDED MONITORING

Response to rest and medication should be monitored with a follow-up lameness evaluation and imaging or rectal palpation as appropriate for the injury.

PROGNOSIS AND OUTCOME

- Osteoarthritis of the coxofemoral joint: Guarded for long-term soundness as an active high-level athlete but depends on response to treatment
- Fractures: Horses with fractures of the tuber coxa and tuber ischium and stress fractures of the ileum have a good prognosis for return to athletic use. Horses with fractures of the proximal femur and ileal body and wings with little displacement have a fair prognosis for pasture soundness. Horses with capital femoral and acetabulum fractures have a grave prognosis for soundness in adults. Acetabular fractures in foals with minimal displacement may have a fair to good prognosis for soundness.
- Stress fracture of the ileal wing: Good prognosis for return to athletic soundness
- Coxofemoral luxation: Grave prognosis for pasture soundness

AUTHOR & EDITOR: **ANDRIS J. KANEPS**

Lameness of the Stifle

BASIC INFORMATION

DEFINITION

Soreness that originates within the stifle and associated soft tissues that causes lameness

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses from 6 months to 2 years of age may present with osteochondrosis of the stifle.

GENETICS AND BREED PREDISPOSITION Fast-growing, large-breed horses are predisposed to osteochondrosis (Warmbloods, Quarter Horses).

RISK FACTORS Horses that use a high degree of hindlimb impulsion, such as dressage, jumper, cutting or reining horses, may be more likely to experience stifle injury.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Horses with traumatic injuries present with acute, moderate to severe lameness often after a fall or encounter with a hard object such as a fence or wall. Horses with osteochondrosis may also have a history of acute lameness with turnout or exercise that may subside somewhat with restriction of activity. Complete upward fixation of the patella results in the horse dragging its limb behind its body because of the inability to flex the joint. Most horses with stifle injuries have effusion of the joints as a presenting complaint.

PHYSICAL EXAM FINDINGS Effusion, lameness, localized to the stifle with manipulative tests, and intraarticular anesthesia. With upward fixation of the patella, the horse may lock the stifle, making it unable to advance the limb.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Osteoarthritis: Often associated with osteochondrosis or cystlike lesions, joint instability
- Soft tissue injury: Patellar ligament desmitis, intermittent or complete upward fixation of the patella, meniscal injury, meniscal ligament injury, collateral ligament desmitis, cruciate ligament desmitis, synovitis
- Developmental orthopedic disease: Osteochondrosis, cystlike lesions
- Trauma: Fractures or luxation of the patella, fracture of the intercondylar eminence of the proximal tibia, distal femur or proximal tibia, tibial crest fracture or avulsion
- Infection: Septic arthritis

INITIAL DATABASE

- Lameness examination with manipulative tests (full limb flexion, localized stifle flexion, cruciate ligament stress test, stress of the medial collateral ligament).
- Diagnostic anesthesia to localize the lameness. To completely desensitize the stifle, all three joints should be blocked.
- Radiography, ultrasonography, or both.

ADVANCED OR CONFIRMATORY TESTING

If the lameness is subtle or could not be localized with diagnostic anesthesia, nuclear scintigraphy may be indicated.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce pain and inflammation.
- Treat the inciting cause (eg, debride osteochondrosis lesions).
- Provide rehabilitative exercise to strengthen the hindlimbs and lower back.

ACUTE GENERAL TREATMENT

- Osteoarthritis: Nonsteroidal antiinflammatory drugs (NSAIDs), oral joint support such as glucosamine/chondroitin, injectable systemic joint support such as polysulfated glycosaminoglycans or hyaluronan, or intraarticular injection with hyaluronan and corticosteroids or polysulfated glycosaminoglycans. If not responsive to the aforementioned treatments, injection with autologous conditioned plasma should be considered.
- Soft tissue injuries: Rest, NSAIDs, extracorporeal shock wave therapy, diagnostic arthroscopy with possible debridement of meniscal and cruciate injuries
- Developmental orthopedic disease: Arthroscopic debridement of osteochondrosis lesions and cystlike lesions,

ElibVet.com

ultrasonographic or arthroscopically guided injection of corticosteroid in cystlike lesions, rest with follow-up radiography in young horses without significant lameness.

- Intermittent upward fixation of the patella: Build strength in the quadriceps muscles by backing for 5 to 10 minutes twice daily, working over ground poles, and walking up and down hills if the horse is capable of that type of work without excessive upward fixation. If not responsive to strengthening, consider medial patellar ligament splitting or transection. Horses with complete upward fixation may need medial patellar ligament transection to permit ambulation.
- Fractures: Small, nonarticular patellar fractures heal with fibrous union after rest. Larger articular or horizontal patellar fractures may be repaired with screws or wires but have a high incidence of fixation failure. Moderate-sized articular patellar fractures may be evaluated arthroscopically, and the fragments may be removed.
- Other fractures: Arthroscopic evaluation should be done for all articular fractures to determine the extent and condition of associated soft tissues. Extraarticular fractures of the tibia or femur may require internal fixation.

CHRONIC TREATMENT

Intraarticular injections of hyaluronan and (if appropriate) corticosteroids may help return the joint to a comfortable state.

POSSIBLE COMPLICATIONS

- Intraarticular injuries may result in secondary osteoarthritis.
- Soft tissue injuries may require prolonged time for healing (6–9 months).

RECOMMENDED MONITORING

Follow-up lameness evaluation and radiography is indicated to determine the condition of the joint(s).

PROGNOSIS AND OUTCOME

- Soft tissue injuries: Prognosis for soundness depends on the extent of injury because horses with mild to moderate injuries have a fair prognosis for soundness but those with extensive soft tissue injuries have a guarded prognosis.
- Osteochondrosis lesions that are debrided in horses younger than 2 years have a fair to good prognosis for soundness. Horses with cystlike lesions treated arthroscopically also have a good prognosis. Conservative treatment for either condition results in soundness about 50% of the time.
- Horses with patellar upward fixation usually respond favorably to rehabilitative exercise and to surgical treatment if it is necessary.
- Fractures that are not articular and heal with rest or fixation have a good prognosis for soundness. Intraarticular fractures with minimal joint disruption may also have a good prognosis, but injuries that result in osteoarthritis may require management of the arthritis.

PEARLS & CONSIDERATIONS

Localization of the lameness and detailed imaging are required to make a specific diagnosis.

SUGGESTED READING

AUTHOR & EDITOR: **ANDRIS J. KANEPS**

Lameness of the Tarsus

BASIC INFORMATION

DEFINITION

Conditions of the tarsal bones or joints that result in lameness

SYNONYMS

Hock soreness, spavin

EPIDEMIOLOGY

SPECIES, AGE, SEX There is no species or sex predilection. Juvenile horses may present with developmental orthopedic disease or traumatic injuries. Mature horses may present with degenerative conditions such as osteoarthritis (OA) or traumatic injuries.

RISK FACTORS Premature birth or neonatal sepsis may predispose to incomplete mineralization of the cuboidal bones. Fast-growing young horses are predisposed to osteochondrosis. Mature horses with straight hindlimb conformation may be predisposed to OA.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Neonatal incomplete mineralization of the tarsal bones often results in abnormal conformation of the tarsus ("sickle hock"). The foal may be reluctant to stand.
- Trauma usually causes acute, moderate to severe lameness with accompanying soft tissue swelling or effusion.
- OA usually causes varying levels of stiffness and reluctance to change canter leads, jump, or drive forward using the hindlimbs.

PHYSICAL EXAM FINDINGS Varying degrees of lameness depending on the cause

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Neonatal: Incomplete mineralization of the cuboidal bones
- Mature: OA of the distal tarsal joints
- Any age: Trauma resulting in fracture; luxation; desmitis of collateral ligaments; osteomyelitis or septic arthritis involving the tarsal sheath, sustentaculum tali, or tuber calcis

INITIAL DATABASE

- General physical and lameness examinations, including flexion tests if appropriate
- Radiography

ADVANCED OR CONFIRMATORY TESTING

Diagnostic ultrasonography if soft tissue involvement is possible

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce and manage pain.
- If trauma or incomplete mineralization is a cause, confine to a stall.
- Treat the inciting cause if trauma or infectious origin.

ElibVet.com

ACUTE GENERAL TREATMENT

- Nonsteroidal antiinflammatory drugs (NSAIDs) are very useful for most causes of tarsal pain.
- External coaptation with cast or bandage may be needed to provide more stability of the tarsus for luxations, incomplete mineralization, or fractures.
- Antibacterial medications should be administered if an open wound or infection is present.

CHRONIC TREATMENT

For OA, the hierarchy of treatment from minimal to most effective is (1) oral joint support supplements such as those containing glucosamine and chondroitin, (2) NSAIDs (parenteral or topical), (3) intraarticular medication such as hyaluronan and steroids, and (4) facilitated ankylosis of the affected joints.

RECOMMENDED MONITORING

- Lameness should be monitored until the problem resolves or the situation is at a manageable level.
- Radiographic evaluations should be made at appropriate intervals (often every 6 to 12 months).

PROGNOSIS AND OUTCOME

The outcome depends on the disease process. OA is usually manageable for most uses of the horse, fractures may heal with resultant OA that may require management, and incomplete mineralization of cuboidal bones may resolve without problems or result in juvenile OA caused by malformation of tarsal articulations.

Laminitis, Acute

BASIC INFORMATION

DEFINITION

- A painful inflammatory condition of the hoof-lamellar interface (HLI) that causes lameness, abnormal hoof growth and appearance, and separation of the hoof from underlying dermal connective tissue.
- The affected HLI is permanently weakened and predisposed to recurrence.

SYNONYM(S)

Founder

GENETICS

- Pony breeds at greater risk than are horse breeds.
- Acute laminitis and sloughing of the hoof in foals is a component of junctional epidermolysis bullosa in the Belgian and American Saddlebred breeds.
- One report of laminitis in a foal resulting from inherited deficiency of the plectin protein (a critical cytoplasmic component of hemidesmosomes).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Classification of laminitis categories
  - Acute laminitis: Hoof lamellar inflammation has been activated for the first time and is associated with pain.
  - Chronic laminitis:
    - The HLI has been compromised by the laminitic condition.
    - May or may not be associated with pain at any one time
    - Acute laminitis evolves into chronic laminitis at some arbitrary point.
    - There is evidence of abnormal hoof growth on physical examination.
  - Developmental laminitis
    - Period of time that transpires between the onset of an acute laminitis-provoking event and the first signs of acute laminitis (eg, endotoxemia associated with acute typhlocolitis)
    - HLI is compromised and at risk for structural failure (acute laminitis)
  - Endocrinopathic laminitis: Acute or chronic laminitis arising in the context of underlying hormonal influence such as hypercortisolism or insulin resistance
    - Pasture-associated laminitis: Acute or chronic laminitis arising in the context of grazing pasture grasses
    - Weight-bearing (contralateral limb) laminitis: Acute laminitis arising in an opposite limb as a complication of primary lameness in any limb

PHYSICAL EXAMINATION FINDINGS

- The clinical presentation of acute laminitis differs depending on which foot and in how many feet the disease develops.
- More common in adult horses than in foals (affected foals may have genetic disease).
- Most commonly presents as severe pain affecting both forelimbs.
- Pain-associated conjunctival membrane injection
- Tachycardia
- Tachypnea
- Characteristic apprehensive facial expression
- Reluctance to move
- Stiffness
- Subcutaneous edema of the distal limbs (because of reduced mobility)
- Affected feet are often warm
- Digital arterial pulses are very prominent ("bounding" pulses)
- Recumbency
- Reluctance to move or to stand up
- When forced to stand and bear weight, stiffness and a characteristic stance make it clear that acute laminitis has developed.
- Horses stop moving around in their environment.
- Tendency to "oscillate in situ" (attempting to seek a comfortable stance by transferring the center of gravity toward the pelvis and shifting the weight between both forelimbs).
- The pelvic limbs are drawn forward under the body and both forelimbs are extended out in front of the body.
- Horses walk in a manner such as to reduce weight bearing by the dorsal aspect (toe) of the forefeet, preferring to extend the forelimbs and bear greater weight at the heel.
- Walking movements are careful, slow, and deliberate, and the patient tends to bear increased weight in the pelvic limbs, giving rise to the descriptor "walking on eggshells."

ElibeVet.com

- Systemic signs of pain such as sweating, trembling, muscle fasciculations, and rapid breathing
- Shaking of the affected limbs (especially affected pelvic limbs)
- Hoof pain is accentuated by turning sharply on a hard surface.
- Moving affected horses on hard surfaces may worsen laminitis and convert subtle signs of stiffness and lameness into a more severe and clinically prominent manifestation.
- Serosanguineous discharge at the coronary band (intracapsular necrosis)
- Sloughing of the affected hoof or hooves (exunguilation)
- Unwillingness to bear weight on the opposite affected hoof (difficult to pick up the foot)
- "Resting" the opposite limb after one hoof has been picked up for examination and released
- The strength of the digital arterial pulses increases during the examination as a result of forcing the patient to bear weight.
- Coronary band develops a trough/shelf or depression
- Hemorrhage at the coronary band (coronary vessel rupture)
- Hoof testers yield a pain reaction at the toe (both false-positive and -negative reactions to hoof testers)
- Signs of preexisting laminitis may be evident, including prominent circumferential growth rings in the hoof wall, palmar or plantar divergence of growth rings, broadening of the white line zone, and the development of a "dropped" sole.
- Conservative paring of the sole may reveal flecks of hemorrhage as a result of either chronic or acute laminitis.
- Sudden or unanticipated "improvement" in the extent to which weight is borne by the primary limb during fracture management (implicative for laminitis in the contralateral limb)
- Laminitis may develop in one hoof when a sufficiently severe inflammatory process is present within the hoof for other reasons (eg, unresolved sole abscesses, nail or other foreign body penetrations, or exercise on hard surfaces ["road founder"]).

DIAGNOSIS

- Medical history
- Inspection and physical examination of all four feet
- Plain film radiography is essential for purposes of corroborating the diagnosis, characterizing the severity and extent of laminitis, and establishing the baseline appearance of the affected foot for purposes of monitoring responses to treatment and making a prognosis.

RADIOGRAPHIC CHARACTERIZATION

- It is important to emphasize the value of a meticulous approach for the acquisition of valuable and meaningfully diagnostic radiographic images.
- Acquisition of helpful radiographic metrics necessitates excellent lateromedial projection technique.
- Zero hoof-to-film distance minimizes magnification and standardizes the resulting images for serial comparisons during treatment.
- Use a radiopaque marker at the dorsal aspect of the hoof (starting at the point at which the coronary band connects with the hoof wall).
- Specific components of the lateromedial view of the equine hoof that should be carefully scrutinized include:
  - The palmar/plantar angle of the third phalanx (angle of palmar margin of the third phalanx relative to the bearing surface of the hoof)
  - The hoof-lamellar (H-L) zone width (distance between the outer surface of the dorsal aspect of the hoof wall and the dorsal aspect of the third phalanx; usually measured at a point just distal to the pyramidal process and also at the distal tip of the third phalanx)
  - The distance between the extensor process and the coronary band (vertical distance between the dorsal limit of the pyramidal process and the point at which the haired skin stops at the coronary band)
  - The sole depth at the tip and at the wing of the third phalanx
  - Evidence of remodeling or fracture of the third phalanx (implicative for chronic laminitis)
- Reference measurements in healthy hooves
  - The palmar/plantar angle of the third phalanx should be positive and in the range of 3 to 5 degrees.
  - The H-L zone width should be between 15 and 19 mm depending on the size of the horse.
  - The vertical distance between the pyramidal process and the coronary band should not exceed approximately 14 mm.
  - Sole depths at the tip and at the wing of the third phalanx are generally given as 20 and 23 mm, respectively.
- Dorsopalmar/plantar views of the affected hoof are essential for identification of (uncommon) axial rotational displacements of the third phalanx and for complete characterization of bone pathology that develops in cases of chronic laminitis.
- Readers are directed to more extensive descriptions (see Suggested Reading) for more information.

DIFFERENTIAL DIAGNOSIS

- Any condition causing inflammation in the hoof (positive response to hoof testers, results of distal limb anesthesia, pronounced digital arterial pulse strength)
- Sole abscess
- Nail binding
- Foreign body perforation
- P3 fracture
- Navicular bone fracture
- Distal interphalangeal joint inflammation
- Deep solar bruising
- Some other conditions may be mistaken for acute laminitis by virtue of clinical signs associated with abnormal stance, reluctance to move, or protracted periods of recumbency.
  - Polysaccharide storage myopathy
  - Tetanus
  - Botulism
  - Equine motor neuron disease
  - Colic
  - Rhabdomyolysis
  - Vertebral trauma
  - Protozoal myelitis
  - Hyperkalemic periodic paralysis
  - Aortic or iliac thrombosis

INITIAL DATABASE

- Physical examination data (including vital signs)
- Radiographic images
- Hematology and plasma biochemical profile (primary inflammatory condition elsewhere in the body)
- Etiologic test protocols (eg, fecal microbiology)
- Endocrine testing

ADVANCED OR CONFIRMATORY TESTING

- Retrograde digital venography
- Computed tomography
- Magnetic resonance imaging

TREATMENT

GENERAL PRINCIPLES

- Treat underlying or predisposing primary conditions (examples include restoration of the circulation during management of typhlocolitis, administration of effective antimicrobial agents for the treatment of gram-negative pleuropneumonia, and the removal of placental remnants and irrigation of the uterus after placental retention in mares).
- Prevent access to ingested laminitis-inducing toxins and drugs (eg, corticosteroids).

ElibeVet.com

- Expedient institution of effective emergency treatment for acute laminitis may both impede progression of the disease and serve to rescue the HLI.
- Be skeptical of many unfounded and unscientific treatment approaches.
- Clinical improvement could be a result of either the action of treatment or the natural progression of the disease.

LAMINITIS PREVENTION DURING THE DEVELOPMENTAL PHASE OF LAMINITIS

- The HLI is at risk during the developmental phase; institute laminitis prevention strategies.
- Restrict patient movements.
- Further injury to the HLI may be prevented with the provision of sole support in the form of deep bedding, Styrofoam pads; Lily pads; or a fast-setting, customized two-component silicone rubber insert against the sole.
- Sole support must not exert pressure between the sole and the point toward which the third phalanx might be displaced (just in front of the point of the frog).
- Consider application of foot casts (eg, plaster of Paris).
- Avoid very hard, inflexible surfaces such as concrete.
- Accommodate on deep sand, pea gravel, thick shavings, or peat moss.
- Additional strategies intended to promote stability of P3 include removing shoes (if worn) and simply providing a deeply littered bedding.
- Rasp the dorsal aspect of the toe to facilitate breakover.
- Special reusable tape-on shoes (Redden modified Ultimate shoes) may be used in conjunction with silicone putty applied over the palmar/plantar aspect of the sole or frog. (These shoes also provide heel elevation, if indicated, to reduce the tensile pull of the deep digital flexor tendon and a "rolled" toe that serves to move the point of breakover to a more palmar/plantar location, thus relieving forces on the dorsal aspect of the HLI.)
- Optimize circulation (blood volume and plasma colloidal oncotic pressure).
- Address endotoxemia as needed (eg, polymixin B).
- Administer nonsteroidal antiinflammatory drugs (NSAIDs) such as phenylbutazone.
- Continuous distal limb cryotherapy (3°–5° C) is well tolerated for up to 7 days and has been shown to be very safe and effective.
- Avoid dietary strategies that might promote hyperglycemia (eg, feeding grain).

TREATMENT OF ACUTE LAMINITIS

- Restrict patient movements.
- Do not discourage the patient from lying down.
- Provide deep, soft bedding to minimize the risk of decubital ulcers.
- Continuous distal limb cryotherapy may be helpful for the management of acute laminitis.
- Provide sole support (see previous section).
- Consider using a sling to reduce pressure in the HLI.

DRUGS USED FOR THE MANAGEMENT OF ACUTE LAMINITIS

- It is important to emphasize that scientifically validated drugs do not exist for the predictably successful prevention or treatment of laminitis.
- Drug strategies include analgesic drugs, drugs intended to promote blood flow, and antiinflammatory drugs.
- Strive to reduce pain (humane consideration; reduction of pain might promote blood flow).
- Note that reduction of pain may worsen damage in the HLI.
- NSAIDs such as phenylbutazone (2.2 mg/kg IV q12h), flunixin meglumine (1.1 mg/kg IV q12h), ketoprofen (2.2 mg/kg IV q24h), or firocoxib (0.1 mg/kg PO q24h) may be administered to reduce inflammation in the HLI and to improve comfort.
- Phenylbutazone is the most commonly used NSAID for management of laminitis.
- Use of firocoxib for the management of laminitis is untested.
- Use of other NSAIDs (eg, naproxen) in horses should be considered carefully because pharmacologic data are either not available or suggest that oral bioavailability may be unsatisfactory.
- Strategies that might minimize NSAID toxicosis should be considered because protracted administration of NSAIDs is associated with risk of gastrointestinal ulceration and renal papillary necrosis.
- Reduce the dependence on effective NSAID administration by using other drugs that have different pharmacologic mechanisms of (analgesic) action.
- Butorphanol tartrate: 0.03 to 0.05 mg/kg, IM q6h
- Dimethyl sulfoxide (DMSO): 0.5 to 1.0 g/kg mixed as a 10% solution in physiologic crystalloid
- Tramadol: 2 mg/kg PO q8–12h (Data supporting demonstrable analgesic effect and appropriate dose for horses are lacking; low bioavailability PO.)
- Gabapentin: 3 to 10 mg/kg PO q8h (data supporting demonstrable analgesic effect and appropriate dose for horses are lacking; low bioavailability PO; should be given at lower doses if there is hypoproteinemia because this is a protein-bound drug.)
- Ketamine hydrochloride: 0.25 to 0.5 mg/kg IM q8h (Use as a "rescue" analgesic on days when pain is worse to avoid giving more NSAIDs.)
- Pentoxifylline: 8 to 10 mg/kg PO q8–12h (Should be given at lower doses if there is hypoproteinemia because this is a protein-bound drug.)
- Acetyl-L-carnitine: 0.02 mg/kg PO q24h (Advocated for treatment of neuropathic pain; evidence for value to reduce diabetic peripheral neuropathy in humans.)
- Transdermal fentanyl patches seem to be ineffective for the management of laminitic pain. Compared with other species, extremely high serum concentrations of fentanyl are needed for significant antinociceptive action in horses. It is unlikely that application of fentanyl patches to the skin will accomplish these high serum concentrations and, if they work, it is likely that the patient would be affected with significant central nervous system excitation
- Misoprostol (5 µg/kg PO q12h) and omeprazole (2–4 mg/kg PO q24h) may be co-administered with NSAIDs to reduce the risk of ulceration of the gastrointestinal tract.
- When faced with severe pain in a hospitalized setting, further relief may be provided via an IV constant-rate infusion (CRI) of one or several other analgesic drugs. Selected drugs may include butorphanol tartrate, detomidine hydrochloride, xylazine hydrochloride, acepromazine, ketamine hydrochloride, and lidocaine hydrochloride.)
- Administration of morphine sulfate (0.1 mg/kg in 50 mL isotonic saline) via an epidural catheter
- Drugs that may inhibit activated matrix metalloproteinases in the HLI include oxytetracycline (7.5 mg/kg IV q12h) and pentoxifylline (8–10 mg/kg q12h)
- Drugs that have been advocated for the management of laminitis based on their purported ability to promote perfusion of the HLI include nitroglycerine, isoxsuprine hydrochloride, aspirin, heparin, and pentoxifylline. However, studies undertaken to demonstrate a benefit for HLI perfusion have yielded negative or conflicting results.

FARRIERY

- There are many approaches, but the best results occur when there is a good veterinarian–farrier team.

ElibVet.com

- There is no all-encompassing treatment that works best for all cases of laminitis.
- Planning should be based on the physical and radiographic appearance of the affected hoof.
- Nailing on a shoe may be detrimental to the stability of the HLI.
- Consider removal of shoes and provision of sole support.
- Overgrown hoof wall should be trimmed judiciously to promote breakover in the developmental or acute stages of laminitis.
- Application of permanent therapeutic shoes should be delayed until 4 to 6 weeks after the acute phase of laminitis has transitioned into the chronic phase and HLI stability has been established.
- Serial radiographic examinations are essential (assessment of response and progress).
- Commonly used farriery techniques that often meet the needs of the foundered patient include trimming back the toe to facilitate breakover and reduce (detrimental) loading stresses in the dorsal aspect of the HLI, provision of palmar/plantar support (heel wedge or elevation) to offset tension on the HLI resulting from the pull of the deep digital flexor tendon, resection of the aspects of the hoof capsule that have become undermined by necrosis and infection, and hoof wall resection or grooving of the coronary band to promote restoration of hoof wall growth.

EUTHANASIA

- Severe laminitis and specific physical findings may warrant consideration of euthanasia.
- Prognosis is unfavorable if signs of pain are refractory and unresponsive to analgesics.
- Sunken or collapsed coronary band (especially when evident throughout the circumference of the coronary band)
- Prolapse of the coronary band
- Complete physical separation of the hoof capsule from underlying connective tissues (exunguilation)
- Radiographic evidence of infection involving the third phalanx, air densities resulting from intracapsular separation during the acute phase of the disease, vertically oriented distal displacement ("sinking")
- A satisfactory outcome for the treatment of a case of laminitis characterized by solar attenuation (<15 mm) and a reduced (<2 degrees) or negative palmar/plantar angle of the third phalanx should be regarded as challenging.
- Severe reduction of hoof perfusion using retrograde digital venography or perfusion scintigraphy points to an unfavorable prognosis.

RISK FACTORS

- Idiosyncratic and genetic predisposition
- Evidence of preexisting chronic laminitis
- Ponies are at greater risk than horses.
- Any primary lameness
- Extensive unresolved intracapsular inflammation
- Endocrinologic risk factors (obesity, hypercortisolism, insulin resistance, pregnancy)
- Dietary risk factors include those associated with ingestion of specific plants (noted above)
- Feeding either forage (pasture or hay) or concentrates (grain) that contain high concentrations of simple sugars, starch, or oligofructans
- Standing or exercising on hard, inflexible surfaces (eg, concrete) for prolonged periods of time
- Medical conditions that are characterized by gastrointestinal ulceration or endotoxemia (systemic inflammation)

EDITOR: **PHILIP J. JOHNSON**

Laminitis, Chronic

BASIC INFORMATION

DEFINITION

- A painful inflammatory condition of the hoof-lamellar interface (HLI) that causes lameness, abnormal hoof growth and appearance, and separation of the hoof from underlying dermal connective tissue
- The HLI has been compromised by the laminitic condition.
- May or may not be associated with pain at any one time
- Acute laminitis evolves into chronic laminitis at some arbitrary point.
- There is evidence of abnormal hoof growth on physical examination.
- The development of chronic laminitis is an inescapable consequence of the acute laminitic condition, whatever the cause.
- When laminitic pain is diagnosed for the first time in a horse with hoof growth changes and radiographic abnormalities implicative for underlying chronic laminitis, the episode is usually referred to as subacute laminitis.
- Insidious-onset, chronic laminitis may result from underlying endocrinopathic influences such as insulin resistance or corticosteroid influence and is commonly identified in horses that have been grazing pastures ("pasture associated laminitis" [PAL]).
- Also classified depending on the clinical behavior of the condition over time
- Recurrent, exacerbative, or refractory (chronic) laminitis is characterized by repetitive and recurrent bouts of activated inflammation in the HLI that cause progressive deterioration of the integrity of the hoof and persistent pain.
- Chronic subacute laminitis refers to the situation in which pathologic changes in the HLI are recognized by the abnormal manner with which the affected hoof has grown but tends not to be so readily associated with pain and lameness.

SYNONYM(S)

Founder

CLINICAL PRESENTATION

- Abnormal hoof growth is usually evident with or without pain (lameness).
- When present, lameness and hoof pain are similar to those described for

ElibeVet.com

acute laminitis (see "Laminitis, Acute" in this section).
- When exercised on hard ground, chronically affected horses are likely to develop bilateral forelimb lameness, and the digital arterial pulses become transiently prominent.
- Visual inspection of the hoof reveals prominent circumferential growth lines, palmar/plantar divergence of the growth lines, bunching up of growth lines at the dorsal aspect of the hoof, slippering of the toe, broadening of the white line zone (especially at the toe), seedy toe, solar convexity, and heel contracture.
- Conservative paring of the solar aspect of the hoof often reveals flecks of hemorrhage.
- The chronically foundered hoof is prone to developing recurrent sole abscesses.
- Coronary band develops a trough/shelf or depression.

DIAGNOSIS

- May be diagnosed several days after the development of painful acute laminitis (see "Laminitis, Acute" in this section)
- May also be diagnosed based on observation of characteristic physical abnormalities observed on examination of the hoof (see above) in the absence of overt signs of pain or lameness
- The patient may develop bilateral lameness and increased prominence in the digital arterial pulse strength when exercised on hard ground surfaces.
- Confirmed by radiography
- Examine the patient for evidence of underlying predisposing endocrinopathy such as pituitary pars intermedia dysfunction (PPID) and equine metabolic syndrome (EMS).
- Endocrinologic tests performed on horses affected with laminitis may yield falsely positive results as a result of stress and pain (cortisol response and reduced insulin sensitivity).

RADIOGRAPHY

See section on hoof radiography in "Laminitis, Acute" in this section.

TREATMENT

GENERAL PRINCIPLES

- The two essential goals are pain management and restoration of the structural integrity of the hoof.
- The athletic capability of many affected horses will be reduced or nullified as a consequence of laminitis.
- Sometimes the prognosis for severe laminitis is unfavorable and warrants euthanasia.
- Emphasize to the owner that the prognosis may become clearer after some time has passed to allow the effects of treatment to be assessed and that treatment may be labor intensive and lengthy.
- Be cautious about enthusiastically encouraging horse owners to pursue treatment for severe laminitis without first discussing the fact that it might not be effective.
- Specific treatments for chronic laminitis are applied to the continuum of treatments started when acute laminitis first occurred.
- Treatments that must be addressed include both those pertaining to rehabilitation of the affected hoof and those that promote the general health of the patient.
- Treatment and management of chronic laminitis is usefully addressed under the following categories: rest and stall confinement, stabilization of P3, pain management, hoof trimming and farriery, surgical treatments, nutritional factors, endocrinopathic factors, and miscellaneous
- There are no validated reports for the predictably successful prevention or treatment of laminitis using drugs.
- Both rehabilitation of the affected hoof and the prognosis depend on new hoof growth. (The rate of new hoof growth along a chronically diseased HLI is slower than it is in the healthy horse.)
- When successful, the management of chronic laminitis typically requires at least 6 to 12 months of closely invested care.

REST AND STALL CONFINEMENT

- The patient's movement should be restricted (large stall confinement) to minimize further mechanical damage and to promote healing of the HLI.
- Premature exercise (eg, as soon as signs of hoof pain have abated) often causes further damage to the HLI (and pain).
- Allow time to establish stability in the HLI akin to the value of stabilization during bone fracture repair.
- Limited and strictly regulated hand-walking exercise should only be contemplated after evidence has been demonstrated that the HLI has stabilized (see below).

STABILIZE P3

- Although it is not possible to completely stabilize P3 in the same manner that internal fixation techniques may be used to immobilize bone fractures, strategies aimed at promoting stability of P3 within the hoof capsule are helpful from the perspectives of both pain management and optimal healing (promoting reestablishment of the normal relationship between P3 and the hoof capsule).
- Effective stabilization of P3 inhibits further damage to the compromised HLI.
- Evaluation of the effectiveness of stability-promoting strategies includes observation of a reduction in pain (especially after pain medications such as phenylbutazone are withdrawn) and (objectively) the use of serially acquired hoof radiographs.
- Radiographic evidence of stability can be attributed to the effects of stability-promoting treatments as well as the effects of healing.
- Provision of stability is intended to relieve loading of the compromised aspects of the HLI (commonly at the dorsal aspect of the hoof) and redistribute loading to the more palmar/plantar aspects of the HLI and the ground-bearing surface of the hoof (sole and frog).
- Stability may also be promoted by reducing the turning force ("moment") acting on the dorsal HLI by the pull of the deep digital flexor tendon (DDFT) through the distal interphalangeal joint.
- Reduction of the distal interphalangeal joint moment is not recommended for horses affected by distal displacement of the (entire) third phalanx ("sinking").
- Stability promoting strategies include restriction of movement, removing the patient's shoes (standing on regular shoes tends to increase tension in the HLI), and simply providing a deeply littered bedding.
- The provision of sand or pea gravel for bedding is often helpful.
- Patients should not be discouraged from lying down.
- Support to the sole or frog may also be provided in the form of high-density styrofoam cut to the shape of the hoof and attached using tape.
- Other commonly used treatments include the application of Lily pads to the frog, silicone putty, and plaster of Paris casts applied to fill in the concavities of the sole.
- The dorsal aspect of the wall at the toe should be beveled using a rasp to facilitate breakover.
- Specially designed reusable tape-on shoes (Redden modified Ultimate shoes) can be used in conjunction with silicone putty applied over the palmar/plantar aspect of the sole or frog to provide heel elevation (if indi-

ElibeVet.com

cated) to reduce the tensile pull of the DDFT and a "rolled" toe that serves to move the point of breakover to a more palmar/plantar location.

PAIN MANAGEMENT

- It is important from the perspective of humane consideration to reduce the systemic consequences of pain-associated stress and facilitate weight redistribution to reduce the risk of laminitis at other locations (increased loading).
- Analgesic treatments that were initiated for acute laminitis are generally continued into the chronic phase.
- Promoting stability of P3 within the hoof capsule is important from the perspective of reducing pain (see above).

HOOF TRIMMING AND FARRIERY

- Complete discussion of surgical farriery for chronic laminitis is beyond the scope of this chapter; readers are directed elsewhere (see Suggested Reading below).
- There is not a single shoeing method or approach that is uniformly effective for all cases of chronic laminitis.
- Before embarking on substantial trimming or the application of therapeutic shoes, sufficient time should have transpired after the acute phase of laminitis to allow for stabilization of the HLI (attenuation of the degradative processes and the facilitation of healing).
- Trimming and farriery should be considered approximately 4 to 8 weeks after onset of acute laminitis.
- "Normal farrier landmarks" for trimming and application of shoes are not applicable (position of P3 with respect to the hoof capsule has changed as a consequence of mechanical failure in the HLI).
- Optimal approach entails discussion between veterinarian and farrier and must be based on current hoof radiographs.
- Special shoes are not needed in all cases. Chronic laminitis may be managed by simply trimming the affected hoof (especially if solar depth is adequate).
- Targets for trimming include establish a normal angle of alignment between P3 and the ground surface, reduce the "breakover distance" (the distance between the hoof wall or shoe ground contact and the distal margin of P3), and maintain sole depth (in the healthy hoof, there normally exists a positive angle between the solar margin of P3 and the ground of 2 to 5 degrees).
- If adequate tissue healing and growth occur, the normal (parallel) relationship between the dorsal aspects of P3 and the hoof capsule should be reestablished (a relatively long-term objective that will not be achieved in all cases).
- Evaluate the thickness of the sole, especially in the dorsal part of the sole.
- Sole thickness is ideally 15 to 20 mm or greater at the dorsal aspect of the hoof near the tip of P3.
- If the solar depth is sufficient, the hoof may be trimmed with a single plane of flatness at the weight-bearing surface (if there is insufficient solar depth at the dorsal part of the sole, trimming will cause bruising, pain, and instability).
- If solar depth is insufficient, it must *not* be trimmed, and a special shoe, intended to support weight at the palmar aspect of the hoof and to relieve weight bearing at the dorsal aspect, should be helpful. (Trimming for purposes of establishing a normal angle of alignment between P3 and the ground surface can then only be undertaken at the palmar or plantar aspect of the hoof by creating two separate planes of flatness on the weight-bearing surface.)
- Trimming the palmar aspect of the hoof increases tension in the DDFT and may cause further pain. (Additional pain-reducing treatments such as temporary heel elevation, further nonsteroidal antiinflammatory drug [NSAID] administration, or solar padding may be indicated at this time.)
- Three important principles for selection of an appropriate shoe are position of the facilitated point of breakover, whether to provide support for the weight-bearing surfaces of the sole and the frog, and whether to elevate the heels.
- Moving back the point of breakover reduces stress in the dorsal aspect of the HLI and can be accomplished by several shoe design principles such as simply rolling or squaring the toe (taking care to preclude pressure at the sole), setting the shoe back to the more palmar aspect of the hoof, or using a curved or "rocker" shoe.
- Shoeing methods that promote weight-bearing support at the sole or frog include the use of a simple bar or heart bar, incorporation of pads, and insertion of a synthetic composite (eg, silicone putty) between a pad and the frog.
- Heel elevation reduces the pull of the DDFT, diminishes tension in the dorsal HLI, and is helpful for foundered horses that tend to walk by bearing weight on the toe first.
- Heel elevation may be accomplished using wedge pads or wedged shoes or through the application of rails.
- An especially practical approach that uses many of the principles discussed using a plywood-based wooden construct for shoeing foundered horses has been recently described (see Suggested Reading below).

SURGICAL

- Resection of part of the hoof wall is indicated when underlying connective tissue is infected. (Resection of parts of the dorsal hoof wall may minimize stress in the underlying HLI during breakover.)
- Resection of the hoof wall (to relieve the tourniquet effect of the hoof wall) has been advocated as a potential salvage procedure (in preference to euthanasia) for extreme cases (eg, sinking).
- Grooving of the coronary band may be considered as an alternative to extensive hoof wall resection; provision of a groove just below the coronary band serves to disconnect the (potential) new wall growth from the more distal wall. (This procedure may both stimulate new wall growth and promote better alignment between the new growth and P3.)
- Transection of the DDFT may be used to reduce tensile stress in the dorsal HLI (generally regarded as a salvage procedure because most treated horses will not return to athletic performance).

NUTRITIONAL FACTORS

- Dietary energy content should meet the needs of a physically inactive convalescent patient without being excessive and without causing starvation.
- The patient's rations must provide sufficient protein and should be appropriately balanced from the perspective of meeting mineral and vitamin requirements.
- Feeding should be undertaken on a continual or semi-continual basis.
- Discourage provision of intermittent glycemic meals (prevent glucose and insulin spiking).
- Dietary strategies should be aimed at reversing obesity (if present).
- Pasture grazing should be discouraged.
- Obtain laboratory analysis of forage and do not provide forage with a high nonstructural carbohydrate (NSC) content (>12% on a dry-matter basis).
- The NSC content of some hay may be reduced by soaking in water for 60 minutes.

ENDOCRINOPATHIC FACTORS

- Horses with PPID-associated chronic laminitis should be managed using orally administered low-dose pergolide, cyproheptadine, or trilostane.

ElibVet.com

- Metformin (15–20 mg/kg PO q6–8h) may be administered to EMS-affected horses to promote insulin sensitivity
- Thyroxine (Thyrol-L) may be administered to EMS-affected horses to promote insulin sensitivity and weight loss.

MISCELLANEOUS

- Supplementation with vitamins such as biotin may promote healing and strengthen the hoof tissues (poorly supported by the scientific literature).
- Antibiotic treatment (coupled with appropriate surgical drainage) should be considered if chronic laminitis has been complicated by infection (infection may arise in either or both P3 and the solar/HLI connective tissues).
- Consider IV regional digital perfusion of antibiotics.
- Intraosseous infusion of the distal phalanx as a delivery route targeting the HLI. (Infusion of a drug into P3 leads to effective and high concentrations of the drug within the HLI, facilitating use of expensive and powerful drugs for "topical" localized treatment with less concern for oral bioavailability or toxic systemic side effects.)

RECOMMENDED MONITORING

- Careful attention to the growth of the hoof
- Signs of pain may vary over time.
- Maintain records of the patient's pain or lameness. These observations will be keyed to use of analgesic drugs such as phenylbutazone.
- Photographic documentation (every 8 weeks) of the appearance of the surface of the hoof
- Radiographic records (every 2–6 months) of the appearance of P3 and its position with respect to the hoof capsule
- Records of body condition score and feeding program
- Monitoring for evidence of NSAID-induced gastrointestinal ulceration (colic, inappetence, decreased passage of feces, bruxism, hypoalbuminemia, and anemia) or renal disease (water consumption, urinalysis, and plasma creatinine concentration)

SPECIFIC FINDINGS SUGGESTIVE OF AN UNFAVORABLE PROGNOSIS

- Signs of pain that are refractory and unresponsive to analgesic medication
- Development of a sunken or collapsed coronary band (especially when this abnormality is evident throughout the circumference of the coronary band)
- Prolapse of the coronary band
- Complete physical separation of the hoof capsule from the underlying connective tissue (exunguilation)
- Radiographic evidence of infection involving the third phalanx
- Radiographic demonstration of vertically oriented distal displacement ("sinking") is also implicative for an unfavorable prognosis.
- Although the severity of capsular rotation of the third phalanx has been traditionally regarded as useful for prognosis, a more useful marker for prognosis before embarking on the treatment of laminitis may be the thickness of the sole coupled with the angle of palmar margin of P3 relative to the weight-bearing surface of the hoof.
- Satisfactory outcome for the treatment of a case of laminitis characterized by solar attenuation (<15 mm) and a reduced (<2 degrees) or negative angle should be regarded as challenging.
- Either retrograde digital venography or perfusion scintigraphy may be used to demonstrate severe reduction of hoof perfusion (indicating an unfavorable prognosis).

EUTHANASIA

- Severe refractory, chronic laminitis may warrant consideration of euthanasia.

Large Colon: Congenital Abnormalities

BASIC INFORMATION

DEFINITION

Abnormal development of the large colon resulting in alterations in the anatomy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Foals with atresia coli present within the first days of life.
- Information on other congenital abnormalities of the large colon is restricted to case reports, personal communications, and clinical experience; therefore accurate information on epidemiology is not available. Because of the congenital cause of the problem, it is presumed that horses with defects that result in signs of abdominal disease will be relatively young at presentation. However, one case report described a 27-year-old mare, illustrating that horses of any age may be affected.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Described malformations associated with signs of abdominal pain include atresia coli, diverticula, duplication cyst, and defects in the mesentery.

HISTORY, CHIEF COMPLAINT Clinical signs are variable depending on the abnormality.

- Foals with atresia coli present with acute, sometimes severe signs of colic and abdominal distension. Complete lack of fecal production is a hallmark clinical sign.
- The presence of a diverticulum may result in intermittent impaction or obstruction, resulting in signs of recurrent colic.
- In the case report describing a large duplication cyst, the affected horse had clinical signs of recurrent colic and a pendulous abdomen.
- Defects within the mesentery allow displacement or volvulus of the colon through the defect, resulting in signs of colic; there have been no reports of

ElibVet.com

strangulation of the segment of the intestine.

PHYSICAL EXAM FINDINGS Findings on physical examination during an episode of colic will be consistent with a nonstrangulating obstruction, including tachycardia, abdominal distension, decreased or absent borborygmi, and signs of dehydration.

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause and heritability of these congenital defects is unknown because of the low number of cases reported.
- The defects may result in obstruction caused by alterations in the flow of ingesta or extraluminal obstruction associated with displacement or volvulus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of colic and lack of fecal production in foals: Meconium impaction, lethal white syndrome, and acute colitis.
- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal (GI) tract such as feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large intestinal intraluminal obstructions, small colon impactions, and ileal impactions.
- Other causes of large intestinal distension on examination per rectum: Feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large colon volvulus, and other intraluminal obstructions.

INITIAL DATABASE

- Atresia coli
  - Foals with atresia coli have no meconium staining when their rectal temperature is taken and after repeat enemas.
  - Contrast studies of the GI tract (barium swallow or enema) are diagnostic.
- Other congenital abnormalities
  - Findings on examination per rectum vary depending on the defect. Distension of the large colon or cecum secondary to obstruction or impaction of the large colon is possible.
  - Nasogastric reflux is unexpected.
  - Bloodwork is expected to be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
  - Abdominal fluid analysis is expected to be within normal limits.

TREATMENT

THERAPEUTIC GOAL(S)

- Removal or repair of congenital defect
- Supportive care

ACUTE GENERAL TREATMENT

- Surgical exploration is required for diagnosis and repair of the defect.
- Personal communications on attempts to bypass atresia coli indicate that success may be limited because of concurrent disease and abnormalities in motility adjacent to the affected segment.
- Resection of the affected portion has been reported to be curative in cases of diverticula.
- Closure of the mesenteric defect has been reported to be curative in cases of mesenteric defects.

PROGNOSIS AND OUTCOME

If surgical correction is possible, prognosis appears good with the exception of atresia coli.

PEARLS & CONSIDERATIONS

Congenital defects of the large colon are an uncommon cause of colic in horses.

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Large Colon: Impaction (Feed)

BASIC INFORMATION

DEFINITION

Obstruction of the flow of ingesta, gas, or both in the large colon by dehydrated feed material

SYNONYM(S)

Feed impaction, impaction, pelvic flexure impaction

EPIDEMIOLOGY

SPECIES, AGE, SEX Appears most common in horses older than 1 year of age

GENETICS AND BREED PREDISPOSITION Clinical experience suggests that Miniature Horses may be predisposed.

RISK FACTORS Numerous risk factors have been suggested or identified, including:

- Change in activity: Increased stall time, change in exercise program, transport
- Diet: High-grain diet
- Stall vices: Cribbing and windsucking
- Concurrent disease: Hospitalization, recent lameness
- Parasites: More than 12 months since use of ivermectin or moxidectin
- Dental prophylaxis
- Medications: Amitraz, atropine, glycopyrrolate, morphine, general anesthesia, nonsteroidal antiinflammatory drugs (NSAIDs); the effect of NSAIDs on motility is poorly understood and controversial

GEOGRAPHY AND SEASONALITY Clinical experience suggests that changes in weather may predispose horses to the development of large colon impactions. Cold water associated with cold weather may decrease water consumption and increase the risk.

ASSOCIATED CONDITIONS AND DISORDERS Infiltrative inflammatory disease and neurologic dysfunction of the large colon associated with large colon impactions have been reported.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Large colon impactions can be separated into primary and secondary subtypes. This entry focuses on primary impactions. However, large colon impaction may occur secondary to other conditions. Secondary impactions are associated with other large colon obstructions such as right dorsal displacement (impaction within the right dorsal colon), enteroliths, feca-

ElibeVet.com

liths, bezoars, and foreign bodies (see chapters on these conditions).
- Dehydration of feed material within the large colon is frequently associated with small intestinal obstructions (so-called "secondary impactions"). Although this is not a true impaction (ie, it does not obstruct the flow of ingesta), differentiation can be difficult.

HISTORY, CHIEF COMPLAINT

Horses with large intestinal impactions present with signs of mild to moderate abdominal pain (colic) and decreased to absent fecal production. Historical findings may indicate any of the risk factors identified in the epidemiology section.

PHYSICAL EXAM FINDINGS

- Horses with large intestinal impactions are generally cardiovascularly stable with signs of mild to moderate dehydration and mild elevation in heart rate (associated with pain).
- Other findings may include mild to moderate abdominal distension and decreased or absent borborygmi.

ETIOLOGY AND PATHOPHYSIOLOGY

- Risk factors described in the epidemiology section likely affect motility, particle size of feed material, and water content of ingesta.
- The most common intestinal sites for impaction are areas where the lumen size decreases. The pelvic flexure–left ventral colon is the most common site for impaction because the lumen dramatically narrows at the left dorsal colon. The right dorsal colon and transverse colon are other common sites because of narrowing as the ingesta passes into the transverse and small colons, respectively.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal (GI) tract such as sand impaction, enterolithiasis, large colon displacements, large intestinal intraluminal obstructions, tympany, small colon impactions, and ileal impactions
- Other causes of large intestinal distension on examination per rectum: Sand impaction, enterolithiasis, tympany, large colon displacements, and other intraluminal obstructions.
- Dehydration of feed within the large intestine may occur secondary to small intestinal obstruction.

INITIAL DATABASE

- Findings on examination per rectum depend on the location of the impaction. Pelvic flexure–left ventral colon impactions are frequently palpable. Whereas primary impactions are typically smooth and rounded, dehydrated feed secondary to small intestinal obstruction will have a corrugated surface.
- Impactions within the right dorsal colon or transverse colon are not palpable; instead, the resulting distension of the large colon and cecum is the primary palpable abnormality.
- Secondary impactions of the right dorsal colon associated with right dorsal displacement can be differentiated from pelvic flexure impactions based on the location of the ingesta-filled viscus. Secondary impactions of the right dorsal colon are caudal and lateral to the cecum and are generally more cranial in the abdomen than pelvic flexure impactions. Additionally, the end of the pelvic flexure should be identifiable in horses with pelvic flexure impactions.
- Nasogastric reflux is uncommon but may occur.
- Blood work may be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
- Abdominal fluid analysis is generally within normal limits. Impaction of the large colon may predispose to enterocentesis.

TREATMENT

THERAPEUTIC GOAL(S)

- Hydration of the ingesta
- Pain management
- Appropriate monitoring to identify any progression of the disease resulting in intestinal or cardiovascular compromise

ACUTE GENERAL TREATMENT

- Withhold *all* feed
- Fluid therapy
  - Enteric isotonic or slightly hypotonic fluids: Experimentally, this is the most effective method of hydrating ingesta within the large colon. Balanced electrolyte solution prevents electrolyte disturbances associated with saline; 3 to 6 L every 2 to 4 hours or continuous administration at rate of 2 to 3 L/hr is recommended.
  - IV isotonic fluids: Replace fluid deficits associated with dehydration and allow fluid administration if nasogastric reflux is present. Provide overhydration to prevent dehydration with use of osmotic cathartics; at least two times maintenance (120 mL/kg/d) is recommended.
- Cathartics or laxatives: Hydrate ingesta or promote transit
  - Mineral oil: Lubricant and intestinal transit marker (12–24 hr after administration normally); 5 to 10 mL/kg is recommended.
  - Dioctyl sodium sulfosuccinate (DSS): Surfactant that allows water and fat to penetrate the fecal mass; the recommended dose is 16.5 to 55 mg/kg. It is important to stick to the recommended dose.
  - Osmotic cathartics such as $MgSO_4$ (0.5–1.0 g/kg) and polyethylene glycol 3350 (not well evaluated) draw water into the lumen of the intestine with an osmotic gradient.
- Analgesics are important to control pain during hydration and passage of the impaction. NSAIDs (primarily flunixin meglumine) are used most frequently because of the minimal affect on motility. The use of intermittent doses of an α_2 agonist with or without butorphanol may be necessary in severe impactions. Other analgesic options include lidocaine and butorphanol continuous rate infusions. It is important to monitor for any signs of systemic or GI deterioration while administering analgesics.
- Surgical treatment may be required if pain is unrelenting or systemic or GI deterioration occurs.

CHRONIC TREATMENT

- Treatment of recurrent impactions is not well documented.
- Methods of treatment may include:
  - Dietary modification: Some clinicians report success with low-residue diets such as complete pelleted feeds and fresh grass.
  - Stimulation of water consumption: Salt feed or hay, warm water in cold weather, electrolyte water.
  - Make any changes to daily routine (stall hours, diet, exercise) as gradually as possible.
  - In severe cases unresponsive to medical management, large colon resection may be recommended.

DRUG INTERACTIONS

- Combining DSS with mineral oil may result in systemic absorption of the mineral oil with unknown consequences.
- Combining DSS with $MgSO_4$ may increase the potential for systemic toxicity of the Mg.

POSSIBLE COMPLICATIONS

- Complications are uncommon with medical management but may include intestinal rupture and diarrhea.

ElibVet.com

- Complications that have been reported with surgical treatment include intestinal rupture, diarrhea, incisional complications, and septic peritonitis. Intestinal rupture during exteriorization of the colon may occur in up to 20% of cases.

RECOMMENDED MONITORING

- Monitoring for resolution of the impaction should include fecal output and repeat examination per rectum.
- During treatment, horses should be monitored for signs of unrelenting pain, nasogastric reflux, progressive abdominal distension, systemic deterioration (climbing heart rate, cardiovascular compromise), and GI deterioration (abdominocentesis may be useful).

PROGNOSIS AND OUTCOME

Overall, the prognosis for large colon impaction is very good. The prognosis appears better for horses that respond to medical management compared with horses that require surgical management.

PEARLS & CONSIDERATIONS

COMMENTS

- Consider large colon impaction as an important differential diagnosis in horses with signs of mild to moderate abdominal pain with consistent findings on examination per rectum.
- Mainstays of treatment include withholding feed, fluid therapy, cathartics, and analgesics.

PREVENTION

Avoiding risk factors is a key to prevention.

CLIENT EDUCATION

Education of clients about risk factors may decrease the incidence of colic caused by large colon impactions.

AUTHOR: **KIRA L. EPSTEIN**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Large Colon: Intraluminal Obstruction

BASIC INFORMATION

DEFINITION

Obstruction of the flow of ingesta, gas, or both associated with the presence of an ingested foreign body; a fecalith (concretion of feces); or a bezoar (concretion of plant material [phytobezoar], hair [trichobezoar], or combination [trichophytobezoar])

EPIDEMIOLOGY

SPECIES, AGE, SEX Foals and young adults may be predisposed.

GENETICS AND BREED PREDISPOSITION

- Fecaliths are the most common cause of surgical colic reported in Miniature Horses.
- Clinical experience suggests that Miniature Horse foals are also predisposed to trichophytobezoars.

RISK FACTORS

- Suggested risk factors for fecaliths include poor-quality roughage, poor dentition, and decreased water consumption.
- Although no studies are available describing risk factors for the development of obstruction with bezoars or foreign material, clinical experience suggests that foals that chew on their mare's tail may be predisposed to forming trichophytobezoars, and access to foreign material and inadequate exercise may predispose horses to consuming foreign material.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Clinical signs are consistent with simple obstruction of the large or small colon, including mild to moderate abdominal pain (colic) and decreased or absent fecal production. Signalment and risk factors should be recognized.

PHYSICAL EXAM FINDINGS Horses with obstruction associated with fecaliths, bezoars, and foreign bodies have similar physical examination findings to horses with other simple obstructions of the large or small colon (see "Large Colon: Impaction" and "Small Colon: Impaction" in this section).

ETIOLOGY AND PATHOPHYSIOLOGY

- The development of fecaliths and bezoars is not well understood but may be associated with the accumulation and dehydration of feed and foreign material larger than the normal particulate size of properly chewed and digested feed material.
- Obstruction may occur in any part of the large intestine, including the large, transverse, and small colons. Obstruction of the small colon appears common with fecaliths in Miniature Horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal tract such as large colon impactions (feed and sand), enterolithiasis, large colon displacements, tympany, small colon impactions, and ileal impactions (see respective chapters)
- Other causes of large intestinal distension on examination per rectum: Tympany, large colon impactions (feed and sand), enterolithiasis, and large colon displacements (see respective chapters)

INITIAL DATABASE

- Findings on examination per rectum depend on the location of the impaction (see "Large Colon: Impaction" and "Small Colon: Impaction" in this section). Distension of the large colon and cecum are common with the addition of distension of the small colon if the fecalith or bezoar is within the small colon. It is uncommon to palpate the obstruction.
- Nasogastric reflux is uncommon but may occur
- Blood work may be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated

 ElibeVet.com

packed cell volume, elevated total protein).
- Abdominal fluid analysis is generally within normal limits.

TREATMENT

THERAPEUTIC GOAL(S)

Remove the obstruction

ACUTE GENERAL TREATMENT

- Surgical exploration and removal. If pressure necrosis is present, resection may be required.
- Perioperative supportive care as required

CHRONIC TREATMENT

Risk factors should be addressed to prevent recurrence. This should include appropriate dental care, providing plenty of fresh water, and providing plenty of good-quality roughage.

POSSIBLE COMPLICATIONS

- Postoperative complications may include diarrhea, inappetence, and impaction at the surgery site if damage to the intestinal wall has occurred that results in inflammation or fibrosis.
- Although not specifically reported, it is possible that pressure necrosis could occur at the site of obstruction. Clinical signs and diagnostic findings are similar to those described for pressure necrosis associated with enterolithiasis.

PROGNOSIS AND OUTCOME

Prognosis is likely excellent if surgical removal is pursued.

PEARLS & CONSIDERATIONS

COMMENTS

- Fecaliths and bezoars are important differential diagnoses in young Miniature Horses that present with signs of simple obstruction.
- Although uncommon, obstruction of the large intestine with a foreign body should be considered as a differential diagnosis in young horses.
- Surgical removal generally results in a good prognosis.

PREVENTION

Changes in management as described under Chronic Treatment may also serve as methods of prevention.

CLIENT EDUCATION

Client education may be useful in prevention.

Large Colon: Intussusception

BASIC INFORMATION

DEFINITION

One segment of the colon telescoping (intussusceptum) into an adjacent segment of the colon (intussuscipiens)

SYNONYM

Colo-colic intussusception

EPIDEMIOLOGY

SPECIES, AGE, SEX As with other intussusceptions, younger horses (younger than age 3 years) appear predisposed.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT
- Reported cases have had a history of mild, recurrent colic, and soft feces.
- Increased severity of colic signs occurs with progressive obstruction.

PHYSICAL EXAM FINDINGS Physical examination reveals mild tachycardia with variable decreased borborygmi and increased temperature.

ETIOLOGY AND PATHOPHYSIOLOGY
- As with other intussusceptions, hypermotility is believed to contribute to the development of colo-colic intussusceptions.
- Although not reported for colo-colic intussusceptions, it is possible that an intussusception may occur in association with an intramural mass at the leading edge of the intussusceptum.
- Colo-colic intussusceptions have been reported in the left ventral and dorsal colons and the pelvic flexure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal tract such as feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large intestinal intraluminal obstructions, small colon impactions, and ileal impactions
- Other causes of large intestinal distension on examination per rectum: Feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large colon volvulus, and other intraluminal obstructions
- Other causes of fever associated with recurrent mild colic: Peritonitis
- Other causes of colitis: salmonellosis and sand colitis or impaction

INITIAL DATABASE

- Distension of the large colon and cecum secondary to obstruction of the lumen by the intussusceptum is the most consistent finding on examination per rectum. The ability to palpate the intussusception is variable. If palpable, the intussusception will feel like a doughy mass.
- Nasogastric reflux is unexpected.
- Leukocytosis has been reported in cases of colo-colic intussusception. Hyperfibrinogenemia has also been reported.
- Increased abdominal fluid, nucleated cell count, and a variable increase in peritoneal fluid total protein have been reported.
- Although not performed in reported cases, it is possible that abdominal ultrasonography could provide a pre-

ElibVet.com

operative diagnosis. Intussusceptions in other regions have a bulls-eye pattern when imaged with ultrasonography. The ability to image the intussusception depends on its location adjacent to the body wall, accumulation of gas in surrounding segments of bowel, and luminal contents of the affected segment.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduction or resection of the intussusception
- Supportive care

ACUTE GENERAL TREATMENT

Surgical treatment has been described in several case reports. The ability to reduce the intussusception has been variable. In cases in which reduction is possible and no ischemic damage has occurred, no further treatment is required. In cases in which reduction is not possible, resection of the region is successful.

PROGNOSIS AND OUTCOME

Based on the limited number of cases in the literature, the prognosis appears good with surgical treatment.

PEARLS & CONSIDERATIONS

Intussusception of the large colon is an uncommon cause of progressive, recurrent colic and fever in young horses.

AUTHOR: **KIRA L. EPSTEIN**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Large Colon: Left Dorsal Displacement

BASIC INFORMATION

DEFINITION

- Displacement or entrapment of the large colon within the nephrosplenic space (between the spleen and the left kidney)
- Some clinicians include displacement of the large colon lateral to the spleen.

SYNONYM(S)

Nephrosplenic entrapment, renosplenic entrapment

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No age predisposition has been reported, and left dorsal displacement of the large colon (LDDLC) has been reported in horses of all ages, including weanlings.
- Some studies have reported that geldings are predisposed, but other studies have reported no sex predisposition.

GENETICS AND BREED PREDISPOSITION Clinical experience suggests that larger breed horses are predisposed. There have been no reported cases of LDDLC in ponies or Miniature Horses.

RISK FACTORS A deep nephrosplenic space may predispose horses to LDDLC.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of LDDLC are variable depending on the tension on the nephrosplenic ligament, pull on the mesentery, distension of the large colon, and secondary gastric distension. Most affected horses show signs of moderate pain, but severe pain may occur. Some horses may have chronic displacement with little gas distension and little to no signs of discomfort.
- Horses frequently have decreased to absent fecal production and may have abdominal distension. In some horses, the visible distension is confined to the area of the left paralumbar fossa.

PHYSICAL EXAM FINDINGS

- Because LDDLC is generally a nonstrangulating obstruction, affected horses are cardiovascularly stable.
- Physical examination findings may include tachycardia, abdominal distension, decreased or absent borborygmi, and signs of dehydration.
- As distension becomes more severe, compromise to the cardiovascular system and respiratory system are possible. With chronicity or severe distension, ischemia of the entrapped region of the left colons may occur, and clinical signs and physical examination will reflect the associated cardiovascular compromise.

ETIOLOGY AND PATHOPHYSIOLOGY

- It is likely that changes in motility or gas distension of the large colon result in abnormal migration of the pelvic flexure.
- The left large colon may migrate lateral to the spleen and dorsally until it reaches the nephrosplenic space or the pelvic flexure may migrate cranially and then back caudally to pass through the nephrosplenic space from cranial to caudal.
- Frequently, the left colon rotates 180 degrees such that the left dorsal colon is ventral to the left ventral colon.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal tract such as feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large intestinal intraluminal obstructions, small colon impactions, and ileal impactions
- Other causes of large intestinal distension on examination per rectum: Feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large colon volvulus, and other intraluminal obstructions

INITIAL DATABASE

- Typical findings on examination per rectum are distended large colon caudal to the nephrosplenic space and compressed within the nephrosplenic space.
- Other findings may include gas distension (sometimes marked) of the cecum and ventromedial displacement of the spleen. Palpation of the nephrosplenic space may be difficult, especially with severe distension of the large colon and in large-breed horses. It is important to remember that with severe distension of the large colon from any cause (eg, impaction, enterolithiais, tympany), the bands of the large colon may course toward the nephrosplenic space and mimic LDDLC.
- Nasogastric reflux is present in up to 43% of horses with LDDLC. This may

 ElibeVet.com

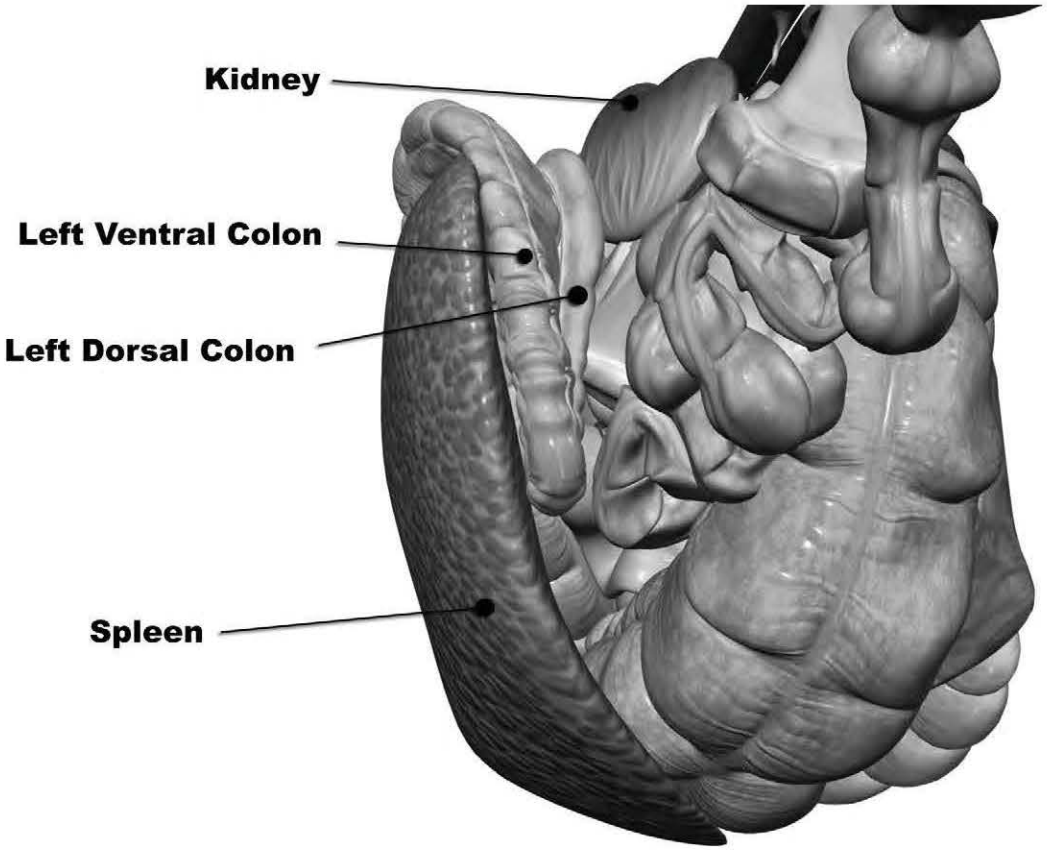

FIGURE 1 Diagram showing left dorsal displacement of the colon (caudal view). (From The Equine Colic CD 2007. The Glass Horse Project LLC and University of Georgia Research Foundation Inc. Used with permission.)

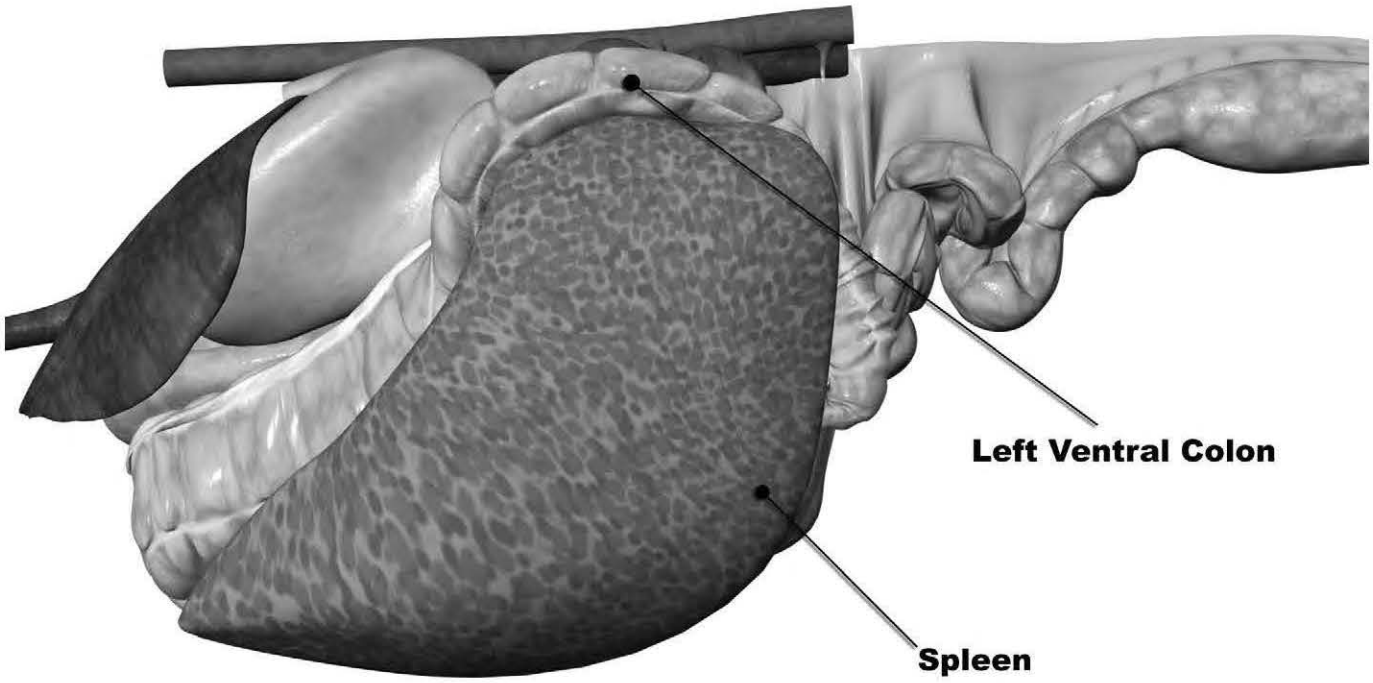

FIGURE 2 Diagram showing left dorsal displacement of the colon (left lateral view). (From The Equine Colic CD 2007. The Glass Horse Project LLC and University of Georgia Research Foundation Inc. Used with permission.)

ElibVet.com

be caused by pressure on the duodenum or tension on the mesentery associated with LDDLC.
- Blood work is frequently normal. Some clinicians believe that a relatively low PCV in the face of dehydration indicates sequestration of red blood cells within the spleen associated with LDDLC.
- Abdominocentesis may result in splenic blood (packed cell volume > peripheral blood) in up to 25% of horses with LDDLC.
- Ultrasonography (percutaneous): In horses with LDDLC, gas within the large colon will obscure the caudodorsal aspect of the spleen. The ability to image the kidney adjacent to the spleen does not appear as accurate as gas obscuring the caudodorsal aspect of the spleen. In some cases of LDDLC, it is possible to obtain an image of the kidney adjacent to the spleen, and in many cases of other sources of colic, it is not possible to obtain the same image.
- If ischemic damage has occurred, blood work and abdominal fluid may be altered.

TREATMENT

THERAPEUTIC GOAL(S)

- Correction of the displacement
- Supportive care

ACUTE GENERAL TREATMENT

- If pain and distension are not severe, medical management is frequently attempted, and good success rates have been reported. The two main methods for medical management are administration of phenylephrine and rolling the horse under general anesthesia.
  - The administration of phenylephrine at 3 to 6 µg/kg/min for 15 minutes results in splenic contraction and a dramatic decrease in the size of the spleen. During administration, horses should be monitored for reflex bradycardia, and administration should be discontinued if bradycardia becomes severe. Horses are given phenylephrine and walked, jogged, or lunged to encourage the colon to come out of the nephrosplenic space.
  - Horses can be rolled under general anesthesia. They should be anesthetized, placed in right lateral recumbency, and rolled over their back into left lateral recumbency. While in dorsal recumbency, horses can be jostled to encourage the colon to come out of the nephrosplenic space. The administration of phenylephrine and manipulation per rectum in conjunction with rolling has also been described.
- Surgical exploration is recommended for horses that present with severe pain or that are unresponsive to attempts at medical management. Surgical exploration may also be recommended in horses with severe gas distension because of the potential for increased complications associated with medical management.

POSSIBLE COMPLICATIONS

- Recurrence rates ranging from 3% to 21% have been reported.
- Reported complications of medical management have included rupture and displacement or volvulus of the large colon.

RECOMMENDED MONITORING

If medical treatment is pursued, horses should be monitored for signs of unrelenting pain, nasogastric reflux, progressive abdominal distension, and systemic deterioration (climbing heart rate, cardiovascular compromise).

PROGNOSIS AND OUTCOME

Prognosis is good to excellent.

PEARLS & CONSIDERATIONS

COMMENTS

- Diagnosis of LDDLC is based on examination per rectum and ultrasonography.
- Medical management of horses with LDDLC can be very successful.
- Multiple methods of surgical prevention of recurrence are available.

PREVENTION

- In cases of recurrent LDDLC, surgical prevention of recurrence may be recommended.
- Multiple methods of laparoscopic and hand-assisted laparoscopic closure of the nephrosplenic space have been reported. Complications appear rare.
- Other methods of surgical prevention include closure of the nephrosplenic space via a rib resection, colopexy, and large colon resection. However, these procedures are not preferred because of an increased frequency and severity of complications associated with these procedures and longer lay-up time after surgery.

Large Colon: Nonstrangulating Infarction

BASIC INFORMATION

DEFINITION

Loss of blood supply to the colon not associated with strangulation

SYNONYM(S)

Mural infarction, thromboembolic colic

EPIDEMIOLOGY

RISK FACTORS

- High parasite load and inappropriate deworming programs may predispose to *Strongylus vulgaris* infestation.
- Coagulopathies associated with severe gastrointestinal (GI) disease and sepsis may predispose to thromboembolic disease.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Verminous arteritis of the cranial mesenteric artery caused by *S. vulgaris* larval migration may present in acute or chronic forms.
- Conditions associated with systemic inflammatory response syndrome (SIRS) such as severe GI disease and

ElibeVet.com

sepsis may result in coagulopathies and thromboembolic disease that may present as nonstrangulating infarction of the large colon.

HISTORY, CHIEF COMPLAINT The history and presenting complaints are variable depending on the cause of the nonstrangulating infarction. Whereas acute cases of verminous arteritis have rapid onset of colic, chronic cases have recurrent colic and weight loss. In cases associated with coagulopathies, the history will indicate the primary disease (see the various entries on colitis) with acute progression or development of signs of colic.

PHYSICAL EXAM FINDINGS

- Physical examination findings are variable depending on the cause of the nonstrangulating infarction, the degree of vascular compromise, and the amount of bowel affected.
- Variable tachycardia, tachypnea, and fever are associated with pain and endotoxemia.
- Other findings may include abdominal distension, decreased or absent borborygmi and alterations in fecal consistency and production.
- Endotoxemic shock may present with hyperemic or toxic mucous membranes, prolonged or decreased capillary refill time, poor pulse quality, cold extremities, and decreased jugular refill.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathophysiology of verminous arteritis is not well understood. Although some cases have obvious thrombosis, enlargement, aneurysm, or abscessation of the cranial mesenteric artery, other cases have no evidence of physical obstruction, and vasospasm has been proposed as the inciting cause of ischemia.
- Diseases associated with SIRS are frequently associated with coagulopathies caused by the procoagulant nature of many proinflammatory mediators. In horses with colitis, loss of antithrombin (a major anticoagulant protein) out of leaky vessels within the inflamed colon may also contribute to a procoagulant state.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of colic: Feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large intestinal intraluminal obstructions, small colon impactions, ileal impactions, strangulating small intestinal obstructions, large colon volvulus, and colitis.
- Other causes of endotoxemia: Colitis and large colon volvulus.
- Other causes of peritonitis: Idiopathic cases, GI rupture, and other strangulating GI lesions such as small intestinal or large colon volvulus.

INITIAL DATABASE

- Findings on examination per rectum are variable. Distension of the large colon and cecum is possible but not consistent. If venous occlusion has led to formation of edema and hemorrhage within the wall of the intestine, ischemic regions may be thickened on palpation if they can be accessed.
- Nasogastric reflux is unexpected.
- Findings on routine blood work vary with the cause of the infarction. Chronic parasitism may be associated with anemia, hypoalbuminemia (if associated with protein-losing enteropathy), or hyperglobulinemia (if associated with chronic inflammation). Endotoxemia is frequently accompanied by leukopenia caused by neutropenia with left shift. Horses with colitis often have hypoproteinemia and may have electrolyte abnormalities. Thromboembolic disease may affect multiple organ systems, and as a result, blood work may reveal evidence of insufficiencies (eg, azotemia with renal insufficiency).
- Abdominal fluid is frequently consistent with peritonitis with changes in color (serosanguineous), increased total nucleated cell count, and increased total protein concentration. However, normal peritoneal fluid analysis may occur even with severe ischemia to large portions of the large colon.
- If the ischemic region is edematous, abdominal ultrasonography may reveal a thickened, hypoechoic bowel wall.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove ischemic bowel
- Treat the underlying cause
- Provide supportive care

ACUTE GENERAL TREATMENT

- Depending on the accessibility and size of the segment of affected bowel, surgical resection may or may not be possible.
- The underlying disease and degree of endotoxemia may make some affected animals poor surgical candidates.
- Supportive care required may include all or some of the following: fluid therapy, colloid support, and antiendotoxic treatment.

CHRONIC TREATMENT

A good deworming program should be started if verminous arteritis is the underlying cause.

PROGNOSIS AND OUTCOME

- Prognosis is variable based on the extent of the lesion and the severity of the underlying disease.
- Prognosis is best if the region affected is small and easy to resect. However, the infarction can progress to other segments after surgery.
- If the cranial mesenteric artery is palpably enlarged, has an aneurysm, or is associated with an abscess at the time of surgery, prognosis is guarded to poor.
- Clinical experience suggests that infarction associated with colitis has a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Nonstrangulating infarction of the large colon is an uncommon cause of colic in horses.
- Nonstrangulating infarction may be associated with verminous arteritis or coagulopathies secondary to inflammatory diseases, most commonly colitis.

PREVENTION

Appropriate deworming appears to have decreased the incidence of nonstrangulating infarction of the large colon associated with *S. vulgaris*.

ElibeVet.com

Large Colon: Other Displacements

BASIC INFORMATION

DEFINITION

- Displacement of the large colon (primarily the left dorsal and ventral colons)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The most commonly reported malpositioning of the large colon aside from right dorsal displacement of the large colon (RDDLC) and left dorsal displacement of the large colon (LDDLC) is retroflexion or cranial flexion of the pelvic flexure.
- Other entrapments that have been reported include displacement through a rent in the mesoductus deferens, through a rent in the gastrosplenic ligament, through a rent in the diaphragm, and through the epiploic foramen.
- The author has also observed the sternal and diaphragmatic flexure displaced cranial to the stomach. Some clinicians include nonstrangulating large colon volvulus or torsion in this category. With the exception of entrapment in the epiploic foramen, these displacements generally result in nonstrangulating obstruction of the large colon.

HISTORY, CHIEF COMPLAINT

- Clinical signs of displacement of the large colon are variable depending on the degree of displacement and associated pull on the mesentery and distension of the large colon.
- Signs of colic range from chronic mild signs of pain to severe signs of colic.
- Other clinical signs may include decreased to absent fecal production and abdominal distension.

PHYSICAL EXAM FINDINGS

- Because malpositioning of the large colon generally results in nonstrangulating obstruction, affected horses are cardiovascularly stable.
- Physical examination findings may include tachycardia, abdominal distension, decreased or absent borborygmi, and signs of dehydration.
- As distension becomes more severe, compromise to the cardiovascular system and respiratory system are possible.
- If entrapment results in ischemia of the entrapped region of the colon, the clinical signs and physical examination will reflect the associated cardiovascular compromise.

ETIOLOGY AND PATHOPHYSIOLOGY Similar to the more common displacements (RDDLC and LDDLC), it is likely that changes in motility or gas distension of the large colon result in abnormal migration of the pelvic flexure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal tract such as feed or sand impaction, enterolithiasis, large colon tympany, right or left dorsal displacement of the large colon, large intestinal intraluminal obstructions, small colon impactions, and ileal impactions.
- Other causes of large intestinal distension on examination per rectum: feed or sand impaction, enterolithiasis, large colon tympany, right or left dorsal displacement of the large colon, large colon volvulus, and other intraluminal obstructions.

INITIAL DATABASE

- Findings on examination per rectum vary with the type of displacement and the degree of gas distension. Distension of the cecum and an inability to palpate the pelvic flexure are common findings. Distension of the large colon may also be palpable. It is important to remember that these findings are not specific for displacement and may result from other nonstrangulating obstruction of the large colon (eg, impaction, enterolithiasis, tympany).
- Nasogastric reflux may be associated with distension of the large colon adjacent to the duodenum resulting in gastric outflow obstruction.
- Bloodwork may be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
- Abdominal fluid analysis is generally within normal limits.
- If ischemic damage has occurred, bloodwork and abdominal fluid may be altered.

TREATMENT

THERAPEUTIC GOAL(S)

- Correction of the displacement
- Supportive care

ACUTE GENERAL TREATMENT

- If pain and distension are not severe, medical management can be attempted. Horses can be held off feed, placed on IV fluids, and monitored for signs of progression or resolution. It is impossible to determine how successful medical management will be because definitive preoperative diagnosis is not possible. However, a percentage of horses may resolve with this therapy.
- Surgical exploration is recommended for horses that present with severe pain or that are unresponsive to attempts at medical management.

RECOMMENDED MONITORING

If medical treatment is pursued, horses should be monitored for signs of unrelenting pain, nasogastric reflux, progressive abdominal distension, and systemic deterioration (climbing heart rate, cardiovascular compromise).

PROGNOSIS AND OUTCOME

Prognosis is good to excellent for horses with nonstrangulating displacements of the large colon.

PEARLS & CONSIDERATIONS

COMMENTS

- Displacement of the large colon should be considered as a differential diagnosis in any horse presenting for colic with cecal and large colon distension.
- Definitive diagnosis requires surgical exploration.

PREVENTION

In cases of recurrent large colon displacement, surgical prevention of recurrence may be recommended. Methods of surgical prevention include colopexy and large colon resection. Both of these procedures have potentially life-threatening

ElibVet.com

complications and are generally not recommended before the second or third episode of displacement confirmed at surgery.

SUGGESTED READING

Johnston JK, Freeman DE: Diseases and surgery of the large colon. *Vet Clin North Am Equine Pract* 13(2):317, 1997.

Sullins KE: Diseases of the large colon. In Colohan PT, Merritt AM, Moore JN, et al (eds). *Equine medicine and surgery,* St Louis, 1999, Mosby, pp 741–768.

AUTHOR: **KIRA L. EPSTEIN**

EDITOR: **TIM MAIR**

Large Colon: Right Dorsal Displacement

BASIC INFORMATION

DEFINITION

Right dorsal displacement of the large colon (RDDLC) is displacement of the large colon lateral to (to the right of) the cecum.

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Clinical experience suggests that larger breed horses are predisposed, and ponies and miniature horses are uncommonly affected.

ASSOCIATED CONDITIONS AND DISORDERS RDDLC can be associated with impaction of the right dorsal colon (see "Large Colon Impaction" in this section) and a variable degree of rotation along the long axis (see "Large Colon Volvulus" in this section).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Clinical signs of RDDLC are variable depending on the degree of displacement and associated pull on the mesentery and distension of the large colon. Signs of colic may range from chronic mild signs of pain to severe signs of colic. Other clinical signs may include decreased to absent fecal production and abdominal distension.

PHYSICAL EXAM FINDINGS Horses with RDDLC are frequently cardiovascularly stable. Physical examination findings may include tachycardia, abdominal distension, decreased or absent borborygmi, and signs of dehydration. As distension becomes more severe, compromise to the cardiovascular system and respiratory system are possible.

ETIOLOGY AND PATHOPHYSIOLOGY

- It is likely that changes in motility or gas distension of the large colon result in abnormal migration of the pelvic flexure.
- Most commonly, the pelvic flexure migrates counterclockwise (viewed from the ventral aspect of the abdomen). Initially, the pelvic flexure moves cranially, then across the abdomen toward the right body wall, then lateral to the cecum, then around the caudal aspect of the cecum, and finally again cranially to the level of the sternum.
- Less commonly, the pelvic flexure migrates clockwise (viewed from the ventral aspect of the abdomen). Initially, the pelvic flexure moves toward the right body wall caudal to the cecum and then migrates cranially to the right of the cecum to the level of the sternum.
- Variable degrees of rotation around the long axis (volvulus) are possible with RDDLC. The volvulus is generally nonstrangulating (see "Large Colon: Volvulus" in this section).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal tract such as feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large intestinal intraluminal obstructions, small colon impactions, and ileal impactions.
- Other causes of large intestinal distension on examination per rectum: Feed or sand impaction, enterolithiasis, large colon tympany, other large colon displacements, large colon volvulus, and other intraluminal obstructions.

INITIAL DATABASE

- Typical findings on examination per rectum are distended large colon with bands coursing transversely across the abdomen. The colon is caudal and lateral to the cecum, and it is generally not possible to palpate the ventral band of the cecum. It is also not possible to palpate the pelvic flexure. It is important to remember that with severe distension of the large colon from any cause (eg, impaction, enterolithiasis, tympany), the anatomy can be distorted, and findings on examination per rectum are similar, but a final diagnosis requires surgery.
- Nasogastric reflux may occur associated with distension of the large colon adjacent to the duodenum.
- Blood work may be normal or consistent with mild to moderate dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein). Elevation of gamma-glutamyl transferase is believed to be associated with partial obstruction of the duodenum.
- Abdominal fluid analysis is generally within normal limits.

TREATMENT

THERAPEUTIC GOAL(S)

- Correction of the displacement
- Supportive care

ACUTE GENERAL TREATMENT

- If pain and distension are not severe, medical management is frequently attempted. Horses are held off feed, placed on IV fluids, and monitored for signs of progression or resolution. It is impossible to determine how successful medical management is because preoperative diagnosis of RDDLC is impossible. However, a percentage of horses with findings consistent with RDDLC on physical examination and examination per rectum resolve with this therapy.
- Surgical exploration is recommended for horses that present with severe pain or that are unresponsive to attempts at medical management. Surgical exploration and correction is the only way to definitively diagnose and treat RDDLC.

POSSIBLE COMPLICATIONS

Redisplacement can occur and has been reported as early as 48 hours after surgical correction.

RECOMMENDED MONITORING

If medical treatment is pursued, the horse should be monitored for signs of unrelenting pain, nasogastric reflux, progressive abdominal distension, and systemic

ElibeVet.com

deterioration (climbing heart rate, cardiovascular compromise).

PROGNOSIS AND OUTCOME

Prognosis is good to excellent.

PEARLS & CONSIDERATIONS

COMMENTS

- RDDLC should be considered as a differential diagnosis in any horse presenting for colic with large colon distension and tight bands traversing the abdomen on examination per rectum.
- Definitive diagnosis requires surgical exploration.

PREVENTION

In cases of recurrent RDDLC, surgical prevention of recurrence may be recommended. Methods of surgical prevention include colopexy and large colon resection. Both of these procedures have potentially life-threatening complications and are generally not recommended before the second or third episode of RDDLC confirmed at surgery.

AUTHOR: **KIRA L. EPSTEIN**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Large Colon: Tympany

BASIC INFORMATION

DEFINITION

Accumulation of gas in the large colon secondary to excessive fermentation or functional obstruction (ileus)

SYNONYM(S)

Gas colic, spasmodic colic

EPIDEMIOLOGY

RISK FACTORS

- Changes to diets that are rapidly fermentable such as high-carbohydrate feeds (grain) and roughage with a high surface area (mowed grass) are commonly associated with tympany. In some horses, beet pulp appears to cause excessive gas production.
- There is an association between tapeworm infestation and tympany.
- Other factors that have been associated with simple obstruction and gas distension of the large colon (eg, impaction) include history of previous colic, recent (past 4 weeks) lameness, travel in the past 24 hours, recent change in exercise, increasing time spent stabled, crib biting or windsucking, increasing time since last dental examination, and longer than 12 months since deworming with ivermectin or moxidectin.

ASSOCIATED CONDITIONS AND DISORDERS Large colon tympany may predispose horses to displacement and volvulus of the large colon.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Horses with large colon tympany present with signs of abdominal pain (colic) and distension. Historical findings may indicate any of the risk factors identified in the epidemiology section.

PHYSICAL EXAM FINDINGS Horses with large colon tympany are generally cardiovascularly stable. They may have elevations of heart rate associated with pain, abdominal distension, decreased or absent borborygmi, and signs of mild dehydration. If distension becomes severe, compromise to the cardiovascular and respiratory systems can occur.

ETIOLOGY AND PATHOPHYSIOLOGY Risk factors described in the epidemiology section likely affect motility and bacterial flora within the large colon. These changes result in stasis, increased gas production, or both within the large colon, leading to distension and pain.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of mild to moderate abdominal pain: Simple or nonstrangulating obstructions of the gastrointestinal (GI) tract such as feed or sand impaction, enterolithiasis, large colon displacements, large intestinal intraluminal obstructions, small colon impactions, and ileal impactions.
- Other causes of large intestinal distension on examination per rectum: Feed or sand impaction, enterolithiasis, large colon displacements, large colon volvulus, and other intraluminal obstructions

INITIAL DATABASE

- Examination per rectum reveals a variable degree, possibly severe, of gas distension of the large colon. Distension of the cecum may occur as the duration of the obstruction increases.
- Nasogastric reflux is uncommon.
- Blood work may be normal or consistent with mild dehydration (prerenal azotemia, elevated packed cell volume, elevated total protein).
- Abdominal fluid analysis within normal limits.

TREATMENT

THERAPEUTIC GOAL(S)

- Pain management
- Supportive care

ACUTE GENERAL TREATMENT

- Withhold feed.
- Most horses with large colon tympany have a good response to analgesics (flunixin meglumine, α_2 agonists, butorphanol). Analgesics minimize sympathetic inhibition of motility.
- Some clinicians recommend administration of mineral oil to decrease the absorption and speed the intestinal transit of the feed material responsible for the increase in gas production.
- Some horses may benefit from IV fluids to support the cardiovascular system and treat any dehydration.
- Trocharization of the large colon (right or left flank depending on distension) has been described for the treatment of horses with severe large colon tympany. Because of the potential for complications (peritonitis, abscess formation) and the difficulty in completely ruling out other more serious, causes of large colon distension, the

ElibVet.com

use of trocharization remains controversial. Before performing trocharization, the clinician should take into account the cardiovascular status of the horse and the potential for referral and surgery.
- Gentle exercise (eg, walking) may stimulate GI motility and the natural evacuation of gas.

CHRONIC TREATMENT

- As with large colon impactions, treatment of recurrent tympany is not well documented.
- Similar to large colon impactions, methods of treatment focus on avoiding risk factors and may include:
  - Avoiding feed that results in rapid production of gas
  - Making any changes to daily routine (stall hours, diet, exercise) as gradually as possible
  - Routine parasite and dental care
- In severe cases unresponsive to medical management, large colon resection may be recommended.

RECOMMENDED MONITORING

- During treatment, horses should be monitored for signs of unrelenting pain, nasogastric reflux, progressive abdominal distension, and systemic deterioration (climbing heart rate, cardiovascular compromise).
- Progression of signs may indicate an inability to resolve the gas distension medically or progression to a large colon displacement or volvulus. Surgical exploration may be required.

PROGNOSIS AND OUTCOME

The prognosis is excellent.

PEARLS & CONSIDERATIONS

COMMENTS

- Large colon tympany is one of the most common causes of colic caused by gas distension of the large colon.
- Lack of response to analgesics or systemic deterioration may indicate a more serious cause of colic.

PREVENTION

Avoiding risk factors is a key to prevention.

CLIENT EDUCATION

Education of clients about risk factors may decrease the incidence of colic caused by large colon tympany.

SUGGESTED READING

Rakestraw PC, Hardy J: Large intestine. In Auer JA, Stick JA (eds). *Equine surgery*, ed 3, St Louis, 2006, Saunders Elsevier, pp 436–478.

Sullins KE: Diseases of the large colon. In Colohan PT, Merritt AM, Moore JN, et al (eds). *Equine medicine and surgery*, St Louis, 1999, Mosby, pp 741–768.

AUTHOR: **KIRA L. EPSTEIN**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Large Colon: Volvulus

BASIC INFORMATION

DEFINITION

Rotation of the colon around the mesenteric axis (which is also the long axis of the large colon)

SYNONYM(S)

Large colon torsion, "twisted gut"

EPIDEMIOLOGY

SPECIES, AGE, SEX
- Mares are overrepresented.
- Large colon volvulus is uncommon in immature horses.

RISK FACTORS
- Postpartum mares appear to be at increased risk.
- A recent diet change and recent introduction to lush pasture may also predispose horses to the development of large colon volvulus.

GEOGRAPHY AND SEASONALITY Because postpartum mares are at increased risk, regions with a high density of broodmares and times of year when parturition is more frequent have an increased incidence.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Large colon volvulus may be strangulating or nonstrangulating. Volvulus of 270 degrees or more results in strangulation. The findings associated with strangulating volvulus are discussed here. Nonstrangulating volvulus results in findings similar to large colon displacements (see "Large Colon: Left Dorsal Displacement" and "Large Colon: Right Dorsal Displacement" in this section).

HISTORY, CHIEF COMPLAINT In almost all cases, horses present with a history of rapid onset of severe, intractable pain. In most cases, the episode of colic is acute; less frequently, horses have a history of mild or moderate colic for a longer duration that progresses rapidly.

PHYSICAL EXAM FINDINGS
- Physical examination findings depend on the duration and degree of colonic compromise and distension. Initially, because of the very acute nature of the disease, physical examination may reveal normal vital signs, decreased to absent borborygmi, and severe pain.
- As distension progresses, respiratory and cardiovascular collapse may result.
- As endotoxemia occurs, compromise to the cardiovascular system worsens. Physical examination reveals signs of hypovolemic or endotoxemic (maldistributive) shock, including hyperemic or toxic mucous membranes, prolonged or decreased capillary refill time, poor pulse quality, cold extremities, and decreased jugular refill.

ETIOLOGY AND PATHOPHYSIOLOGY
- It is possible that, similar to large colon displacements, changes in motility or distension of the large colon result in abnormal migration of the colon.
- Because of the increased incidence in postpartum mares, some have suggested that a sudden increase in the volume available for the colon to occupy plays a role in the development of large colon volvulus.
- The most common location for large colon volvulus is at the level of the cecocolic ligament. Less frequently, volvulus may include the cecum or occur at the level of the sternal-diaphragmatic flexure.
- The direction of the large colon volvulus is almost always with the ventral colon rotating dorsomedially (counterclockwise when viewed from a ventral midline incision), but rotation in the other direction may also occur.

ElibEVet.com

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of severe colic: Strangulating lesions of the small intestine such as small intestinal volvulus, epiploic foramen entrapment and strangulating lipoma, severe colitis
- Other causes of large intestinal distension on examination per rectum: Feed or sand impaction, enterolithiasis, large colon tympany, large colon displacements, and other intraluminal obstructions
- Other causes of endotoxemia: Colitis and nonstrangulating infarction of the large colon

INITIAL DATABASE

- Examination per rectum may be within normal limits in the acute stage. As the disease progresses, severe gas distension of the colon and cecum results.
- Nasogastric reflux is unlikely.
- Blood work varies depending on the degree of cardiovascular compromise and endotoxemia. Progressive increase in packed cell volume (PCV), decrease in total protein (TP), and leukopenia caused by neutropenia with a left shift indicate an increased severity of systemic compromise. Hyperlactatemia is associated with poor perfusion and ischemia of the strangulated region.
- Abdominal fluid is frequently normal even in cases with severe ischemic damage. An increase in TP is associated with a decreased prognosis.
- Thickening of the large colon wall may be evident on ultrasonography. However, the severity of pain generally makes ultrasound evaluation difficult and unnecessary.

TREATMENT

THERAPEUTIC GOALS

- Preoperative stabilization
- Correction of volvulus
- Determination of viability of the colon
- Supportive care

ACUTE GENERAL TREATMENT

- Preoperative stabilization generally requires rapid fluid resuscitation. Trocharization may decrease abdominal distension and can be performed based on clinician discretion.
- Correction of large colon volvulus requires surgery. The level of pain displayed by almost all horses with large colon volvulus makes the decision for surgery fairly obvious.
- During surgery, viability can be assessed, although accurate determination can be very difficult. Resection of the large colon is at the discretion of the surgeon.
- Supportive care required may include all or some of the following: fluid therapy, colloid support, antiendotoxic treatment, antimicrobials, and pain management.

POSSIBLE COMPLICATIONS

Recurrence of large colon volvulus may occur.

RECOMMENDED MONITORING

Intensive postoperative monitoring is generally required to manage horses with large colon volvulus.

PROGNOSIS AND OUTCOME

- Reported prognosis ranges from approximately 60% to more than 80%.
- Prognosis is related to the severity of compromise and amount of intestine affected. Early recognition and surgical treatment result in a better prognosis.
- Preoperative parameters associated with decreased prognosis include tachycardia (>80 beats/min), elevated PCV (>50%), fever (>102° F), and hyperlactatemia.

PEARLS & CONSIDERATIONS

COMMENTS

- Large colon volvulus should be considered in any horse with a rapid onset of uncontrollable signs of colic.
- Rapid detection and treatment are important to maximize the prognosis.

PREVENTION

Methods of surgical prevention include colopexy and large colon resection.

Laryngeal Hemiplegia

BASIC INFORMATION

DEFINITION

Chronic and progressive degenerative neuropathy of the recurrent laryngeal nerve (RLN) resulting in loss of motor function of the intrinsic muscles of the larynx, which leads to paresis or paralysis of the associated arytenoid cartilage

SYNONYM(S)

Recurrent laryngeal neuropathy, laryngeal paralysis, "roaring"

EPIDEMIOLOGY

GENETICS AND BREED PREDISPOSITION Large breeds are more commonly affected than small breeds and ponies. Familial correlation has been investigated with equivocal results. Height was also found to be associated with the incidence of RLN. RLN probably has a phenotypic as well as inherited component.

RISK FACTORS

- In most cases, RLN is idiopathic without defined risk factors.
- Trauma or diseases associated with the neck or larynx can affect either side but are considered more likely associated if the dysfunction is on the right side of the horse. Trauma includes perivascular jugular vein or carotid

ElibeVet.com

artery injection, surgery associated with the neck or larynx, and blunt or penetrating trauma to the neck.
- Diseases include guttural pouch mycosis and empyema, strangles abscessation, septic jugular thrombophlebitis, neoplasia of the neck, various central nervous system diseases, and toxicities.

ASSOCIATED CONDITIONS AND DISORDERS Vocal fold collapse

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Most commonly left laryngeal hemiplegia.
- Right laryngeal hemiplegia is uncommon and is usually associated with some type of trauma to the right RLN in the neck.

HISTORY, CHIEF COMPLAINT
- Respiratory noise on inspiration, exercise intolerance
- Clinical signs will not be demonstrated in horses that are not exercising

PHYSICAL EXAM FINDINGS On palpation of the throatlatch region, there is atrophy of the cricoarytenoideus dorsalis muscle on the affected side.

ETIOLOGY AND PATHOPHYSIOLOGY
- Idiopathic. The left nerve is thought to be affected more significantly because of its greater length relative to the right RLN.
- Chronic degenerative neuropathy of the RLN resulting in loss of the motor function of the intrinsic muscles of the larynx
- Distal axonopathy with demyelination and proliferation of Schwann cells, endoneurium, and perineurium in the RLN with most of the changes observed distally

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Arytenoid chondropathy
- Vocal fold collapse
- Axial deviation of the aryepiglottic fold
- Pharyngeal collapse

INITIAL DATABASE
- Physical examination: The muscular process of the affected side will be more prominent than the contralateral side as a result of the muscle atrophy caused by the neuropathy.
- Upper airway endoscopy: Incomplete abduction or motion of the affected arytenoid without a change in shape of the arytenoid is indicative of RLN.

ADVANCED OR CONFIRMATORY TESTING
- Treadmill endoscopy: Dynamic collapse of the arytenoid during exercise
- Ultrasound examination: An increased echogenicity of the cricoarytenoid lateralis on the affected side is reflective of RLN.

TREATMENT

THERAPEUTIC GOAL(S)
Stabilization of the arytenoid cartilage corniculate process so that it does not collapse axially during inhalation.

ACUTE GENERAL TREATMENT
- Ventriculocordectomy (unilateral or bilateral)
- Ventriculectomy
- Prosthetic laryngoplasty
- Partial arytenoidectomy
- Neuromuscular pedicle graft or laryngeal reinnervation

POSSIBLE COMPLICATIONS
- With prosthetic laryngoplasty: Chronic coughing, aspiration pneumonia, seroma, abscess, prosthesis failure
- With arytenoidectomy: Dyspnea, dysphagia, chronic coughing, aspiration pneumonia
- With ventriculectomy or ventriculocordectomy: Mucocele, granuloma

RECOMMENDED MONITORING
Follow-up endoscopy

PROGNOSIS AND OUTCOME

- Prognosis depends on the use of the horse and the surgical procedure performed.
- In racehorses, prosthetic laryngoplasty plus ventriculocordectomy is the treatment of choice. Success ranges from 48% to 71%.
- Partial arytenoidectomy, which can be used as a first choice surgery or for failed laryngoplasty has a 61% to 78% prognosis of return to racing. This surgery is primarily used for horses with arytenoid chondritis. Partial arytenoidectomy apparently does not have the same success as laryngoplasty for treatment of RLN.
- Laryngeal reinnervation: Success ranges from 53% to 65%. It is important to note that it can take up to 12 months before a response is observed and the horse can return to training.
- In competition horses (non-racehorses), any of the above procedures can be performed. Ventriculocordectomy has been shown to be effective at reducing respiratory noise and improving performance both experimentally and clinically. This procedure is associated with fewer and less significant complications than the other laryngeal surgeries used to address RLN and may be considered as a primary treatment, particularly for those horses that have mild dysfunction.

PEARLS & CONSIDERATIONS

COMMENTS
- For show, sport, or performance horses, ventriculocordectomy alone may be considered as the primary treatment of choice. This procedure has the least complications and can be effective at reducing respiratory noise.
- Prosthetic laryngoplasty with ventriculocordectomy is the treatment of choice for racehorses because it improves upper airway mechanics and eliminates respiratory noise.

Lead Poisoning

BASIC INFORMATION

DEFINITION

Lead is a heavy metal that has been associated with poisonings around the world for thousands of years. It has been used in a variety of products, including but not limited to paints (before 1977 in the United States), shotgun pellets, car batteries, leaded gasoline and oil, pipes, and roofing material. Environmental contamination may occur near lead mining and smelting facilities; battery factories and battery recycling centers; and on a smaller scale, areas where lead paint has been used and then removed by sand blasting or high-pressure washing, and burn piles.

SYNONYM(S)

Lead toxicosis, plumbism

EPIDEMIOLOGY

SPECIES, AGE, SEX Young animals are at higher risk.

- Young animals absorb lead more efficiently from the gastrointestinal (GI) tract.
- Young animals are more prone to dietary indiscretion.

RISK FACTORS Dietary deficiencies of calcium, iron, zinc, or vitamin D may enhance lead absorption.

CONTAGION AND ZOONOSIS Lead is not an infectious agent and therefore is not contagious or zoonotic. However, if lead toxicosis is diagnosed in a domestic animal, people living in the area should be assessed for possible environmental exposure.

GEOGRAPHY AND SEASONALITY Worldwide distribution

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute lead poisoning
- Chronic lead poisoning (more common in horses)

HISTORY, CHIEF COMPLAINT

- The horse lives near a battery factory or a lead mine or smelter.
- The barn was built before 1977 (in the United States).
  - Paint may have recently been removed by power washing or sand blasting.
  - There may be evidence of chewing on painted wood.
- Clinical signs of acute lead poisoning
  - Seizures
  - Colic
  - Unexpected death
- Clinical signs of chronic lead poisoning include:
  - Depression
  - Ataxia
  - Weight loss
  - Change in voice, stridor
  - Muscle fasciculations
  - Dysphagia, drooping lips or ears

PHYSICAL EXAM FINDINGS

- Laryngeal paralysis
- Secondary aspiration pneumonia
- Peripheral neuropathy
- Facial nerve deficits
- Emaciation
- Metallic foreign body in GI tract on radiographs

ETIOLOGY AND PATHOPHYSIOLOGY

Lead causes its clinical effects by competing with calcium ions in bones, muscles, and nerves and at binding sites on proteins. Lead may affect zinc-containing enzymes. Lead also binds to sulfhydryl groups on enzymes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rabies
- Other viral encephalitides
- Equine protozoal myeloencephalitis
- Hepatic encephalopathy
- Equine leukoencephalomalacia
- Equine nigropallidal encephalomalacia
- Equine motor neuron disease

INITIAL DATABASE

- Packed cell volume and blood smear
  - Anemia
  - Basophilic stippling of erythrocytes
  - Nucleated red blood cells

ADVANCED OR CONFIRMATORY TESTING

- Elevated blood lead concentrations
- Elevated liver or kidney lead concentrations
- Environmental lead testing to determine the source such as:
  - Paint chips
  - Soil
  - Water
  - Feed

TREATMENT

THERAPEUTIC GOAL(S)

- Provide symptomatic and supportive care.
- Remove lead from the GI tract.
- Remove free lead from the soft tissues (chelation).
- Remove lead from the horse's environment.

ACUTE GENERAL TREATMENT

- Stabilization as necessary
  - Seizure control
  - Treat cerebral edema if needed
- Symptomatic and supportive care
  - Fluid and electrolyte therapy
  - Maintain hydration during chelation therapy
  - Provide nutritional support
  - Treat aspiration pneumonia if needed
  - Provide thiamin (efficacy not known in horses)
- GI decontamination: Cathartics
  - Magnesium sulfate and sodium sulfate may decrease absorption
- Chelation: Calcium ethylenediaminetetraacetic acid (EDTA)
  - 75 mg/kg diluted and divided over two doses per day for 3 to 5 days; slow IV infusion over 30 minutes
  - Dilute to 6.6% in normal saline or 5% dextrose
  - Follow initial treatment with 2 days of rest and another 5 days of treatment if needed

CHRONIC TREATMENT

Supportive care

DRUG INTERACTIONS

Calcium EDTA may bind nutritional minerals such as zinc, copper, iron, and calcium.

POSSIBLE COMPLICATIONS

- Do not substitute sodium EDTA for calcium EDTA; sodium EDTA will cause acute hypocalcemia.
- EDTA is nephrotoxic.
  - Maintain hydration
  - Monitor renal function
- EDTA may cause anorexia, diarrhea, or depression.
- EDTA may cause pain if injected subcutaneously or intramuscularly.
- EDTA may mobilize lead from the bone, causing an early increase in circulating lead.

RECOMMENDED MONITORING

- Monitor blood lead concentrations at least weekly through the treatment period.
- Monitor renal function if chelating with EDTA.

ElibeVet.com

PROGNOSIS AND OUTCOME

- May be fatal without treatment
- Guarded if clinical signs are severe
- Good if clinical signs are relatively mild

PEARLS & CONSIDERATIONS

COMMENTS

- Toxicity
  - The acutely toxic dose for lead in horses is estimated to be 500 to 700 mg/kg.
  - The chronic toxic dose for lead in horses is estimated to be 1.7 to 7 mg/kg/d for several weeks.
    - 80 ppm lead (dry matter) in the diet is associated with toxicosis.
- Sources of calcium EDTA:
  - Contact human hospital pharmacies to obtain Food and Drug Administration–approved products (expensive).
  - Contact veterinary compounding pharmacies to obtain compounded products (less expensive). Consult a veterinary toxicologist for information on drug sources.

PREVENTION

- Prevent exposure to lead.
  - Have paint tested in old buildings and before moving animals in or remodeling.
  - Contaminated soil may need to be removed.
  - Remove point sources of lead (old batteries and trash such as roofing materials, oil, and gasoline) from pastures and hay fields.

CLIENT EDUCATION

- See Prevention.
- It is important to determine the source of lead to prevent further exposure to animals and humans.
- Blood lead concentrations from children and adults living in the same area of the horses may be needed to determine if they have been exposed.

AUTHOR: **KARYN BISCHOFF**

EDITOR: **CYNTHIA L. GASKILL**

Lethal White Foal Syndrome

BASIC INFORMATION

DEFINITION

Congenital ileocecocolonic aganglionosis caused by a genetic mutation seen in some all-white overo-overo Paint Horse crosses

SYNONYM(S)

Enteric angiogliosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Signs are present shortly after birth.
- Seen in all-white or predominantly white foals of either sex produced by overo-overo Paint Horse crosses when both parents are carriers of the mutated gene

GENETICS AND BREED PREDISPOSITION Caused by an autosomal recessive mutation seen predominantly in American Paint Horses with an overo coat color pattern, although not all overo horses carry the mutated gene

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Affected foals are usually full-term foals with no trouble standing and nursing after birth.
- Colic and meconium retention are noted shortly after birth, and progressive abdominal distension occurs with nursing.

PHYSICAL EXAM FINDINGS

- Affected foals are all-white or mostly white and have blue or pink eyes.
- With the exception of colic and abdominal distension, no other significant abnormalities are typically identified on general physical examination.
- Digital rectal examination may reveal the absence of meconium in the rectum.

ETIOLOGY AND PATHOPHYSIOLOGY

- Lethal white foal syndrome is caused by an autosomal recessive mutation in the endothelin receptor type B (*ENDRB*) gene.
- The *ENDRB* gene regulates migration and development of both melanocytes and neural crest cells in the developing fetus. When two copies of the mutated allele are present, melanocyte migration essentially fails, resulting in the white coat color, and neural crest migration is altered, resulting in failure of neuronal development in the ileum, cecum, and colon.
- The resulting intestinal aganglionosis results in a dysplastic, amotile hindgut. Signs of colic thus occur shortly after birth because of an inability of the gastric and jejunal contents to be expelled into the hindgut when the foal nurses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Meconium impaction
- Atresia coli

INITIAL DATABASE

- Complete blood count and serum biochemistry profile: Usually within normal limits.
- Abdominal imaging: Abdominal radiography and ultrasonography usually reveal mild to moderate gas distension of the small intestine.

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic evaluation of the intestine showing lack of enteric ganglia is necessary for definitive diagnosis. However, presumptive diagnosis is often made based on parentage, coat color, and failure to respond to medical management for meconium impaction.
- If exploratory celiotomy is performed because of a failure to respond to medical therapy for meconium impaction, a presumptive diagnosis can be made based on identification of a small, dystrophic, pale ileum, cecum, and colon with more proximal intestinal distension.

ElibeVet.com

TREATMENT

ACUTE GENERAL TREATMENT

- There is no effective treatment for lethal white foal syndrome.
- However, in suspect cases, medical therapy for meconium impaction (see "Meconium Impaction" in this section) should be initiated because not all white foals born to overo–overo crosses have this syndrome. If medical therapy is ineffective, then exploratory celiotomy or euthanasia is indicated.

PROGNOSIS AND OUTCOME

Grave

PEARLS & CONSIDERATIONS

COMMENTS

Not all foals with lethal white foal syndrome are all white, and not all all-white foals have lethal white foal syndrome.

PREVENTION

Genetic testing for the mutated *ENDRB* gene is available for potential carriers. Paint Horses used for breeding should be tested and crosses between two carriers avoided if possible because there is a 25% chance that a cross between carriers will result in a lethal white foal.

SUGGESTED READING

AUTHOR: **KELSEY A. HART**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Listeriosis

BASIC INFORMATION

DEFINITION

A disease caused by a gram-positive bacterium that causes encephalitis, septicemia, conjunctivitis, and abortion in animals

SYNONYM(S)

Silage disease

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Central nervous system (CNS) infections: No predilection
- Mares: Abortion
- Foals: Septicemia

RISK FACTORS

- Found in soil, water, vegetation, and silage. In horses, infection is highly associated with feeding of fermented feeds. Shed in feces of carrier animals, including horses. Shed in urine, uterine discharge, aborted fetal tissues, and milk. Abortions tend to occur in the winter months.
- Listeriosis infections are highly associated with horses located on farms where disease has occurred previously.

CONTAGION AND ZOONOSIS

- *Listeria monocytogenes* is considered a zoonotic agent. Clinical listeriosis in humans occurs most often in pregnant women and immunocompromised patients.
- Possible sources for human infections include exposure to contaminated soil and food or to human and animal carriers. Most human epidemics have been traced to food sources of animal origin. Horse meat used for human consumption has been contaminated with *L. monocytogenes*.
- Direct transmission from animals to humans is uncommon.

GEOGRAPHY AND SEASONALITY

- Bacteria can multiply efficiently in cold temperatures from 39° F to 113° F (4°–45° C).
- Grows best at high pH, especially when the pH is above 5.4
- Problem in Icelandic horses fed silage

ASSOCIATED CONDITIONS AND DISORDERS

- Immunodeficiency
- Pregnancy
- Ophthalmic corticosteroids

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Encephalitis
- Septicemia
- Keratitis and ophthalmitis
- Abortion

HISTORY, CHIEF COMPLAINT

- Encephalitis: Sudden onset of change in mentation or sudden death
- Septicemia: Weakness and severe depression
- Keratitis and ophthalmitis: Bilateral or unilateral blepharospasm
- Abortion: Late gestation in winter months

PHYSICAL EXAM FINDINGS

- Encephalitis: Characterized as a meningoencephalitis with the pathology in horses demonstrating a granulomatous encephalitis with microabscessation on histopathology. Animals may exhibit normal mentation with circling similar to ewes; however, severe mental depression is the most frequent presentation. Animals become unresponsive to external stimuli and usually die within 3 to 5 days.
- In Icelandic horses, many are febrile and inappetent, with diffuse diarrhea and death.
- Septicemia: Clinical signs include depression, anorexia, fever, diarrhea, and abdominal pain. Weakness, seizures, ataxia, jaundice, and respiratory distress have been reported as well.
- Conjunctivitis and keratitis: Range from purulent conjunctivitis to deep ulcerative keratitis and ophthalmitis
- Abortion: Sudden spontaneous abortion about 48 to 72 hours after infection in a dam. Fetuses are infected late in gestation and acquire septicemia. The fetus will be fairly fresh and is either dead at expulsion or dies shortly thereafter. Dams are usually normal and do not exhibit problems after abortion.

ETIOLOGY AND PATHOPHYSIOLOGY

- *L. monocytogenes* infection
- The organism usually enters through ingestion.
- Oral and pharyngeal abrasion allows infection.
- For encephalitis, bacteria likely travel transaxonally as they do in other species. In ewes, the trigeminal (V) and hypoglossal (XII) cranial nerves are considered the most likely routes for CNS invasion.

ElibeVet.com

- Replication in the pons and medulla occurs.
- If bloodstream infection occurs, the gravid uterus is a site of localization.
- Direct infection of monocytes and macrophages occurs, and the organism evades the immune system and initiates an inflammatory cascade that is consistent with septic shock and leads to tissue necrosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Encephalitis
  - Rabies
  - Flavivirus encephalitis: West Nile virus, Japanese encephalitis virus, Kunjin virus
  - Alphavirus encephalitis: Eastern, Western, and Venezuelan equine encephalitis virus
  - Hepatoencephalopathy
  - Theiler's disease
  - *Halicephalobus gingivalis* infection
- Septicemia
  - Gram-negative sepsis in foals
  - Neonatal asphyxia
  - Equine herpesvirus-1 (EHV-1) Infection
- Abortion
  - Noninfectious late-term causes of abortion
  - EHV-1
  - Nocardioform abortion
  - *Neorickettsia risticii* infection
  - Ascending bacterial infections (*Streptococcus equi* subsp. *zooepidemicus* and *Actinobacillus equuli* most common)

INITIAL DATABASE

- Complete blood count: Leukopenia or leukocytosis consistent with bacterial infection
- Hyperfibrinogenemia
- Serum biochemical analysis: Elevated liver enzymes
- Cytologic examination of a direct smear from infected tissue or body fluids, corneal scrapings, or aborted tissue for the presence of gram-positive rods

ADVANCED OR CONFIRMATORY TESTING

- Microbiologic culture of feces, blood or affected organs, including the liver, spleen, and brain.
- Culture of feedstuffs, especially silage
- Polymerase chain reaction has also been described but has not been used in horses.
- Genotyping of isolates to confirm feed contamination with fecal isolates of horses has been performed.
- At necropsy, histopathology, culture, and immunohistochemistry are needed to confirm a diagnosis. It is difficult to culture organisms from the brain in neural listeriosis, so the laboratory must do cold enrichment.

TREATMENT

THERAPEUTIC GOAL(S)

Correct and timely identification to allow early intervention

ACUTE GENERAL TREATMENT

- *L. monocytogenes* is susceptible to many antibiotics, including penicillin. Very large loading dosages for systemic signs are recommended.
- However, isolates from a corneal scraping and from blood cultures from three foals were all resistant to ceftiofur.

PROGNOSIS AND OUTCOME

- Encephalitis: Usually poor prognosis because of limited antemortem detection of infection
- It is difficult to give an accurate prognosis for foals and adults with clinical listeriosis.
- Listerial keratitis has resolved after topical antibiotic therapy.

SUGGESTED READING

EDITORS: **DEBRA C. SELLON** and **MAUREEN T. LONG**

Liver: Parasitic Conditions

BASIC INFORMATION

DEFINITION

Parascaris equorum, *Strongylus edentates*, *Strongylus equinus*, and occasionally *Strongylus vulgaris* migrate through the liver during larval development; however, these parasites cause little permanent liver damage. *Fasciola* spp. and *Echinococcus equinus* may affect the liver more directly, although clinical disease with either is rare.

SYNONYM(S)

- Liver flukes
- Hydatid cysts

EPIDEMIOLOGY

SPECIES, AGE, SEX

- *P. equorum* is usually a problem in younger animals because adults develop effective immunity.
- *Strongylus* spp. may affect animals of any age.
- *Fasciola hepatica* is the most common liver fluke infecting large animals and may affect Equids of all ages.
- *E. equinus* infections in horses tend to involve older animals.

RISK FACTORS Uncontrolled home slaughter and offal disposal are probably the main factors associated with persistence of *Echinococcus* infection.

CONTAGION AND ZOONOSIS Although cystic echinococcosis is an important public health disease in many parts of the world, *E. equinus* does not appear to be infective to humans.

GEOGRAPHY AND SEASONALITY

- Fascioliasis in horses has been reported all over the world, and the disease may be more common in areas with high infection rates in cattle and sheep.
- The life cycle of the liver fluke depends on the availability of water and the presence of appropriate *Lymnaeid* snail hosts in grazing areas. Temperatures above 50° F (10° C) are necessary for completion of the life cycle.
- Most cases of equine echinococcosis in North America have occurred in animals imported from the United Kingdom.

ElibEVet.com

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- *S. edentates*, *S. equinus*, and *P. equorum* infestations are most commonly characterized by nonspecific signs of weight loss or poor growth, rough hair coat, and poor performance. No clinical signs are associated with migration of these parasites through the liver.
- Vague signs of poor performance, loss of condition, and diarrhea have been described in horses living in areas with high *F. hepatica* infection rates in cattle.
- *E. equinus* infection is usually asymptomatic. When clinical signs do appear, they are usually related to pressure of the cyst on adjacent organs.

PHYSICAL EXAM FINDINGS In many cases, findings on physical examination are nonspecific, as described above. Few, if any, findings are referable to hepatic involvement.

ETIOLOGY AND PATHOPHYSIOLOGY

- Disease caused by *S. edentates*, *S. equinus*, or *P. equorum* infection is primarily attributable to the gastrointestinal (GI) effects of these parasites rather than direct effects on the liver.
- In other species, infection with *F. hepatica* may cause acute or chronic disease.
- Acute disease occurs after migration of immature flukes through the hepatic parenchyma.
- Chronic disease is caused by the effects of mature parasites within the bile ducts.
- Cystic echinococcosis (hydatid disease) in horses is caused by *E. equinus*.
- The life cycle is indirect; horses are intermediate hosts, and the carnivorous definitive host is usually canid.
- In the intermediate host, ingested larvae penetrate the intestinal wall and form hydatid cysts in various organs, most often in the liver and occasionally the lungs.
- Cystic echinococcosis is often an incidental finding in horses; if clinical signs occur, they are usually caused by pressure on adjacent organs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Few, if any, clinical signs are typically related to liver disease in these parasitic infections.
- Differential diagnoses are likely to include diseases causing weight loss, poor growth rates, and poor performance.

INITIAL DATABASE

- Complete blood count: Mild anemia and leukocytosis with or without eosinophilia
- Fibrinogen concentration: Normal to increased
- Serum or plasma biochemistry
  - Hypoalbuminemia, β-globulinemia, and increased immunoglobulin G(T) concentrations may be present.
  - There are typically no changes in the serum biochemistry related to liver dysfunction.

ADVANCED OR CONFIRMATORY TESTING

- Patent parasitic infections with nematodes may be detected by fecal examination using one of several qualitative or quantitative concentration techniques.
- Eggs are typically shed intermittently in animals with liver fluke infections.
- Hydatid cysts may be identified ultrasonographically in some cases.

TREATMENT

THERAPEUTIC GOAL(S)

- Hepatic migration of the GI nematodes through the liver is not accompanied by clinical signs, and there is no evidence of long-term injury to the liver. Therefore specific treatment is not indicated.
- Triclabendazole (12 mg/kg) has been used with apparent efficacy to control *F. hepatica* infection in horses (and donkeys). This is an off-license use of this anthelmintic, but it appears to be safe.
- Treatments for human cystic echinococcosis have included surgery and chemotherapy with benzimidazole compounds. More recently, percutaneous cyst puncture followed by aspiration injection of chemicals, and re-aspiration has been used. None of these therapies have been described in horses.

ACUTE GENERAL TREATMENT

Specific acute treatment is generally not required for patients with these conditions.

PROGNOSIS AND OUTCOME

These conditions result in little to no long-term effects on liver function.

PEARLS & CONSIDERATIONS

- Parasitic migration through the liver has little or no long-term effect on the liver because of its tremendous ability to regenerate.
- Horses appear to have pronounced resistance to establishment of infectious *Fasciola* spp., and the incidence of clinical disease in this species is very low compared with that of sheep, goats, and cattle.
- Hydatid cysts in horses are usually an incidental finding and do not appear to pose a human health threat.

AUTHOR: **BRETT TENNENT-BROWN**

EDITOR: **MICHELLE HENRY BARTON**

Locoweed Toxicosis

BASIC INFORMATION

DEFINITION

- Locoweeds (*Astragalus* and *Oxytropis* species) are native plants of North America that can cause a variety of systemic effects, especially on the central nervous system (CNS) and reproductive system. They can also affect the heart, intestinal system, and lymphocytes of horses and other livestock species.
- In addition, some locoweed species are selenium accumulators.

SYNONYM(S)

Locoism, a term derived from the Spanish word *loco*, meaning "crazy," describes

ElibeVet.com

the abnormal neurologic signs in horses poisoned by locoweeds (milk vetches) of the *Astragalus* and *Oxytropis* species.

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses, livestock, and wild ruminants are susceptible. Nursing young are most susceptible because the toxic alkaloid in locoweeds is passed through the milk.

RISK FACTORS

- Toxic at all growth stages, locoweeds are most palatable to horses in the spring when the plants are in flower. Some toxicity is retained in the dried plants.
- Although not truly addictive, horses find locoweeds palatable and may seek them out in preference to other forages, especially when the plants are in flower.

GEOGRAPHY AND SEASONALITY

- More than 350 native species of locoweeds belong to the *Astragalus* and *Oxytropis* genera in North America. Relatively few species are important toxicologically.
- Geographically, the toxic species of locoweed are concentrated in the intermountain and southwestern United States. Locoweeds are short-lived perennial legumes that reproduce from seeds that can remain viable in the soil for more than 50 years (Figures 1 and 2).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Depending on the species of *Astragalus* and *Oxytropis*, three distinct toxins may be present: swainsonine, nitrotoxins, or selenium.

HISTORY, CHIEF COMPLAINT Changes in temperament, behavior, incoordination, and weight loss are typical presenting signs

ETIOLOGY AND PATHOPHYSIOLOGY

- Locoism results from the consumption of locoweeds infected with an endophyte (*Embellisia* spp.) that produces the indolizidine alkaloid swainsonine.
  - Swainsonine inhibits α-mannosidase, an enzyme critical in the metabolism of oligosaccharides.
  - Complex sugars accumulate in cells with resulting cellular dysfunction and death.
  - Locoism is a lysosomal storage disease affecting the CNS and many other cells.
  - Impaired lymphocyte function may cause decreased immune response.
  - Asymptomatic mares in the first trimester of pregnancy may produce foals with arthrogryposis.
  - Stallions grazing locoweed may develop temporary infertility similar to the sperm maturation defects seen in rams and bulls grazing locoweed.
  - Horses can be experimentally poisoned with as little as 1 lb/d of dried locoweed for 75 to 85 days.
  - The half-life of swainsonine in the body is 15 to 20 hours.
- Some species of *Astragalus* (milk vetches) contain nitrotoxins.
  - Ruminants are most commonly affected.
  - Nitrotoxins are hydrolyzed in the rumen to toxic 3-nitropropanol and 3-nitropropionic acid.
  - Nitrotoxins induce methemoglobinemia and neuropathy, leading to depression, weakness, ataxia, and death. Horses are rarely affected under natural conditions but are susceptible to the toxins.
- Some species of locoweed only grow in selenium-rich soils and are known as "selenium indicator" species. Their presence in the rangeland indicates selenium soils; therefore other forages and grasses will likely contain selenium that can cause chronic selenium poisoning in horses and other animals grazing the area (see "Selenium Toxicosis" in this section).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Encephalitis: Rabies, West Nile virus, Eastern and Western equine encephalitis virus, equine Venezuelan encephalitis
- Equine herpesvirus
- Sage poisoning
- Pyrrolizidine alkaloid toxicity
- Bracken fern poisoning
- Chronic weight loss from malnutrition, poor teeth, parasites
- Other causes of arthrogryposis (eg, sorghum/sudan grass toxicosis, genetic causes)

INITIAL DATABASE

- Serum protein: Decreased
- Triiodothyronine (T3) and thyroxine (T4) levels: Decreased
- Aspartate aminotransferase: Elevated
- Alkaline phosphatase: Elevated
- Lactate dehydrogenase: Elevated
- Peripheral lymphocytes: Vacuolated cytoplasm in early toxicity

ADVANCED OR CONFIRMATORY TESTING

- Serum swainsonine levels: Obtain serum sample within 2 days of ingestion of locoweeds.
- Serum α-mannosidase activity: Decreased within 24 hours of eating a toxic dose of locoweed. Levels return to normal 6 days after locoweed consumption is stopped.

FIGURE 1 White locoweed (*Oxytropis sericea*).

FIGURE 2 Spotted or blue locoweed (*Astragalus lentiginosus*).

ElibVet.com

- Histopathology: Cytoplasmic vacuoles in brain Purkinje cells, thyroid, lymphoid tissue, hepatocytes, renal tubules, placenta, and intestine after clinical signs are evident.

TREATMENT

THERAPEUTIC GOAL(S)

There is no specific treatment for locoism. Horses will show improvement over time but may never fully recover, especially from residual neurologic deficits.

ACUTE GENERAL TREATMENT

- Remove all locoweed from the animal's diet.
- Provide good-quality hay and concentrate ration.

POSSIBLE COMPLICATIONS

Horses will have compromised lymphocytes while eating locoweeds, which may affect their response to vaccines, and they may be prone to other infectious diseases.

PROGNOSIS AND OUTCOME

- Horses have a guarded to poor prognosis depending on the severity and chronicity of signs.
- Residual neurologic deficits may render horses unsafe to ride.

PEARLS & CONSIDERATIONS

COMMENTS

Locoweed poisoning is a long-standing problem in the western United States and should always be considered in the differential diagnosis of neurologic disease and weight loss in horses.

PREVENTION

- Recognition of locoweeds in a pasture facilitates pasture management to reduce grazing locoweeds.
- Remove horses when locoweed is blooming.
- Avoid overgrazing pasture.
- Selectively use herbicides.

CLIENT EDUCATION

Take inventory of plants in native pasture and rangeland.

AUTHOR: **ANTHONY P. KNIGHT**

EDITOR: **CYNTHIA L. GASKILL**

Lupus Complex

BASIC INFORMATION

DEFINITION

A multisystemic disease caused by the production of multiple autoantibodies, especially those directed against nucleic acids. It usually involves the skin and at least one other organ.

SYNONYM(S)

Systemic lupus erythematosus, SLE

EPIDEMIOLOGY

SPECIES, AGE, SEX Sporadic in onset but rare

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Generally presents as a generalized skin disease with alopecia, dermal ulceration, and crusting
- Antiglobulin-positive anemia
- Glomerulonephritis
- Nonseptic, nonerosive synovitis
- Lymphadenopathy

HISTORY, CHIEF COMPLAINT

- Extensive skin lesions
- Nonspecific lethargy and weakness

ETIOLOGY AND PATHOPHYSIOLOGY

- This is a complex syndrome that results from major dysregulation of the B-cell system.
- It leads to the production of multiple autoantibodies directed against nuclear, cytoplasmic, and cell membrane antigens.
- The pathognomonic antibodies are those directed against nucleic acids.

DIAGNOSIS

The diagnosis of lupus is difficult. As a syndrome, its diagnosis cannot be based on a single diagnostic test but rather on a collection of different lesions and exclusion of other causes

DIFFERENTIAL DIAGNOSIS

- Bacterial or fungal skin diseases
- Pemphigus complex

INITIAL DATABASE

- Complete blood count, including differential leukocyte count and platelet count
- Serum biochemical profile. Abnormalities may reflect chronic inflammation and evidence of glomerulonephritis such as azotemia and hypogammaglobulinemia
- Urinalysis showing possible proteinuria
- Skin cultures ruling out infectious cause
- Skin biopsy may reveal characteristic histologic pattern with inflammatory infiltrates at the dermal/epidermal junction. Also basement membrane degeneration typical of lupus
- If arthritis/synovitis is present, radiographs may show nonerosive joint swelling
- Serum antinuclear antibody titer: Sensitivity and specificity are unclear
- False-positive results occur in other species, in many cases because of drug use
- Variable laboratory standardization
- Lupus erythematosus cell tests are equivocal and rarely useful.

ADVANCED OR CONFIRMATORY TESTING

- Coombs test and rheumatoid factor: Usually negative
- Immunofluorescence testing of the skin biopsy may show the skin basement membrane contains immunoglobulin deposits (a lupus band).

TREATMENT

THERAPEUTIC GOAL(S)

Suppress the animal's excessive immune function so that damage to the skin, kidneys, and other organs is reversed.

ElibeVet.com

ACUTE GENERAL TREATMENT

- Immunosuppressive treatment with steroids and immunosuppressive drugs has generally been unsuccessful, but experience is limited.
- Dexamethasone sodium phosphate solution (0.08 mg/kg PO q24h): After a response has been obtained, progressively decrease the dose to 0.02 mg/kg/d.
- Alternatively, prednisolone (1 mg/kg PO q24h)
- Azathioprine (3 mg/kg PO q24h) may be as effective as dexamethasone. After 30 days, half the daily dose for another 30 days.

CHRONIC TREATMENT

Dexamethasone or prednisolone until resolution of signs (2 weeks); then slow reduction of dose. Lifelong treatment may be required.

POSSIBLE COMPLICATIONS

- Secondary infections after immunosuppression
- Progressive renal damage
- Laminitis secondary to steroid treatment

PROGNOSIS AND OUTCOME

Limited experience suggests that the prognosis is poor.

PEARLS & CONSIDERATIONS

- The diagnosis of lupus is difficult and largely based on excluding other possibilities.
- Biopsy normal skin adjacent to ulcerated areas.

AUTHOR & EDITOR: **IAN TIZARD**

Lyme Disease

BASIC INFORMATION

DEFINITION

Infection with a tickborne, gram-negative helical spirochete, *Borrelia burgdorferi*, which causes disease resulting in equivocal signs of lameness or behavioral changes

SYNONYM(S)

Borreliosis

EPIDEMIOLOGY

- No known breed, age, or sex predilection
- Seroprevalence ranges from less than 1% to 68% in endemic regions.
- Highest seroprevalence in mid-Atlantic and northeastern states, Minnesota, and Wisconsin (30%–40% of ticks are infected with *B. burgdorferi*)
- Rare positive horses in the Rocky Mountain states, North and South Dakota, and Nebraska (only 1%–3% of tick vector population are infected with *B. burgdorferi*)
- Occurs primarily in the spring, summer, and fall, with peak incidence in June and July in most endemic climates
- Not directly zoonotic; unknown if horses serve as source of infection for ticks

CLINICAL PRESENTATION

- History of tick exposure or residing in a Lyme disease endemic area
- Nonspecific clinical signs
- Vague signs of lameness or stiffness (generally in more than one limb)
- Lethargy, depression, decreased performance
- May observe muscle pain, hyperesthesia, or behavioral changes
- Polysynovitis usually with minimal joint effusion
- Low-grade fever
- Distal limb edema
- Rare neurologic signs
- Rarely, anterior uveitis
- Possible muscle wasting and pain over thoracolumbar area with severe cases

ETIOLOGY AND PATHOPHYSIOLOGY

- The spirochete *B. burgdorferi* is the etiologic agent of Lyme disease.
- Prolonged attachment and feeding (>24 hours) of infected adult *Ixodes* spp. ticks transmits the organism.
- Invades the connective tissues, muscle, skin, and nerves and blood vessels near synovial membranes
- A lymphocytic plasmocytic reaction in tissue occurs in association with the organism.
- Unknown whether polysynovitis is the result of an immune-mediated reaction (immune complex deposition) or infection of the joint

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Arthritis: Trauma, osteoarthritis, other immune-mediated arthritis
- Neurologic signs: Equine herpes virus-1, equine protozoal encephalomyelitis, rabies, cervical vertebral malformation, cauda equine syndrome, West Nile virus, Eastern or Western equine encephalitis
- Distal limb edema: Purpura hemorrhagica, equine viral arteritis, equine infectious anemia, cellulitis, hypoproteinemia, *Anaplasma phagocytophilum* infection, or normal "stocking up"

INITIAL DATABASE

- Antemortem diagnosis is generally presumptive.
- Low-grade fever
- Complete blood count and serum chemistries: No significant findings
- Radiography to help rule out other causes of lameness
- Synovial fluid cytology to rule out sepsis; may have neutrophilic inflammation with Lyme disease
- Cannot visualize the pathognomonic erythema migrans rash that is diagnostic in humans

ADVANCED OR CONFIRMATORY TESTING

- Enzyme-linked immunosorbent assay (ELISA), C6 test, indirect fluorescent antibody test, and Western Blot available for serology
- Serology confirms exposure; ELISA titers above 110 U may provide stronger support for infection
- Histopathology: Lymphocytic plasmacytic infiltrate
- May perform polymerase chain reaction or immunohistochemistry on affected tissues to detect the organism

ElibeVet.com

TREATMENT

THERAPEUTIC GOAL(S)

- Eradicate organisms from the host
- Treat symptomatically
- Often treated presumptively

ACUTE GENERAL TREATMENT

- Generally respond to treatment within 2 to 4 days
- Antimicrobial therapy: IV oxytetracycline (thought to be most effective) or PO doxycycline are usually recommended; may add metronidazole for possible cyst forms
- May also treat with enrofloxacin, ceftiofur, or procaine penicillin G
- Judicious nonsteroidal antiinflammatory therapy
- Cold hosing and leg wraps for distal limb swelling and polysynovitis
- Atropine may be required for uveitis
- Intraarticular corticosteroid administration is controversial

CHRONIC TREATMENT

Long-term treatment with antimicrobials is required (>1 month).

POSSIBLE COMPLICATIONS

- Chronic arthritis
- Laminitis
- Damage to the central nervous system
- Possible recurrent uveitis

PROGNOSIS AND OUTCOME

- Prognosis is not easy to determine because it is difficult to definitively diagnose Lyme disease, and it is hard to document the outcome with presumptive diagnoses.
- In other species, the prognosis is fair for survival, but in horses, it is likely to be guarded for return to athletic function.

PEARLS & CONSIDERATIONS

COMMENTS

- Horses may be an important sentinel animal for risk of Lyme disease for humans in a particular area.
- Infection may occur in conjunction with *Anaplasma phagocytophilum* because many ticks are co-infected with both organisms. This may contribute to the observed clinical signs and affect evaluation of response to treatment because *A. phagocytophilum* is very susceptible to tetracyclines.
- Reliable experimental reproduction of Lyme disease in horses has proven to be difficult, limiting the success of Lyme disease research and characterization.

PREVENTION

- Prevent tick exposure or prolonged attachment. Canine tick sprays may be effective for tick repellent.
- Regular grooming and removal of attached ticks.
- Pursue appropriate antimicrobial treatment after exposure to *Ixodes* ticks.
- No vaccine is currently available.

SUGGESTED READING

Lymphangitis, Epizootic

BASIC INFORMATION

DEFINITION

Chronic ulcerative lymphangitis caused by infection with the fungus *Histoplasma capsulatum* var. *farciminosum.*

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses, donkeys, and mules are susceptible.

CONTAGION AND ZOONOSIS Considered both contagious and zoonotic

GEOGRAPHY AND SEASONALITY

- Most common in Egypt, India, North Africa, the Middle East, southern Asia, southern Europe, and areas of Russia
- Endemic in countries that border the Mediterranean

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cutaneous
- Ocular
- Respiratory

HISTORY, CHIEF COMPLAINT Ulcerative nodules with exudate and cording

PHYSICAL EXAM FINDINGS

- Cutaneous disease: Granulomatous, often ulcerated, masses in chains following lymphatic vessels. Lesions eventually heal and scar as others form. The forelimbs, neck, and head are most common sites.
- Ocular: Conjunctivitis; nodular enlargements over facial lymphatics and nasolacrimal lesions. Serous ocular discharge and swelling of the eyelids are observed with nodules on the conjunctiva or nictitans.
- Respiratory: Yellowish papules or nodules in the upper respiratory tract often near the external nares. Lesions may ulcerate and bleed. Pulmonary granulomata may cause fatal disease.
- Disseminated disease: Infrequent.

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused by a dimorphic fungal organism.
- Direct inoculation of fungus through abraded skin or mucous membranes is suspected as the primary mode of transmission.
- Fomites such as harness, mangers, water buckets, and flies may contribute to transmission.
- May be transmitted from stallions to mares during breeding.
- Lower respiratory tract disease may result from inhalation of organisms in dust.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ulcerative lymphangitis: *Corynebacterium pseudotuberculosis*
- Glanders: *Burkholderia mallei*
- Epizootic lymphangitis: *H. capsulatum* var. *farciminosum*

INITIAL DATABASE

Evidence of chronic infection and inflammation

ElibeVet.com

ADVANCED OR CONFIRMATORY TESTING

- Culture of organism from body fluids or tissues is considered the gold standard for diagnosis.
- Cytologic observation of yeast forms in tissue exudates
- Serology: Tube agglutination and passive hemagglutination tests are suggestive of disease if the results are positive but may reflect only past exposure or asymptomatic infection.
- Intradermal testing with soluble antigen may have low specificity.

TREATMENT

THERAPEUTIC GOAL(S)

Reportable disease in many countries with policy of slaughter for eradication

ACUTE GENERAL TREATMENT

In endemic areas where treatment is allowed, oral and IV iodide or amphotericin B may be used. Other antifungals may also be effective.

PROGNOSIS AND OUTCOME

Reportable disease with mandatory slaughter in many countries

PEARLS & CONSIDERATIONS

Mortality from cutaneous disease is uncommon, but an inability to work because of painful nodules can lead to significant economic loss.

SUGGESTED READING

Kohn C: Miscellaneous fungal infections. In Sellon DC, Long MT (eds). *Equine infectious diseases*, St Louis, 2007, Elsevier, pp 431–445.

AUTHOR: **DEBRA C. SELLON**

EDITORS: **DEBRA C. SELLON** and **MAUREEN T. LONG**

Lymphoma, Equine

BASIC INFORMATION

DEFINITION

Neoplasia of lymphoid origin

SYNONYM(S)

Lymphosarcoma; malignant lymphoma (*lymphoma* is currently the preferred term)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common form of hematopoietic neoplasia in horses
- The prevalence at postmortem examination is 2% to 5%.
- Most common in horses age 5 to 10 years but can occur in any age, including neonates

GENETICS AND BREED PREDISPOSITION Genetic causes may exist because rare reports exist of aborted feti affected by lymphoma.

ASSOCIATED CONDITIONS AND DISORDERS Paraneoplastic syndromes that have been reported include hypercalcemia, immune-mediated hemolysis, immune-mediated thrombocytopenia, hypereosinophilia, and polycythemia. A case of generalized pruritus and alopecia was also reported in a horse with lymphoma.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Occurs in four anatomic forms based on the major site of tumor involvement (overlap between forms is common).

- Generalized: Regional lymph nodes are often affected with involvement of the thoracic and abdominal organs. Solitary tumors in various tissues also occur but less commonly. Clinical signs and diagnostic findings depend on the affected tissues. Chronic disease with often acute, severe terminal progression of clinical signs. Most commonly affects horses 5 to 10 years of age, but all ages are at risk.
- Alimentary: Most common in young horses ages 2 to 5 years. Presenting complaints include weight loss, ill thrift, intermittent colic, fever, and chronic diarrhea. Diagnosis can be made by cytologic analysis of peritoneal fluid in 35% to 50% of cases.
- Mediastinal: May cause dyspnea, cough, recurrent pleural effusion. Most commonly affects horses 5 to 10 years of age.
- Cutaneous: Generalized cutaneous or subcutaneous nodules with acute or chronic onset or progression. Lesions may be affected by hormone alterations (eg, pregnancy, estrous).

HISTORY, CHIEF COMPLAINT

- Progressive disease with acute onset of clinical signs related to dysfunction of the affected organs.
- Chronic weight loss is a common presenting complaint.
- Signs are generally nonspecific.

PHYSICAL EXAM FINDINGS

Poor body condition score, peripheral lymphadenomegaly, ventral edema; other findings consistent with the affected organ system

ETIOLOGY AND PATHOPHYSIOLOGY

- Lymphoma in horses is clinically and pathologically quite variable.
- Literature reports do not classify whether T- or B-cell tumors predominate.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Generalized form: Chronic systemic infections, such as internal abscessation or bacterial pneumonia; other forms of metastatic neoplasia (adenocarcinoma, carcinoma)
- Alimentary form: Gastrointestinal parasites, inflammatory bowel disease, chronic bacterial enterocolitis
- Mediastinal form: Bacterial pneumonia or pulmonary abscessation, pleuropneumonia, metastasis of other forms of neoplasia (adenocarcinoma, carcinoma)
- Cutaneous form: Folliculitis, furunculosis, dermatophytosis, nodular necrobiosis, urticaria, amyloidosis

INITIAL DATABASE

- Perform complete blood count (CBC), serum chemistry profile, and urinalysis.
- Laboratory findings are variable. CBC often indicates nonspecific, chronic, inflammatory disease (neutrophilic leukocytosis, anemia, hyperfibrinogenemia, hyperglobulinemia). Lymphocyte count is often normal or low, but atypical or neoplastic cells may be observed on smear.

ElibeVet.com

- Lymphocytic leukemia is rare but is typified by a marked lymphocytosis.
- Hypercalcemia is present in some cases. Decreased serum concentrations of immunoglobulin M have been reported but are not consistent.
- If thoracic or abdominal involvement is suspected, thoracic radiographs or ultrasonography and abdominal ultrasonography often allow visualization of the tumor and facilitate sample collection for cytology or histopathology.

ADVANCED OR CONFIRMATORY TESTING

- Biopsy of enlarged lymph node or abnormal tissue. Fine-needle aspirate of fluid or tissue can also be diagnostic if biopsy is not possible.
- Analysis of pleural or peritoneal fluid may reveal the presence of neoplastic cells in some cases.
- Removal of subcutaneous nodules for analysis is diagnostic for cutaneous form.
- Immunophenotyping (flow cytometry, immunohistochemistry) to confirm T- or B-cell origin.

TREATMENT

THERAPEUTIC GOALS

- Chemotherapy protocols have been used with reported success in the form of case reports only.
- The goal of therapy is complete remission or cessation of clinical signs while maintaining quality of life.

ACUTE GENERAL TREATMENT

- As with all chemotherapeutic agents, appropriate handling is essential for animal, client, and veterinarian safety. Consultation with or referral to a veterinary oncologist or internist is recommended.
- Chemotherapy regimens include a combination of cytotoxic and immunosuppressive drugs. Doses have been extrapolated from humans and small animals because no pharmacokinetic data have been published. The dosages provided below were taken from case reports and proceedings and were judged safe by the authors.
  - Thoracic lymphoma was treated in one mare with cytosine arabinoside (170 mg/m^2 IM twice at a 2-week interval), alternating with cyclophosphamide (142 mg/m^2 IV twice at a 2-week interval), and prednisolone (86 mg/m^2 PO) every 48 hours for the remainder of the horse's life. The horse remained in remission 8 months after therapy.
  - A protocol has been used with variable success that includes cytosine arabinoside (200–300 mg/m^2 SC or IM once every 1–2 weeks), alternating with chlorambucil (20 mg/m^2 PO every 2 weeks), and prednisolone (0.5–1.0 mg/lb PO) q48h. Cyclophosphamide (200 mg/m^2 IV) every 2 to 3 weeks can be substituted for the oral chlorambucil. If the patient responds, remission is expected in 2 to 4 weeks. May add vincristine (0.5 mg/m^2 IV) once weekly if no response is seen.
  - Cytosine arabinoside and cyclophosphamide (dosages above) can also be used as single agents. L-asparaginase (10,000–40,000 IU/m^2 IM) can also be used every 2 to 3 weeks as a single agent.
  - Doxorubicin at a dose of 70 mg/m^2 IV at 3-week intervals is also considered a safe, effective drug choice for systemic chemotherapy.
- Immunosuppressive doses of corticosteroids alone will often transiently decrease the size of the tumor or affected lymph nodes.
- With solitary tumors, complete surgical resection may be curative. Large colon and small intestine resection afforded several months of survival after discharge from the hospital in reports of two horses with intestinal lymphoma.
- Radiation has been used with success in solitary tumors, especially those of the nasal cavity (see "Radiation Therapy" in Section II).
- Cutaneous lymphoma has been treated successfully with corticosteroids, progestins, low-dose systemic chemotherapy, intralesional chemotherapy (with cisplatin), and immunomodulators.

CHRONIC TREATMENT

After remission, horses have been treated long term with prednisolone as mentioned above.

DRUG INTERACTIONS

- Before using chemotherapeutics, consultation with or referral to a veterinary oncologist or internist is recommended.
- Antioxidants such as vitamin E should be avoided in conjunction with doxorubicin.
- Digoxin has reported to interact with several chemotherapy agents (in humans).
- Vincristine should not be given with other drugs that require metabolism by cytochrome P450, including itraconazole.

POSSIBLE COMPLICATIONS

- Acute severe deterioration can occur with generalized disease. Depending on the tissues affected, acute organ failure often occurs.
- Reported reactions to chemotherapy include neutropenia with or without sepsis, thrombocytopenia, colic, laminitis, bone marrow suppression, focal dermatitis at the injection site, and delayed allergic reactions.

RECOMMENDED MONITORING

- CBC should be performed before every dose of chemotherapy.
- Progression of clinical signs is likely without treatment.
- Cutaneous lesions often wax and wane over time without therapy, especially with hormonal variations.

PROGNOSIS AND OUTCOME

Any form of lymphoma can, and usually does, progress despite therapy. There have only been a few reported cases of survival after aggressive therapy, so an accurate outcome and prognosis are difficult to estimate. Most horses present late in the course of disease, which may preclude treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Chemotherapy may successfully manage lymphoma to give good function and quality of life.
- Surgery is appropriate only for localized lesions that are functionally impairing the horse and can be completely resected. Even in those cases, surgery is unlikely to be curative.
- Careful physical examination and sampling for cytologic or histologic analysis is key for diagnosis.

CLIENT EDUCATION

- Treatment may result in comfortable survival with a good quality of life.
- Lymphoma is usually progressive and ultimately fatal.

ElibeVet.com

Malocclusions, Dental

BASIC INFORMATION

DEFINITION

Abnormal occlusal wear patterns involving the premolar and molar arcades

SYNONYM(S)

Hooks, ramps, waves, steps

EPIDEMIOLOGY

RISK FACTORS Age, dental trauma, orthodontic abnormalities, dental dysplasia

ASSOCIATED CONDITIONS AND DISORDERS Periodontal disease, endodontic disease, premature expiration and exfoliation

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most often, no complaint
- Occasionally, poor performance, weight loss, dysphagia, quidding, poor appetite

PHYSICAL EXAM FINDINGS

- Abnormal occlusal wear
- Occasionally, poor occlusal contact
- Occasionally, restricted lateral or rostrocaudal mandibular range of motion (ROM)

ETIOLOGY AND PATHOPHYSIOLOGY

- Unopposed teeth or portions thereof
- Abnormal enamel content or distribution
- Misaligned teeth
- Any abnormality in dental tissue or alignment or restriction of normal mandibular movement can lead to excessive wear in specific areas along the arcades. Compensatory shifts in mandibular position or ROM can lead to secondary malocclusions.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Skeletal curve in dish-faced breeds or individuals can mimic a wave.
- Caudal molar set well into curve of Spee can mimic a hook or ramp.

INITIAL DATABASE

- Oral examination: Identification of malocclusions such as but not limited to:
  - Hooks: Excessive crown height of maxillary 6s or mandibular 11s where the vertical height of the excessive crown is greater than the horizontal length
  - Ramps: Excessive crown height in which the horizontal length of the excessive crown is greater than the vertical height
  - Waves: Gradual increase or decrease in crown heights along the length of the arcade involving two or more teeth
  - Steps: Excessive crown height of a single tooth
- Knowledge of previous dental care
- Age
- Severity of malocclusion
- Amount of clinical crown

ADVANCED OR CONFIRMATORY TESTING

Intraoral radiographs may be necessary to assess severely compromised teeth.

TREATMENT

THERAPEUTIC GOAL(S)

- Reduction or correction of malocclusions to restore more normal masticatory biomechanics
- Promote normal wear patterns to prolong the useful life of individual teeth.

ACUTE GENERAL TREATMENT

- Small malocclusions can often be corrected fully at initial treatment by reducing abnormally tall crowns or portions thereof.
- More severe malocclusions or those involving large portions of the arcades should be corrected in stages over periods of months to years.

CHRONIC TREATMENT

- Severe malocclusions in mature or geriatric horses may not be curable. Treatment should be aimed at improving masticatory biomechanics, preventing pain, preserving compromised dental tissue, preventing disease, and maintaining functional occlusion.
- Regular treatment is necessary to maintain chronic cases in a functional state.

POSSIBLE COMPLICATIONS

- Aggressive corrections can cause damage to sensitive dental tissues, resulting in pain, dysphagia or inappetence, or endodontic disease.
- Iatrogenically induced soft tissue trauma may cause dysphagia.
- Overly aggressive or poorly executed corrections may result in a loss of minimum functional occlusion, causing prolonged dysphagia.

RECOMMENDED MONITORING

- All horses should receive a comprehensive oral and dental examination at least once yearly.
- Patients with severe malocclusions may require examination and treatment every 6 to 9 months.

PROGNOSIS AND OUTCOME

- The vast majority of malocclusions are correctable. All are manageable.
- Early recognition usually leads to more successful outcomes.

PEARLS & CONSIDERATIONS

COMMENTS

- Frequent small corrections are usually the best approach for severe malocclusions.
- Operator expertise is a critical factor in successful outcomes.
- Consider referral to a more experienced colleague for advanced cases.
- Client education and expectation management is key for client compliance (ie, dental malocclusions do not develop overnight). Complete correction takes time and dedication to the goal.

PREVENTION

- All horses should have an oral examination before age 3 years (much earlier if an overjet or underjet is detected) and at least yearly thereafter.
- Malocclusions recognized at this age are typically small and very manageable or completely correctable.

CLIENT EDUCATION

- Prevention requires owner acceptance of the comprehensive dental examination as a fundamental health care necessity from an early age.
- Older horses or those with severe malocclusions may not be candidates for complete correction. Clients must be educated as to realistic outcomes and requirements for long-term management.

AUTHOR: **MARY S. DELOREY**
EDITOR: **JAMES L. CARMALT**

Mast Cell Tumors

BASIC INFORMATION

DEFINITION

A tumor composed of a neoplastic population of mast cells

SYNONYM(S)

Mastocytoma, mastocytosis (indicates systemic involvement)

EPIDEMIOLOGY

SPECIES, AGE, SEX Ages of reported cases range from 9 months to 27 years of age (mean, 9.5 years). Males predominate in these cases.

GENETICS AND BREED PREDISPOSITION Arabians are overrepresented in the reported cases; however, these tumors have been identified in numerous other breeds, including Quarter Horses, Thoroughbreds, ponies, and donkeys.

ASSOCIATED CONDITIONS AND DISORDERS Peripheral eosinophilia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Appears in two forms:

- Most common as a solitary, soft tissue nodule occurring most frequently on the extremities, head, and neck and less commonly on the trunk. Isolated case reports have identified these tumors in such locations as the nares, nasopharynx, trachea, synovium, trabecular bone of P3, sclera, and nictitating membrane. The mass can be either soft or firm but is loosely attached to the underlying tissues except for those that occur on the distal limb that are hard and firmly attached. The mass generally appears as a subcutaneous nodule covered with skin, although the skin may be ulcerated or alopecic. Most often, the mass is slow growing or static in nature. The lesions are most often benign, although local invasion of surrounding tissues and metastatic disease with invasion of local lymph nodes has been reported.
- A congenital form of generalized mast cell tumor development was reported in a neonatal Quarter Horse foal. The foal developed numerous subcutaneous nodules over the trunk and limbs shortly after birth. The nodules began as small subcutaneous masses but later enlarged and then ulcerated before spontaneous regression. The lesions reappeared cyclically during the horse's first year of life. This syndrome has been related to urticaria pigmentosa in humans.

HISTORY, CHIEF COMPLAINT Identification of a soft tissue mass (most likely on the head, neck, or limbs) possibly changing in size or appearance over time

PHYSICAL EXAM FINDINGS

- Generally unremarkable with the exception of the presenting complaint
- Horses with periocular tumors may have ophthalmic abnormalities.
- Tumors associated with a joint or bone may cause lameness in the affected limb; tumors in the respiratory tract may cause respiratory noise or epistaxis.
- Although rare, metastatic disease may cause evidence of systemic illness, including weight loss, lethargy, lymphadenopathy, and dyspnea.

ETIOLOGY AND PATHOPHYSIOLOGY Unknown. Possible theories include a response to chronic inflammation, immune-mediated disease, or parasitic infestation. Mast cell tumors in horses are unique in their appearance, behavior, and histology compared with those of other domestic species.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Variable depending on the lesion's location and appearance: Nodular necrobiosis, abscess, cutaneous habronemiasis, enlarged lymph node, cutaneous lymphoma, sarcoid, fibroma, squamous cell carcinoma, or melanoma

INITIAL DATABASE

- Diagnosis of the mass can often be made on fine-needle aspiration and cytologic examination.
- A complete blood cell count and serum chemistry may reveal a peripheral eosinophilia, which is often associated with more aggressive forms.
- If located on the limb or adjacent to an osseus structure, radiographs are recommended to examine the underlying bone. The tumors may appear calcified on radiographs.

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis relies on biopsy, most often excisional biopsy. Given the relatively benign nature of the solitary mass, adjacent lymph node aspirates and further imaging studies to assess for metastasis are not warranted unless the physical examination and laboratory work reveal other abnormalities.

TREATMENT

THERAPEUTIC GOAL(S)

Removal of the tumor en bloc

ACUTE GENERAL TREATMENT

Complete surgical resection of the tumor with wide margins (2 to 3 cm) as described in small animal practice

CHRONIC TREATMENT

- If complete resection is not possible or if the tumor recurs despite surgical removal, debulking followed by radiation has been used with success.
- Systemic corticosteroid use and sublesional injections of triamcinolone have been reported with variable success as well.
- No other chemotherapy agents have been reported.

POSSIBLE COMPLICATIONS

Removal or manipulation of a tumor can cause systemic signs in the form of diffuse urticaria or local pruritus. The potential for clinical signs of systemic degranulation exists in horses but has not been reported. In small animals, these reactions may be mild and include local swelling, erythema, and pruritus or may be severe enough to cause hypotension and death.

RECOMMENDED MONITORING

With the potential for recurrence and infrequent metastasis, these tumors should be removed and the horse moni-

ElibEVet.com

tored for recurrence or signs of systemic illness.

PROGNOSIS AND OUTCOME

Good with surgical removal

PEARLS & CONSIDERATIONS

Any new mass on a horse should be aspirated for cytologic examination to facilitate early diagnosis.

Meconium Impaction

BASIC INFORMATION

DEFINITION

Retention of meconium in the distal gastrointestinal (GI) tract

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All breeds of newborn foals may be affected.
- Colts may be overrepresented.

RISK FACTORS Weak foals and recumbent foals present an increased risk.

ASSOCIATED CONDITIONS AND DISORDERS Ruptured bladder

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Tail flagging, restlessness, colic signs (lying in dorsal recumbency, looking at flank)
- Straining to defecate; must be distinguished from straining to urinate
- Abdominal distension

PHYSICAL EXAM FINDINGS

- Digital rectal palpation may reveal meconium in the proximal rectum.
- Abdominal distension results in tachypnea.
- Severe abdominal distension results in respiratory distress.
- Weak, recumbent foals and those with altered mentation often exhibit subtle signs such as mild, repeated abdominal press.

ETIOLOGY AND PATHOPHYSIOLOGY Immature pacemaker cells in the neonatal foal's GI tract may contribute to meconium impactions in neonatal foals. Passing of meconium should begin by 2 hours of age and be completed by 48 hours. Intraluminal obstruction with meconium results in gaseous distension of the bowel orad to the impaction.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Intestinal atresia
- Ruptured bladder
- Intestinal aganglionosis (see "Lethal White Foal Syndrome" in this section)
- All other causes of colic

INITIAL DATABASE

- Physical examination: Identify concurrent or contributory disease, if present.
- Digital rectal palpation for detection of meconium in proximal rectum: Lack of meconium in the rectum does not rule out meconium impaction proximal to the rectum.

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiography: Barium enema administered via gravity flow through a 24-Fr Foley catheter (with bulb inflated) will outline intraluminal meconium; also useful to identify or rule out atresia coli and lethal white foal syndrome.
- Abdominal ultrasonography: Intraluminal echogenic masses visualized in the small or large colon are consistent with meconium; hypoechoic free fluid in the abdomen should prompt investigation of the urinary tract.

TREATMENT

THERAPEUTIC GOAL(S)

- Remove impacted meconium
- Control pain
- Restore circulating volume if dehydrated
- Maintain an adequate glucose level

ACUTE GENERAL TREATMENT

- Enema: Warm, soapy water enema made with a non-irritating soap administered via a soft, flexible tube such as a Foley or stallion catheter. The tube is advanced gently until resistance is met; 500 mL to 1 L volume by gravity flow should be used to minimize trauma to rectum. Repeated enemas may be necessary if the initial enema does not resolve the impaction; however, repeated enemas result in irritation and swelling of the rectal mucosa and should therefore be used judiciously.
- Walking: It is often beneficial for the foal to walk around (by leading the dam) after the administration of an enema.
- Laxative: Mineral oil (2–3 mL/kg) may be administered via nasogastric tube if reflux is not present.
- Analgesia: Allows for relaxation of the bowel in straining foals; flunixin meglumine (0.5–1.1 mg/kg IV), butorphanol (0.02–0.04 mg/kg IV or IM).
- IV fluids: If dehydrated; isotonic crystalloids with 2.5% to 5% dextrose if the foal has not been nursing (slow bolus of 10–20 mL/kg).

CHRONIC TREATMENT

- If routine enemas are not successful at resolving the impaction, a retention enema with 4% acetylcysteine may be administered (see "Enema, Retention/High" in Section II).
- Surgical intervention is required in very few cases.

POSSIBLE COMPLICATIONS

Ruptured bladder

RECOMMENDED MONITORING

- Monitor for continued straining after successful enemas; additional meconium may become retained, especially if the small colon and rectum are swollen from multiple enemas.
- Repeated episodes of forceful straining may cause the bladder to rupture; therefore monitor for signs of ruptured bladder (See "Uroperitoneum" in this section).

ElibeVet.com

PROGNOSIS AND OUTCOME

- Foals with meconium impactions generally respond well to medical therapy; surgery is rarely required.
- After the impaction is resolved, normal GI function should return provided that concurrent or secondary disease is not present.

PEARLS & CONSIDERATIONS

- Meconium impactions are the most common cause of colic in neonatal foals.
- Over-the-counter enemas typically contain phosphate. Repeated use of these products may lead to severe electrolyte disturbances, especially hyperphosphatemia.

Megaesophagus

BASIC INFORMATION

DEFINITION

Chronic dilation (ectasia) and atony of the body of the esophagus

SYNONYM(S)

Esophageal ectasia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Congenital megaesophagus is seen in foals and young adult horses.
- Acquired megaesophagus may occur at any age.

ASSOCIATED CONDITIONS AND DISORDERS

- Gastroduodenal ulceration
- Botulism
- Equine grass sickness
- Fourth branchial arch defect

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of esophageal dysphagia:
  - Hypersalivation
  - Regurgitation
  - Weight loss
  - Coughing associated with eating
  - Nasal discharge containing food material
- Onset of signs usually insidious

PHYSICAL EXAM FINDINGS The findings of physical examination confirm the presenting signs, including dysphagia, hypersalivation, and nasal discharge containing food material. Distension of the cervical esophagus may be visible or palpable. The horse may be noted to eructate frequently.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital megaesophagus may be inherited in a similar fashion to congenital megaesophagus in dogs. Some horses affected by fourth branchial arch defect may also have megaesophagus and achalasia of the upper esophageal sphincter.
- Acquired megaesophagus may be secondary to chronic or recurrent esophageal obstruction, esophageal obstruction by tumors and other masses, vascular ring anomalies, neurologic diseases (eg, equine protozoal myeloencephalitis, idiopathic vagal neuropathy), pleuropneumonia (and associated vagal neuropathy), equine grass sickness, botulism, or myasthenia gravis.
- Temporary iatrogenic megaesophagus may occur after sedation with α_2-adrenergic agonists, such as detomidine.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition): Pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, esophageal stricture, esophageal rupture, and equine grass sickness
- Other obstructions of the esophagus: Intramural esophageal cysts, duplication cysts of the esophagus, esophageal neoplasia

INITIAL DATABASE

- The leukogram, hematology, and blood chemistry results are likely to be normal unless they reflect abnormalities associated with any underlying disease.
- Confirmation of megaesophagus is achieved by endoscopic examination (esophagoscopy) and radiography (positive or double-contrast esophagraphy). On endoscopic examination, the esophagus appears dilated, and there is an absence of peristaltic waves. Esophagitis and reflux esophagitis may be noted. Fluoroscopy and contrast radiography may be used to measure the transit time of a bolus from the cervical esophagus to the stomach. Contrast radiography also demonstrates pooling of contrast agent or dilation of the esophageal lumen. Contrast radiography is helpful to identify gastric outflow obstruction in foals.

ADVANCED OR CONFIRMATORY TESTING

- Esophageal manometry can be used to document esophageal pressures.
- Cerebrospinal fluid analysis may be useful to identify underlying neurologic disorders.
- Electromyography may be indicated to diagnose underlying neuromuscular diseases.

TREATMENT

THERAPEUTIC GOAL(S)

- Treat any underlying diseases
- Treat any secondary inhalation pneumonia
- Aid transit of food along the esophagus

ACUTE GENERAL TREATMENT

- Treat any underlying diseases.
- Treat any secondary inhalation pneumonia.
- Dietary modification may help esophageal transit of food boluses to the stomach. Feeding slurries of pellets and feeding from an elevated position may help.
- Metoclopramide or bethanechol may benefit patients with reflux esophagitis associated with megaesophagus by increasing lower esophageal tone and gastric emptying and reducing gastroesophageal reflux.

ElibEVet.com

CHRONIC TREATMENT

Frequent small meals of slurries or fresh grass should be fed.

POSSIBLE COMPLICATIONS

- Inhalation pneumonia
- Weight loss

PROGNOSIS AND OUTCOME

Prognosis is poor in most cases.

PEARLS & CONSIDERATIONS

Megaesophagus should be considered in horses showing chronic signs of esophageal dysphagia.

AUTHOR: **TIM MAIR**

EDITORS: **TIM MAIR** and **CERI SHERLOCK**

Melanoma, Cutaneous

BASIC INFORMATION

DEFINITION

Neoplasm of dermal melanocytes or "nevus cells" within the basal layer of the epidermis

SYNONYM(S)

- Equine melanocytic disease
- Cutaneous melanoma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Occurs mostly in aging, gray and white horses, and mules.
- Bays, chestnut, and other colors are less frequently affected.
- More than 80% of gray horses older than 15 years develop melanoma.
- Some have suggested that all gray horses will develop melanoma over their lifetime.
- Case reports in non-gray horses, usually of the hoof, coronary band, and metacarpal/metatarsal area.
- The juvenile form may occur in horses of any coat color.
- Sex predisposition reported by some but not consistently.

GENETICS AND BREED PREDISPOSITION

- Most common in Lipizzaners, Arabians, and Quarter Horses.
- Arabians are thought to be predisposed because they progressively change color with age; they are usually white by 9 years of age.

RISK FACTORS

- The gray phenotype appears to be a disturbance in melanin metabolism, which stimulates the formation of melanoblasts or increased activity, resulting in overproduction of melanin in the dermis.
- Autosomal dominant trait associated with high incidence of melanoma and vitiligo-like depigmentation (cis-acting regulatory mutation)

GEOGRAPHY AND SEASONALITY

Generally accepted to be more common in sunnier latitudes

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Four distinct clinical syndromes:

- Melanocytic nevus
  - Average age of presentation is 5 years (range, 2 months to 16 years)
  - Approximately 50% of all melanotic tumors in horses
  - Considered benign
  - Gray and non-gray horses
  - Discrete, small, superficial tumors that involve the superficial dermal layer with variable pigmentation and occasional mitotic figures noted on histopathology
  - Studies suggest an Arabian overrepresentation and a female predisposition
- Dermal melanoma
  - Average age of presentation is 13 years (range, 2–19 years)
  - Discrete masses that occur in mature, middle-aged gray horses at various locations (see Physical Exam)
  - Located in the deep dermis and characterized by small, homogenous, indistinct, round tumor cells with condensed chromatin and dense cytoplasmic pigmentation
  - More aggressive forms appear to occur in atypical locations (limbs) and at a younger age
- Dermal melanomatosis
  - Average age of presentation is 17 years (range, 7–29 years); multiple sites or coalescence
  - Older gray horses, frequently in typical locations (tail base, perineum, and genitalia)
  - Histologically similar to dermal melanoma but more confluent
  - High metastatic rate
  - Surgical excision usually not feasible
- Anaplastic melanoma
  - Average age of presentation is 20 years and not exclusively in gray horses
  - May occur more commonly in other colors (chestnut)
  - Extremely pleomorphic, epithelioid cells with poor pigmentation, widespread single-cell invasion of the dermis and numerous mitotic figures noted on histopathology

HISTORY, CHIEF COMPLAINT

- Usually related to size and location of tumor burden
- Physical obstruction of the anal sphincter, penis, prepuce, or vulvar commissure may occur, which may result in dyschezia, dysuria, and difficulty with coitus and parturition.
- Metastatic melanoma: May present for weight loss, colic, epistaxis, ataxia, and respiratory distress
- 43% have peripheral edema from lymphatic obstruction
- Clinical progression: Three forms:
  - Slow growth over a number of years without metastasis
  - Benign growth transforms into malignant lesion and metastasizes
  - Malignant from inception and readily metastasizes

PHYSICAL EXAM FINDINGS

- Occurs mostly on areas of glabrous skin
- Slow-growing, locally invasive masses
- Primary affected sites include the ventral tail, perineum, lips, periocular

ElibeVet.com

region, parotid gland, and external genitalia.
- Progression frequently results in metastasis through direct extension, lymphatics, or blood.
- Necropsy reveals typical metastasis to autonomic nervous system, lungs, lymph nodes, bone, adrenals, eye, skin, intima of the heart, and blood vessels.

ETIOLOGY AND PATHOPHYSIOLOGY
- In Arabians, thought to result from destruction of normal melanocytes through an autoimmune or cytotoxic process
- Consequence of disturbance in melanin metabolism that leads to formation of melanoblasts or increased activity of resident melanoblasts, resulting in overproduction of melanin in a focal area
- In time, hyperplastic melanoblasts undergo malignant transformation (may take up to 20 years).
- Increased ultraviolet light exposure may play a role.
- The STX17 duplication leads to proliferation of dermal melanocytes, thus predisposing to melanoma development.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS
- Melanoma should be considered in any gray horse older than 10 years of age presenting for virtually any clinical condition.
- Other dermal neoplasms: Equine cutaneous mastocytosis, squamous cell papillomas (viral papillomatosis), cutaneous lymphoma, mycosis fungoides

INITIAL DATABASE
- Diagnosis is usually based on the physical appearance of the neoplasm (firm, flat, solitary or multiple cutaneous masses that give skin a cobblestone or verrucous appearance and are usually hyperpigmented) and histopathology.
- Diagnostic tests that are useful in detecting metastatic disease include rectal palpation, ultrasonography, biopsy or fine-needle aspirate of suspect internal metastasis, and cytology of peritoneal fluid.

ADVANCED OR CONFIRMATORY TESTING
- Histopathology may predict clinical behavior.
- Melanocytic nevi should not progress, but malignant transformation may occur in dermal melanoma or melanomatosis.

TREATMENT

THERAPEUTIC GOAL(S)
- A uniform standard therapy for melanoma does not exist.
- The goal of therapy is to manage local and metastatic disease.

ACUTE GENERAL TREATMENT
Relieve immediate obstructive lesions through surgery if possible.

CHRONIC TREATMENT
- Surgical removal of affected tissues is usually curative. Around the anus or tail, surgery is contraindicated because complete removal is not possible and may stimulate more rapid growth of neoplastic tissue.
- Surgery
  - Removal of all affected tissues with wide margins is usually curative for melanocytic nevi and solitary dermal melanomas. Necessary margins for cure have not been established, so as aggressive a surgery as possible is recommended.
  - If wide margins are not achieved, the tumors tend to recur at the surgical site.
  - Multiple surgeries may be necessary over time, and the client should be warned at the outset.
  - Laser ablation has been suggested as an adjunct to achieve complete excision.
- Bacillus Calmette-Guérin
  - Attenuated strain of *Mycobacterium bovis*.
  - Injection into the tumor causes inflammatory response in melanocytic tumors.
  - Not usually effective at stimulating tumor regression.
- Radiotherapy
  - Effective for local management in other species
  - Not yet evaluated in horses
- Cryonecrosis
  - May be used in conjunction with surgery, especially for large, difficult to remove tumors
  - Tend to regrow into sites of previous treatment (may increase the risk of aggressive regrowth)
- Chemotherapy: Intralesional cisplatin is successful with small lesions (<2–3 cm)
  - More effective when a vasoconstrictive agent (epinephrine chloride solution) is added to the formulation.
  - Four intratumoral injection sessions at 2-week intervals. Cisplatin beads surgically implanted after surgical debulking yielded the best result.
- Immunotherapy
  - Cimetidine (a biologic response modifier with antitumor activity and H2 receptor antagonism)
    - Effect through inhibiting suppressor T cells and enhancing cell-mediated immunity
    - Induction dosage: 4 mg/kg PO q8h, then 2.5 mg/kg q12h for maintenance therapy
    - If favorable response is not seen in 3 months, discontinue therapy
  - Interferon-α has become more popular, but evaluation has not been performed.
  - Whole-cell vaccine
    - 2 cm^3 of excised melanoma in Hank's balanced salt solution with 10% fetal calf serum (shipped overnight on ice)
    - Injected into the patient every 14 days for 12 weeks and then every 6 weeks
    - The efficacy of the vaccine is variable and depends on an individual horse's immune response.

POSSIBLE COMPLICATIONS
- Recurrence may be more aggressive than the original lesion.
- Care should be taken in handling cisplatin and all urine excreted for at least 72 hours after cisplatin administration to avoid human exposure.

RECOMMENDED PREVENTION/ MONITORING
Sunscreen has been advocated for horses that are poorly pigmented and cannot be stabled during sunny weather.

PROGNOSIS AND OUTCOME
- Tumor size is considered prognostic in humans and may be prognostic in horses with discrete melanocytic tumors.
- Signalment should help guide; aggressive dermal melanoma in younger horse in an atypical location warrants further investigation.
- High metastatic rate with dermal melanomatosis and anaplastic forms.
- Small tumors often do not cause clinical signs and could be considered a cosmetic blemish.
- May remain benign for as long as 10 to 20 years.
- Survival time depends on the level of disease at diagnosis, location of tumor burden, and surgical resectability.

ElibVet.com

PEARLS & CONSIDERATIONS

COMMENTS

Melanoma should be considered in any gray horse older than 10 years of age presenting for virtually any clinical condition.

PREVENTION

Protect at-risk horses from the sun with shade or sunscreen.

CLIENT EDUCATION

- More than 80% of gray horses older than 15 years develop melanoma.
- Multiple surgeries may be necessary over time.

EDITOR: **JEFFREY N. BRYAN**

Metabolic Syndrome, Equine

BASIC INFORMATION

- Endocrinopathy of energy metabolism in horses
- Associated with insulin resistance (IR) and laminitis (see "Insulin Resistance" in this section)

DEFINITION

- Equine metabolic syndrome (EMS) is a recently described endocrine pathologic condition of obese horses that is associated with IR, laminitis, and fat redistribution.
- IR is the hallmark of EMS.

EPIDEMIOLOGY

SPECIES, AGE, SEX EMS is more commonly reported in middle-aged horses, but unlike Cushing's disease, younger animals can develop EMS.

GENETICS AND BREED PREDISPOSITION

- There is a genetic predisposition to IR and EMS in Saddlebreds, Morgans, Tennessee Walking Horses, Paso Finos, Quarter Horses, and ponies.
- Ponies have the highest prevalence of IR.
- The predisposition to IR and EMS relates to these breeds being prone to obesity.
- These animals require fewer calories to maintain body weight or become obese ("easy keepers").
- There is no evidence that EMS is directly associated with geography or season.
- There appears to be an indirect association with geography that relates to quality of pasture.

RISK FACTORS

- EMS is associated with excessive feeding of carbohydrates and thus is more often reported in developed countries.
- Lack of physical activity contributes to EMS.

CLINICAL PRESENTATION

- Obesity, fat redistribution (tailhead, neck, prepuce, mammary gland, shoulder area, supraorbital fat pads), and laminitis are the clinical features of EMS (and IR).
- A "cresty neck" or "stallion-like" appearance in mares is suggestive of EMS.
- Mares may have a history of infertility.
- Unlike horses with Cushing's disease, horses with EMS have a normal hair coat and shed their coats in the summer.

HISTORY, CHIEF COMPLAINT

- The most common presenting complaint of horses with EMS is laminitis.
- These horses are easy keepers and obese and spend more time grazing.
- A "cresty neck" from fat redistribution is typical of these horses.
- Infertility is a complaint in mares.

ETIOLOGY AND PATHOPHYSIOLOGY

- IR is the key pathophysiologic process that leads to EMS (see "Insulin Resistance" in this section).
- Having fewer insulin receptors or inappropriate receptor response upon insulin stimulation results in IR.
- Depending on the stage of IR, horses with EMS may have hyperinsulinemia with normoglycemia (compensated IR) or with hyperglycemia (noncompensated IR).
- Glucocorticoids appear to be central in the pathogenesis of IR and EMS.
  - Glucocorticoids induce IR by decreasing the receptors response to insulin.
  - Glucocorticoid concentrations are often elevated in horses fed hypercaloric diets.
- Dexamethasone administration in healthy horses induces IR.
- It has been proposed that conversion of inactive cortisone to active cortisol by 11β-hydroxysteroid dehydrogenase in adipocytes may play a role in the pathogenesis of EMS.
- The mechanisms responsible for fat redistribution (regional adiposity) appear to be a combination of IR and increased cortisol concentrations.
- IR leads to less glucose uptake and hyperglycemia, vascular dysfunction and inflammation, vasoconstriction, and increased vascular resistance.
- Laminitis is believed to result from decreased laminar blood flow, decreased endothelial glucose uptake, vascular dysfunction and inflammation, and a pro-oxidative state from insulin insensitivity.
- Insulin mediates vasodilation via nitric oxide.

DIAGNOSIS

- The diagnosis of EMS is based on clinical history, clinical findings, ruling out conditions associated with hyperglycemia and laminitis, and testing for IR.
- Tests for IR include baseline glucose and insulin concentrations, the glucose tolerance test (GTT), the combined glucose/insulin test (CGIT), the euglycemic-hyperinsulinemic clamp (EHC), and the minimal model analysis of a frequently sampled IV glucose tolerance test (FSIGT).
  - Of these, the GTT are CGIT are the most commonly performed.
  - Baseline insulin concentrations should be less than 20 μIU/mL.
  - Insulin level above 30 μIU/mL suggests IR and is consistent with EMS.
- Normoglycemia with hyperinsulinemia (compensated IR) or hyperglycemia with hyperinsulinemia (noncompensated IR) suggests EMS.
- Hyperglycemia with normal or low insulin concentrations indicates diabetes mellitus.

ElibVet.com

- Low thyroid hormone concentrations are frequent findings, but their significance is unclear.
- Liver enzymes can be elevated in some horses with EMS, suggesting hepatic fatty infiltration.
- GTT: See Section II, Procedures and Techniques.
  - A delayed return in glucose concentrations to baseline (>3 hours) suggests IR (EMS).
- CGIT: See Section II, Procedures and Techniques.
  - Glucose concentrations do not decrease below baseline before 90 minutes in horses with IR and EMS.
  - Glucose concentrations above baseline at 45 minutes are consistent with IR and EMS

DIFFERENTIAL DIAGNOSIS

- Obesity, conditions associated with laminitis (Cushing's disease), hypothyroidism.
- Hyperglycemia may be the result of diabetes mellitus.

TREATMENT

ACUTE GENERAL TREATMENT

- Start a weight loss plan.
- Increase physical activity.
- Do not feed carbohydrate-rich diets.
- Limit access to carbohydrate-rich pastures.
- Consider levothyroxine sodium (1–6 mg/100/kg PO q24h) to induce a hypermetabolic state.
- Trilostane, an inhibitor of steroid synthesis, has been used with variable results.
- Metformin, a drug that increases insulin sensitivity, has also been used in horses with IR with promising results.

PROGNOSIS AND OUTCOME

Guarded, depending on response to treatment and owner compliance

PEARLS & CONSIDERATIONS

- The excessive feeding of carbohydrate-rich diets and obesity leads to IR and EMS.
- Lack of recognition between appropriate body condition and obesity is a contributing factor in EMS.
- Do not feed grain to horses that can maintain body condition on pasture.
- Increase physical activity in obese and "easy keeper" horses.

AUTHOR & EDITOR: **RAMIRO E. TORIBIO**

Metacarpal Disease, Dorsal

BASIC INFORMATION

DEFINITION

Dorsal metacarpal disease (DMD) includes two conditions: dorsal metacarpal periostitis ("bucked shins") and dorsal cortical stress fractures of the third metacarpus (MC-III).

SYNONYM(S)

DMD is also known as *bucked shins complex*. The periostitis is sometimes referred to as *sore shins*. The stress fractures are commonly referred to as *saucer fractures*.

EPIDEMIOLOGY

SPECIES, AGE, SEX DMD affects young flat-racing horses. Bucked shins are classically seen in 2- and 3-year-old racehorses in early training. Dorsal cortical stress fractures of MC-III are typically seen in a slightly older population (3 to 5 years and sometimes older).

GENETICS AND BREED PREDISPOSITION Thoroughbred racehorses, racing Quarter Horses, and racing Arabians

RISK FACTORS DMD is seen more frequently in horses training on a dirt surface (vs. grass). Training regimens that have disproportionately high mileage at a gallop and an inappropriately low proportion of high-speed work favor the development of DMD.

GEOGRAPHY AND SEASONALITY The incidence of DMD is comparatively higher in Thoroughbred racehorses in the United States than in Europe. Differences in racing surfaces likely account for much of this discrepancy, with the majority of horses trained on grass in Europe and on dirt in the United States.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Horses with bucked shins present with an acute onset of bilateral soft tissue swelling, heat, and sensitivity over the dorsal aspect of the metacarpi, with an associated lameness or stiffness. Very often this occurs after the first race or first speed work (a "breeze") at near-racing distances. Some horses have a more gradual onset of these signs, with exacerbation after a race or breeze.
- Horses with an acute dorsal cortical stress fracture of MC-III typically exhibit moderate to severe lameness after a high-speed work (breeze) or race.

PHYSICAL EXAM FINDINGS

- In the acute stage, horses with bucked shins exhibit variable degrees of soft tissue swelling, heat, and sensitivity on palpation over the dorsal diaphyses of MC-III. When viewing the metacarpi from the lateral aspect, a distinct dorsal convexity is often seen. Firm pressure in this location often elicits a painful response. Lameness ranges from grade 1 to 3 (American Association of Equine Practitioners scale). These horses exhibit a bilateral stiff or choppy fore-

ElibeVet.com

limb gait at a trot (sometimes mimicking a foot or carpal lameness). When one metacarpus is more severely affected than the other, a distinct head nod may be recognized. After a short period of rest and antiinflammatory treatment, there is generally considerable improvement.

- In horses with acute stress fractures, soft tissue swelling and signs of inflammation are commonly more focal and overlie a corresponding bony knot or periosteal irregularity (hard swelling or exostosis) along the dorsal or dorsolateral diaphysis of MC-III. Firm pressure at the fracture site consistently elicits a painful response and often exacerbates lameness. Acutely, lameness is moderate to severe (typically grade 3 to 4). With a brief period of rest (a few days to a few weeks), horses generally walk comfortably but remain lame at a trot in-hand (grade 2 to 3). Horses with chronic fractures may exhibit only mild lameness at a trot in-hand.

ETIOLOGY AND PATHOPHYSIOLOGY

- Both components of DMD are the result of maladaptive remodeling associated with repetitive strain of the metacarpus.
- Stress fractures are fatigue fractures resulting from accumulated high-strain cyclic loading.
- The majority of horses with dorsal cortical stress fractures of MC-III have experienced clinical bucked shins in the 6 to 12 months before fracture.
- In the United States, the majority of these fractures involve the left forelimb; this is attributed to the counterclockwise direction of racing.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Bucked shins and dorsal cortical stress fractures of MC-III are each a differential diagnosis for the other.

INITIAL DATABASE

- Physical and lameness examinations (diagnostic analgesia is usually not necessary in acute cases)
- Radiography (Figure 1)

ADVANCED OR CONFIRMATORY TESTING

Nuclear scintigraphy may be helpful in differentiating a true stress fracture (focal increased radioisotope uptake [IRIU]) from bucked shins (diffuse IRIU) in cases in which radiographs are negative or equivocal.

FIGURE 1 Lateral radiograph of the left metacarpus of a horse with a dorsal cortical stress fracture of the third metacarpus (MC-III). The fracture exhibits the most common configuration, propagating in a distodorsal-to-proximopalmar direction.

TREATMENT

THERAPEUTIC GOAL(S)

- Bucked shins
  - Reduce acute inflammation
  - Decrease or eliminate further excessive cyclic strains on MC-III and shift the balance from net bone resorption to net bone apposition
- Dorsal cortical stress fractures: promote fracture healing

ACUTE GENERAL TREATMENT

- Bucked shins
  - Local and systemic antiinflammatory therapy initially (cold therapy, poultice, bandage, nonsteroidal antiinflammatory drugs)
  - Stall rest until soft tissue swelling and pain on palpation have subsided
  - Controlled exercise: handwalking 2 to 4 weeks in mild cases; handwalking and paddock turnout for 1 to 4 months in more severe or chronic or recurrent cases
- Dorsal cortical stress fractures: stall rest and antiinflammatory therapy (as above)

CHRONIC TREATMENT

- Bucked shins
  - Modification of the training protocol to promote adaptive remodeling of the dorsal cortices of MC-III.
    - In general, this involves increasing the frequency of high-strain cyclic compressive loading (high-speed exercise or breezes) and decreasing the total distance worked at a gallop.
    - The distances of high-speed work are increased in a slow, incremental manner to allow adaptation.
- Dorsal cortical stress fractures
  - Controlled exercise for 3 to 4 months may be sufficient for healing in some cases.
  - Most horses are best treated surgically to minimize healing time and maximize the likelihood of complete healing (ie, minimize fracture recurrence).
  - Surgical options include osteostixis (cortical drilling), neutral screw placement (unicortical screw), or a combination (Figure 2).
  - Screws are removed in 2 to 3 months, and training can generally resume by 3 to 4 months.

POSSIBLE COMPLICATIONS

In rare cases, a dorsal cortical stress fracture may propagate to a complete, catastrophic fracture of MC-III.

RECOMMENDED MONITORING

Complete fracture healing should be confirmed radiographically before training is resumed.

ElibeVet.com

FIGURE 2 Postoperative lateral radiograph of the fracture shown in Figure 1. This horse was treated with a combination of osteostixis (note drill holes) and unicortical screw placement. (The screw was countersunk; the gap is artifactual.)

PREVENTION

Early detection of shin soreness and early intervention should decrease the incidence of both conditions. Chronic or recurrent bucked shins or stress fractures of MC-III can most often be attributed to premature resumption of training or failure to modify the training protocol in young horses.

AUTHOR: **LANCE H. BASSAGE II**

EDITOR: **ANDRIS J. KANEPS**

PROGNOSIS AND OUTCOME

The prognosis for both components of DMD is very good to excellent if identified early and appropriate treatment is instituted.

PEARLS & CONSIDERATIONS

COMMENTS

Bucked shins are usually bilateral, and stress fractures are typically unilateral.

Milkweed Toxicosis

BASIC INFORMATION

DEFINITION

Milkweeds are native plants of North America comprising about 150 species capable of causing cardiotoxicity or neurotoxicity in horses and other animals. The toxicity of milkweeds varies with the species. Generally, the narrow-leafed species are more toxic than the broad-leafed species.

SYNONYM(S)

Many plant species contain a milky sap, but the term *milkweed* generally refers to plants of the genus *Asclepias*. Other common names for milkweeds include *butterfly weed*, *pleurisy root*, and *silkweed*.

EPIDEMIOLOGY

GEOGRAPHY AND SEASONALITY Milkweeds are found throughout North America but especially in the southern and western states (Figures 1 and 2). Some species of milkweed are invasive, forming spreading colonies. Most are perennials. Milkweeds have a milky sap, broad or narrow leaves, single or branched stems that may be prostrate or erect, and terminal clusters of flowers ranging from white to pink to orange in color. Characteristic pods filled with seeds with silky hairs that aid in wind distribution form in late summer.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Milkweeds are either cardiotoxic or neurotoxic depending on the species. The cardiotoxic species generally have broad, heavily textured leaves that are rarely palatable to animals unless they are without good forage. Examples of the cardiotoxic species are *Asclepias speciosa*, *Asclepias eriocarpa*, and *Asclepias labriformis*. The neurotoxic species generally have narrow (grasslike) leaves and tend to be quite palatable green or dried. Some neurotoxic species also contain cardiotoxins. Examples of the neurotoxic species include *Asclepias subverticillata*, *Asclepias fascicularis*, *Asclepias pumila*, and *Asclepias incarnata*.

HISTORY, CHIEF COMPLAINT Animals eating the broad-leafed milkweeds exhibit cardiotoxic and gastrointestinal signs. Neurotoxic milkweeds cause neurologic signs, including weakness, ataxia, muscle tremors, recumbency, and tetanic seizures.

PHYSICAL EXAM FINDINGS

- Cardiotoxic milkweeds induce primarily a gastrointestinal syndrome characterized by signs of colic, including teeth grinding, reluctance to stand, and diarrhea. Rarely are cardiac dysrhythmias detected. Death may occur suddenly without signs of convulsions.
- Horses that have eaten as little as 1 kg of the neurotoxic species of milkweed show signs of colic, weakness, and

ElibεVet.com

FIGURE 1 Showy milkweed (*Asclepias speciosa*).

FIGURE 2 Whorled milkweed (*Asclepias subverticillata*).

incoordination progressing to recumbency and tetanic seizures. Clonic seizures with paddling of the legs may develop. Death may follow the seizures or the horse may recover.

ETIOLOGY AND PATHOPHYSIOLOGY

- Steroidal glycosides known as *cardenolides* are present in the broad-leafed milkweeds.
- Cardenolides are highest in the sap and early plant growth.
- Neurotoxic milkweeds contain poorly defined glycosides.
- The specific sites of action of the cardenolides and neurotoxic glycosides are poorly understood.
- Milkweeds are potentially toxic at any time, even when dried in hay.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ionophore toxicity
- Oleander (*Nerium oleander*) toxicity
- Foxglove (*Digitalis* spp.) toxicity
- Viral encephalitis, rabies, Eastern and Western equine encephalitis
- Other causes of CNS signs, such as viral, bacterial, and parasitic infections

INITIAL DATABASE

- Hematocrit: Reflects dehydration.
- No specific serum biochemical or CBC analysis abnormalities are characteristic of milkweed poisoning.

ADVANCED OR CONFIRMATORY TESTING

- A field test for detecting cardenolides in the milkweed latex is available.
- The stomach contents may yield detectable cardenolides.
- No gross lesions are detectable at necropsy.

TREATMENT

THERAPEUTIC GOAL(S)

Manage symptoms as necessary.

ACUTE GENERAL TREATMENT

- No specific antidote is available.
- Use of activated charcoal should be considered when the milkweed has been consumed in the previous few hours.
- General supportive treatment such as IV polyionic fluids should be provided.
- Animals with seizures should be sedated with diazepam.

PROGNOSIS AND OUTCOME

The prognosis depends on the quantity of the toxic milkweeds consumed. Animals observed with clinical signs have a better prognosis because lethal doses usually cause acute death.

PEARLS & CONSIDERATIONS

COMMENTS

Milkweed poisoning is only likely to occur when horses are deprived of adequate nutrition and are hungry. Hay should always be carefully inspected before it is fed to horses because the narrow-leafed milkweeds remain toxic even when dried.

PREVENTION

- Feed weed-free hay.
- Selective herbicides can be used to control invasive perennial species.

CLIENT EDUCATION

Recognition and removal of milkweed species in the environment can do much to prevent milkweed poisoning.

ElibeVet.com

Mitral/Tricuspid Regurgitation, Acquired

BASIC INFORMATION

DEFINITION

- Mitral valve regurgitation is the most important valvular condition affecting athletic performance in horses. It may be caused by dysfunction of any part of the mitral valve apparatus, including the valve annulus, leaflets, chordae tendineae, or papillary muscles.
- The etiology remains unclear. Degenerative myxomatous changes as well as cellular infiltration with lymphocytes, histiocytes, and fibroblasts in the valves leading to general or nodular thickening are often reported. In addition, physical training may result in regurgitation because of training-induced myocardial hypertrophy. This may expand the valvular annulus, leading to valvular incompetence, but in these cases, the valves may also be affected pathologically.
- Whereas mitral regurgitation may affect athletic performance, tricuspid valve regurgitation rarely gives rise to clinical signs in horses.

SYNONYM(S)

- Mitral or tricuspid insufficiency
- Mitral or tricuspid valve disease
- Atrioventricular (AV) valve regurgitation or insufficiency

EPIDEMIOLOGY

SPECIES, AGE, SEX Horses of all ages and both sexes can be affected, but degenerative changes are most frequently seen in middle-aged or older horses.

GENETICS AND BREED PREDISPOSITION There is no genetic predisposition, but the prevalence appears higher in Standardbreds and Thoroughbreds compared with the general horse population.

ASSOCIATED CONDITIONS AND DISORDERS Depends on the severity of the regurgitation

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Mitral or tricuspid regurgitation incidentally diagnosed in clinically normal horses
- Mitral (or very rarely tricuspid) regurgitation causing clinical signs of reduced performance or in severe cases signs of heart failure

HISTORY, CHIEF COMPLAINT

- With mild regurgitation, there are no clinical signs. This may also be the case with even severe tricuspid regurgitation.
- If regurgitation is more severe, there may be signs of poor performance (eg, increased respiratory effort after or during work, reduced exercise tolerance).

PHYSICAL EXAM FINDINGS

- A systolic cardiac murmur will be heard at the apical area of the left hemi-thorax (mitral regurgitation) or right hemi-thorax (tricuspid regurgitation). The intensity of the murmur is not always an accurate guide to the severity of the disease. However, in general, loud murmurs occurring throughout systole are more often associated with significant disease than quiet murmurs of shorter duration, particularly if a palpable thrill accompanies the loud murmur.
- Depending on the severity of the regurgitation, one or more of the following signs may be observed:
  - Resting tachycardia
  - Resting tachypnea
  - Cough
  - Distension or pulsation of the jugular veins
  - Dependent edema (primarily ventral, not limb)
  - Increased respiratory sounds
  - Cardiac arrhythmia (eg, atrial fibrillation or atrial premature complexes [APCs])
  - Nasal froth caused by pulmonary edema (only in cases of severe heart failure)
  - Prolonged capillary refill time (only in cases of severe heart failure)
  - Weight loss

ETIOLOGY AND PATHOPHYSIOLOGY

- Initiating factors leading to degenerative changes of the valvular apparatus are unknown.
- An insidious onset of mitral regurgitation can generally be completely compensated for years without clinical signs.
- Compensatory mechanisms include atrial and ventricular dilatation; eccentric hypertrophy; and increased resting HR, contractility of the ventricles, and lymphatic drainage.
- For a minor proportion of horses with mitral regurgitation, the valvular regurgitation can no longer be compensated, leading to signs of left-sided heart failure with pulmonary edema. Initially, this may only manifest during high demand such as more strenuous exercise, but as the disease progresses, compensatory mechanisms fail, and tachycardia, coughing, and frothy fluid at the nostrils are observed when the horse is at rest. Eventually, signs of right-sided heart failure may appear, including edema and distension of the jugular veins.
- Rarely, acute mitral regurgitation develops (eg, secondary to rupture of major chorda tendineae), and in these situations, pulmonary pressures increase abruptly with development of pulmonary edema. Shortly thereafter, signs of right-sided heart failure develop with dependent edema and distension of the jugular veins.
- Severe mitral regurgitation is the most common cause of heart failure in horses.
- The mitral valve and the aortic valve are the most common locations for bacterial endocarditis (see "Endocarditis, Infective" in this section); however, the disease is not commonly encountered.
- Tricuspid regurgitation rarely causes clinical signs. If the regurgitation is severe, signs of right-sided heart failure may develop with jugular distension, jugular pulsation, and dependent edema.
- Murmurs of tricuspid, mitral, and aortic regurgitation are often detected in Standardbred and Thoroughbred racehorses. They may develop in response to training, and the prevalence may increase with age and training. However, the regurgitations are generally mild and remain constant over time, with no negative effect on racing performance documented.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Functional murmur (systolic flow murmur, systolic ejection murmur). Large stroke volume and large diameters of the great vessels induce turbulent blood flow in the aortic and pulmonary artery roots in early systole, which leads to early or mid-systolic murmurs heard at the basal area that are of no clinical significance.
- Physiologic murmurs caused by systemic diseases such as colic, anemia, septicemia, or endotoxemia.
- Endocarditis.
- Ventricular septal defect (VSD). This is an important differential diagnosis for tricuspid regurgitation. Typically, the murmur associated with VSD is lower on the chest wall toward the sternum. In addition, a systolic murmur over the pulmonary valve on the left hemi-

ElibeVet.com

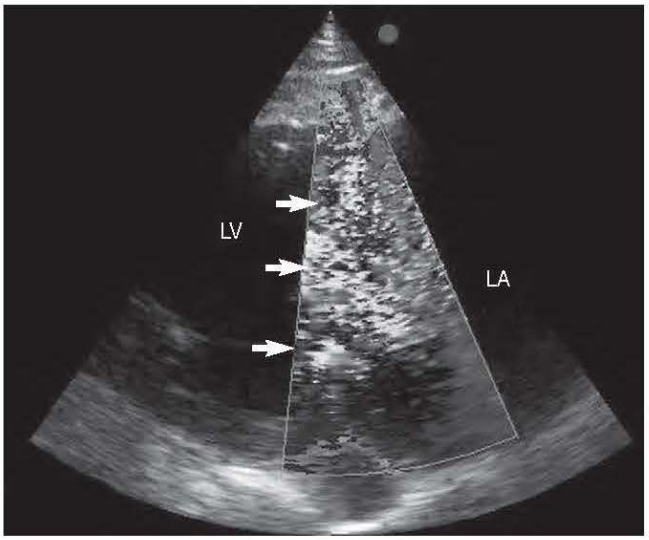

FIGURE 1 Long-axis color flow Doppler echocardiogram of the left atrium and ventricle obtained from the left cardiac window showing severe mitral regurgitation (*arrows*). LA, left atrium LV, left ventricle.

thorax is often heard because of relative pulmonic stenosis.

INITIAL DATABASE

- Definitive diagnosis of mitral or tricuspid regurgitation requires echocardiographic examination with the regurgitant jet visualized by Doppler echocardiography (Figure 1).
- The severity of the disease can be assessed by echocardiography. Generally, extensive nodular changes on the valve and ruptured chordae tendineae indicate more severe pathology. In addition, the dimensions of the left ventricle, left atrium, and pulmonary artery are of significant importance when evaluating mitral regurgitation. The size of the regurgitant jet can be estimated by Doppler echocardiography. However, the size of the jet is influenced by a variety of factors and should always be compared with the size of the cardiac chambers as well the contractility of the myocardium.
- Electrocardiography (ECG) for diagnosing arrhythmias such as atrial fibrillation and atrial premature complexes
- Complete blood cell counts and serum biochemistry results are usually unremarkable.

ADVANCED OR CONFIRMATORY TESTING

To assess the significance of the valvular regurgitation during exercise, exercising ECG is of great value. If possible, exercise testing on a treadmill is preferable because arterial oxygen measurements can be obtained continuously during exercise. Stress echocardiography immediately after exercise may be helpful to assess myocardial function.

TREATMENT

THERAPEUTIC GOAL(S)

- In most equine patients with valvular disease, specific therapy is not indicated, and management is aimed at periodic monitoring of cardiac function and progression of disease along with providing client information.
- Supportive therapy is indicated if heart failure is present. Treatment of horses in heart failure is primarily recommended to make the horse more comfortable. This is most often used for some breeding horses and horses to which the owner is very emotionally attached and wishes to try any treatment to prolong lifespan.

ACUTE GENERAL TREATMENT

- Supportive treatment of patient in heart failure includes diuretics to reduce congestion (furosemide 1–2 mg/kg IV q12h) in combination with a vasodilator such as an angiotensin-converting enzyme (ACE) inhibitor (eg, enalapril 0.5 mg/kg IV q24h) (see "Cardiac Failure" in this section).
- If severe tachycardia is present, digoxin can be given at a dose of 0.0022 mg/kg IV q12h or 0.011 mg/kg PO q24h. For more treatment details, see "Cardiac Failure" in this section.

CHRONIC TREATMENT

As for acute treatment (see "Cardiac Failure" in this section), with drugs and doses tailored to the individual horse's clinical signs

POSSIBLE COMPLICATIONS

- Reoccurrence of heart failure or no effect of treatment
- Tachyarrhythmias
- Syncope or ataxia

RECOMMENDED MONITORING

- Clinical exam findings such as attitude, appetite, weight, respiratory rate and effort, heart rate, and exercise tolerance should be monitored by the owner regularly. Any changes should prompt a veterinary reexamination.
- Periodic ECGs and echocardiograms to assess progression of regurgitation or heart failure.

PROGNOSIS AND OUTCOME

- For mitral regurgitation, a good prognosis can be given if the regurgitant jet is small, no structural changes of the valve are identified, and the size of the cardiac chambers and myocardial function are within normal values. However, the progression can be unpredictable, so the significance of mitral regurgitation for future athletic use is difficult to predict at the time of initial examination. Serial examinations to gauge changes over time will help to predict more long-range progression.
- For tricuspid regurgitation, the prognosis is generally good, although severe cases may lead to right-sided heart failure.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- The owner should be informed of common signs of heart failure to recognize them if they develop and should be in the habit of checking the horse regularly.
- Athletic performance may be negatively affected by valvular insufficiency; therefore, a reduction of activity level may be needed.
- Because of the unpredictable nature of the progression of mitral regurgitation, this is regarded as a preexisting condition by most insurance companies and may thus be subject to exclusion from the insurance policy. In addition, the resale value of the horse may be affected because future buyers may be discouraged. Therefore, the sale prices of horses are often reduced in cases of diagnosed valvular regurgitation greater than insignificant or mild.

Motor Neuron Disease, Equine

BASIC INFORMATION

DEFINITION

An acquired destruction of lower motor neurons in the brainstem and spinal cord of affected horses leading to clinical signs characterized by postural weakness and muscle atrophy

SYNONYM(S)

Equine motor neuron disease (EMND) resembles progressive muscular atrophy (a form of amyotrophic lateral sclerosis [ALS], or Lou Gehrig's disease) seen in humans. However, only lower motor neurons are affected with EMND in contrast to upper and lower motor neurons with ALS.

EPIDEMIOLOGY

SPECIES, AGE, SEX Age: Older horses are at a higher risk than young animals (range, 2–23 years). Peak incidence occurs at 16 years of age and then declines.

GENETICS AND BREED PREDISPOSITION

- Breed: Quarter Horses appear to be more likely to develop the disease. Appaloosas, Standardbreds, and Thoroughbreds are also reported.
- Genetic factors: A mutation affecting vitamin E metabolism occurs in other species with similar conditions.

RISK FACTORS

- Unknown and likely multifactorial mechanism of acquiring disease.
- A depleted vitamin E status is strongly incriminated as a causal factor in the disease. Affected animals have lower levels than normal control subjects on the same premises.
- The vast majority of cases have limited or no access to grass.
- Concentrate feeding with poor-quality hay: Pelleted ration or supplement feeding lacking vitamin E
- Stall confinement
- Pica: Wood
- Coprophagia
- Malabsorption: Concurrent enteric or hepatic disease
- Iron and copper supplementation

GEOGRAPHY AND SEASONALITY

- United States: New England states have highest incidence, decreasing toward the west and south.
- Also reported in Canada, British Isles, Europe, Japan, and South America.
- Sporadic occurrence of isolated cases. Outbreaks have been reported.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- In early cases, weight and muscle loss despite a normal to increased appetite.
- Muscle tremors, sweating, and increased periods of recumbency are seen.
- Tends to stabilize or improve 1 or 2 months after the onset of signs. Muscle tremors and periods of recumbency tend to become less frequent.
- Progression of signs after a period of stabilization does occur.
- Body weight may return to predisease levels as the horse accumulates fat.
- A subclinical syndrome has been recognized; however, the athletic ability is permanently impaired to varying degrees.

PHYSICAL EXAM FINDINGS

- Marked muscle wasting is common, especially of the antigravity muscles (triceps, quadriceps, gluteals). May precede neurologic signs by up to 1 month.
- Horse prefers to stand with the legs gathered beneath them.
- Trembling is exacerbated by standing the horse in a fixed location, with constant shifting of weight from one hindlimb to the other occurring. The horse is more comfortable when walking.
- Unable to engage stay apparatus
- An abnormally low head carriage and short stride length are common.
- No ataxia or loss of proprioception is noted (compare with equine degenerative myeloencephalopathy [EDM]).
- The tail head appears raised (dorsal coccygeal muscle wasting), and excessive sweating is seen in more than half of the patients.

ETIOLOGY AND PATHOPHYSIOLOGY

- The precise cause of EMND is not known.
- Impaired vitamin E metabolism: Absorption or retention may be affected in horses with malabsorptive disease.
- Pro-oxidant factor excess: Elevated iron and copper levels in some affected horses.
- Antioxidant activity deficient in the central nervous system: Similar to EDM.
- Loss of highly oxidative type I muscle fibers: Characteristic antigravity muscle wasting and weakness.
- Endothelial lipopigment: Spinal cord capillaries indicative of oxidative damage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Botulism
- Organophosphate, lead, and other toxicities
- Myositis or myopathy
- Malabsorptive disorders
- Laminitis
- Protozoal myeloencephalitis
- Neglect

INITIAL DATABASE

- No definitive premortem diagnostic test exists.
- Serum chemistry: Signs of myopathy (elevated creatinine kinase, aspartate aminotransferase) but not specific for EMND.
- Plasma glucose concentrations are normal in all horses, but the mean peak value after an oral glucose absorption test may be low.
- Plasma vitamin E concentrations: Significantly lower than in normal control subjects; collect serial samples throughout the day and pool samples to level diurnal variability.

ElibEVet.com

ADVANCED OR CONFIRMATORY TESTING

- Needle electromyographic studies: Consistently abnormal; suggestive of denervation. Prolonged insertional activity, fibrillation potentials and positive sharp waves are frequently recorded in cervical, facial, triceps, quadriceps, and tail head musculature.
- Ophthalmic examination: Varying degrees of a mosaic pattern of dark brown to yellow brown pigment (ceroid lipofuscin) deposited in the pigmented retinal epithelium of 30% of cases; no visual deficits noted.
- Glucose tolerance test, xylose absorption: Low peak absorption may occur.
- CSF: Cytology normal; protein and IgG levels may be increased.
- Muscle biopsy: Atrophy of predominantly type I fibers.
- Nerve biopsy: Ventral branch of spinal accessory nerve; Wallerian degeneration of axons and Schwann cell proliferation is diagnostic; loss of myelination occurs in chronic cases.
- Necropsy: Gross evaluation of peripheral nerves and central nervous tissue are unremarkable.
- Histopathology: Definitive diagnosis. Loss of neurons in ventral horns of the spinal cord (lower motor neuron); degeneration of brainstem cranial nerve nuclei (except III, IV, and VI); ceroid lipofuscin in the retinal epithelium and spinal cord capillaries; angular degeneration of type I muscle fibers; widespread signs of muscle degeneration (denervation atrophy).

TREATMENT

THERAPEUTIC GOAL(S)

Avoid further deterioration in affected horses.

ACUTE GENERAL TREATMENT

- Oral vitamin E supplementation: Appears to have improved the clinical syndrome in a few cases (6000–10,000 IU q24h).
- Antioxidants: Dimethyl sulfoxide may be of benefit initially.
- Antiinflammatory drugs: Corticosteroids may be helpful in acute onset cases.

PROGNOSIS AND OUTCOME

- Grave prognosis for affected animals.
- Progressive deterioration and euthanasia in large percentage of horses (40%) regardless of treatment.
- A similar percentage may stabilize and improve with treatment and management changes in the short to medium term. Recrudescence of disease leads to unremitting progression of disease.
- A minority survive medium term with permanent muscle wasting deficits.

PEARLS & CONSIDERATIONS

COMMENTS

Incidence has decreased with greater awareness of need for vitamin E supplementation in grain-based concentrate rations.

PREVENTION

Vitamin E supplementation (2000 IU q24h) for horses with limited pasture or green hay access for a prolonged period

CLIENT EDUCATION

Neuronal cell death is irreversible.

EDITOR: **STEPHEN M. REED**

Multiple Organ Dysfunction Syndrome

BASIC INFORMATION

DEFINITION

Multiple organ dysfunction syndrome (MODS) typically occurs because of unchecked systemic inflammation as seen in the systemic inflammatory response syndrome (SIRS) or sepsis.

EPIDEMIOLOGY

SPECIES, AGE, SEX Any age or breed may be at risk for MODS because of trauma, infection, or inflammation that remains untreated or unresolved.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Horses with a history of critical illness or traumatic injury with a systemic inflammatory response are at risk for the development of MODS.

PHYSICAL EXAM FINDINGS Physical examination findings are variable and specific to the organ system involved but may include:

- Depression, lethargy
- Injected mucous membranes, increased capillary refill time
- Tachycardia or bradycardia, poor pulse quality, cool extremities
- Tachypnea
- Decreased borborygmi, decreased fecal output, colic
- Fever or hypothermia

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary MODS is organ dysfunction caused by an initial disease or infectious process resulting in injury to an organ system.
- Secondary MODS is organ dysfunction caused by the systemic inflammatory response syndrome or sepsis (see "Systemic Inflammatory Response Syndrome" in this section).
- Organ systems commonly affected include:
  - Central nervous system
  - Respiratory system
  - Renal or urinary system
  - Cardiovascular system
  - Coagulation system
  - Gastrointestinal system
  - Musculoskeletal system
  - Hepatobiliary system

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Insult or injury to an organ system caused by infection or inflammation may occur without organ failure, which indicates sepsis or SIRS but not MODS.

INITIAL DATABASE

- Packed cell volume
- Total protein

ElibEVet.com

- Complete blood count and differential
- Serum chemistry
- Blood lactate
- Blood pressure
- Blood gas
- Coagulation profile
- Urinalysis

ADVANCED OR CONFIRMATORY TESTING

Relates to the specific system involved:

- Central nervous system: Neurologic exam, cerebrospinal fluid analysis
- Respiratory: Thoracic ultrasonography, radiography, transtracheal wash
- Renal: Analysis of fractional excretion of electrolytes, renal biopsy, cystoscopy
- Cardiovascular: Echocardiography, cardiac output monitoring, electrocardiography
- Coagulation system: Additional coagulation tests (D-dimer, protein C, thromboelastography)
- Gastrointestinal: Glucose absorption testing, fecal cultures, fecal egg count, biopsy
- Musculoskeletal: Pedal venogram

TREATMENT

THERAPEUTIC GOAL(S)

- Identify organ failure early.
- Treat the initiating cause of systemic inflammation or primary cause of organ dysfunction.
- Provide supportive care and optimize tissue perfusion.

ACUTE GENERAL TREATMENT

- Therapy is based on the organ systems that are failing; however, general supportive care is indicated as for SIRS.
- Early goal-directed therapy may reduce the risk of tissue hypoxia and shock (see "Shock, Hypovolemic" in this section).
- Fluid therapy
  - Shock-dose fluid administration (see "Shock-Dose Fluid Administration" in Section II) when indicated
  - Maintenance fluids to maintain tissue perfusion without causing tissue edema (see "Dehydration" in this section)
- Inotropes and vasopressors for cardiovascular support (see "Shock, Hypovolemic" in this section)
- Oxygen therapy mechanical ventilation based on response and blood gas analysis
- Antimicrobial therapy: Broad spectrum initially, narrowed by culture results of the local infectious process
- Antiendotoxin therapy
  - Hyperimmune plasma (against *Salmonella typhimurium,* or J5 *Escherichia coli*)
    - Antibodies bind and clear endotoxin using the innate immune system.
    - Dose: 1.5 mL/kg J5 serum diluted twofold in crystalloid solution.
    - Results are conflicting, and therapy may increase endotoxic effects.
    - Drawbacks include high financial cost and risk of adverse immune reactions.
  - Polymixin B
    - Binds to circulating endotoxin and prevents interaction with its receptors
    - Dose: 6000 U/kg diluted to 500 mL IV q8–12h
    - Risk of nephrotoxicity in dehydrated horses
  - Nonsteroidal antiinflammatory medications
    - Block the production of eicosanoids and reduces inflammation
    - Flunixin meglumine appears most beneficial in ameliorating clinical signs (1.1 mg/kg, IV q12h).
    - The antiendotoxin dose (0.25 mg/kg, IV q8h) reduces inflammatory mediators, but does not eliminate signs of endotoxemia.
- Closely monitor serum glucose; may reduce mortality and inflammation (noted in human medicine). Insulin may be supplied (0.1–1 IU/kg/h) to maintain normoglycemia.
- Low-dose corticosteroid therapy may be beneficial for patients with critical illness related to corticosteroid insufficiency.
  - Identified by low serum cortisol and lack of response to exogenous adrenocorticotropin
  - May require low-dose prednisolone or hydrocortisone
  - Risk of laminitis with corticosteroid therapy should be considered
- Treat coagulopathies (see "Disseminated Intravascular Coagulation" in this section)
- Surgically debride septic foci
- Antioxidant therapy
  - Dimethylsulfoxide IV
  - Vitamin E IM
- Gastrointestinal protectants
  - Glutamine may provide supportive nutrition to enterocytes to maintain gastrointestinal barrier.
  - Antiulcer medications are commonly prescribed because of the risk of ulcers with anorexia.
    - Omeprazole is preferred.
    - Ranitidine may be effective in foals (1.5 mg/kg IV q8h).
    - May increase risk of infection because of loss of protective gastric acid

RECOMMENDED MONITORING

- Vital parameters should be monitored closely for change.
- The initial database should be repeated at intervals based on initial findings and new results.

PROGNOSIS AND OUTCOME

- Guarded prognosis
- In humans, as the number of organs involved increases, the mortality rate also increases up to 100% mortality with four organ systems involved.

PEARLS & CONSIDERATIONS

COMMENTS

- Horses with systemic inflammation or a septic process should be monitored closely for changes in any physical parameter and for any sign of impending organ failure.
- Those with one organ failure should be monitored closely for a new system failure, which may greatly reduce prognosis.

PREVENTION

Horses with sepsis or SIRS should be treated aggressively to prevent failure of any organ system.

ElibeVet.com

Mushroom Toxicosis

BASIC INFORMATION

DEFINITION

Clinical condition caused by ingestion of any of a variety of toxic mushrooms. The toxic syndrome produced depends on mushroom type and amount ingested.

SYNONYM(S)

- Gastrointestinal (GI) irritant mushrooms: Large variety of species
- Isoxazole mushrooms: *Amanita gemmata*, *Amanita muscaria*, *Amanita smithiana*, *Amanita strobiliformis*, and *Tricholoma muscarium*
- Muscarinic mushrooms: *Inocybe* spp., *Clitocybe* spp.
- Hallucinogenic mushrooms: *Psilocybe* spp., *Panaeolus* spp.
- Hepatotoxic mushrooms: See "Amanitin Toxicosis" in this section

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All mammalian species are susceptible.
- Reports of nonhepatotoxic mushroom exposures in horses are very rare, so few signs are reported. However, exposure to toxic mushrooms is expected to cause similar signs in horses as in other species.

GEOGRAPHY AND SEASONALITY

- GI: Wide distribution throughout North America; large range of fruiting seasons
- Isoxazoles: Throughout the eastern United States and the Pacific Northwest; coniferous and deciduous forests; fruits in spring and early summer and then again in fall
- Muscarinic: Wide distribution; forests or fields; fruits in fall or early winter in temperate areas and year round in warm, moist climates
- Hallucinogenic: Wide distribution, especially in the Pacific Northwest and Gulf Coast; lawns, gardens, roadsides, open woods; cultivated in homes for recreational use

ASSOCIATED CONDITIONS AND DISORDERS

- GI: Acute, self-limiting GI distress
- Isoxazole: Acute inebriation followed by coma; generally self-limiting
- Muscarinic: Acute muscarinic signs
- Hallucinogenic: Acute central nervous system (CNS) signs, generally self-limiting

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to mushrooms; presence of mushrooms in pasture; presence of mushroom parts in mouth and stomach contents
- GI: Abdominal discomfort, diarrhea within 4 hours of exposure
- Isoxazole: Abdominal discomfort, ataxia, and disorientation progressing to sleep or coma within 4 hours of ingestion
- Muscarinic: Hypersalivation, abdominal discomfort, diarrhea, lacrimation, and bradycardia within 4 hours of ingestion
- Hallucinogenic: Disorientation, dysphoria, ataxia, agitation, and hyperesthesia within 30 minutes to 2 hours of ingestion

PHYSICAL EXAM FINDINGS

- GI: Dehydration possible; abdominal discomfort and diarrhea
- Isoxazole: As described above; seizures may occur rarely
- Muscarinic: As described above; moist lung sounds
- Hallucinogenic: As described above; seizures may occur rarely

ETIOLOGY AND PATHOPHYSIOLOGY

- GI: Several mechanisms proposed, including hypersensitivity, local irritation, induced enzyme deficiencies
- Isoxazole: Muscimol mimics γ-aminobutyric acid (GABA), resulting in sedation; ibotenic acid acts on glutamate receptors to cause CNS stimulation; combined effects result in hyperesthesia, sedation, intermittent agitation, and "hallucinations" (reported in humans)
- Muscarinic: Bind muscarinic acetylcholine receptors in parasympathetic nervous system; prolonged duration because of lack of degradation; does not inhibit acetylcholinesterase
- Hallucinogenic: Stimulate serotonin and norepinephrine receptors in the CNS and peripheral nervous system

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- GI, isoxazole: Primary and secondary colic, GI foreign body
- Isoxazole, hallucinogenic: Encephalitis, hepatic encephalopathy, locoism, equine leukoencephalomalacia
- Muscarinic: Slaframine, organophosphorous and carbamate pesticide toxicosis

INITIAL DATABASE

Complete blood count, serum biochemistry profile

ADVANCED OR CONFIRMATORY TESTING

- Isoxazole: Muscimol can be detected in urine, but this analysis can have a long turnaround time
- GI, isoxazole, hallucinogenic, and muscarinic: No specific necropsy lesions expected

TREATMENT

THERAPEUTIC GOAL(S)

- Manage life-threatening conditions
- Manage clinical signs
- Decontaminate the patient
- Provide supportive care as needed

ACUTE GENERAL TREATMENT

- Manage life-threatening conditions.
  - Control seizures (isoxazole, hallucinogenic mushrooms)
    - Diazepam: 0.05 to 0.4 mg/kg slow IV for foals, 25 to 50 mg total dose slow IV for adults; repeat as needed
    - Barbiturates, gas anesthetics may be required if diazepam is ineffective
  - Excessive bronchial secretions and bradycardia (muscarinic mushrooms)
    - Atropine: 0.01 to 0.02 mg/kg IV
- Manage clinical signs
  - Flunixin meglumine (1.1 mg/kg IV as needed) for abdominal discomfort
  - Xylazine (1.1 mg/kg IV) or detomidine (20–40 µg/kg IV) for agitation, hyperesthesia
  - Cyproheptadine (0.3–0.6 mg/kg PO or per rectum) for dysphoria associated with hallucinogenic mushrooms. Note: This has been used successfully in small animal patients, but efficacy in horses is unknown.
- Decontamination: Activated charcoal (1–4 g/kg) via stomach tube; repeat in 8 hours if signs are still present.
- Supportive care
  - Thermoregulation
  - Confinement for dysphoric, disoriented horses to prevent accidental injury. A quiet, dark, padded environment is preferred.

RECOMMENDED MONITORING

Hydration, electrolytes if severe diarrhea

ElibEVet.com

PROGNOSIS AND OUTCOME

Generally good prognosis with supportive care

PEARLS & CONSIDERATIONS

- Because of the difficulty in differentiating between toxic and nontoxic mushrooms, any ingestion of unidentified mushrooms by horses should merit decontamination (activated charcoal) and monitoring.
- Identification of mushrooms is best done by a mycologist; local college biology departments or museums are potential sources of expertise. The use of keys or photos, in the attempted identification of mushrooms should be avoided because these can be extremely unreliable in the hands of inexperienced individuals.
- Only two case reports of nonhepatotoxic mushroom toxicosis were found in the literature; both of these involved hallucinogenic mushroom ingestions, and the animals made full recoveries.

Myeloencephalitis, Equine Herpesvirus-1

BASIC INFORMATION

DEFINITION

An uncommon manifestation of infection with equine herpesvirus-1 (EHV-1; an α-herpesvirus), resulting in a diffuse and multifocal neurologic disease caused by widespread vasculitis, thrombosis, and ischemic necrosis of neural tissue

SYNONYM(S)

- Equine herpesvirus myeloencephalopathy
- Equine rhinopneumonitis
- Neurologic herpesvirus

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Females are more commonly affected.
- Foals rarely show neurologic disease during outbreaks in adults.
- Horses younger than 3 years are less likely to develop the condition.

GENETICS AND BREED PREDISPOSITION Ponies and smaller breeds are less likely to develop the condition.

RISK FACTORS

- Crowding
- Contact with transient or sale horses
- Presence of latently infected horses in the herd

CONTAGION AND ZOONOSIS

- Sporadic cases or multiple horses over a prolonged period within a limited area.
- Recrudescence of latent infection important in spread of disease, which may occur in close populations of horses.
- Infection is by inhalation or ingestion of infective aerosol of virus. The disease may also spread by direct contact with infected discharges (saliva, ocular, nasal and abortion products) of shedding horses.

GEOGRAPHY AND SEASONALITY

- Ubiquitous virus in worldwide horse population; however, disease reports outside North America are uncommon.
- Seasonality: Peak incidence is in the late fall, winter, and early summer.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute onset of fever, ataxia, or acute recumbency about 1 week after exposure to the virus. Signs may stabilize early in clinical course.
- Recent fever, respiratory disease, or abortion may have occurred on the property.
- Multiple horses may be affected on a single property: Ataxia, paresis, and urinary incontinence.

PHYSICAL EXAM FINDINGS

- Symmetrical pelvic limb ataxia and paresis.
- Limb edema is frequently seen.
- Urinary bladder paralysis and overflow incontinence often occurs.
- Sensory deficits are sometimes present in the trunk, perineum.
- Occasional cranial signs: Depression; diffuse face, jaw, tongue, and pharyngeal weakness.

ETIOLOGY AND PATHOPHYSIOLOGY

- The virus crosses respiratory epithelium. Local replication is in the regional lymph nodes followed by mononuclear cell-associated viremia.
- The virus is thought to invade the endothelium of the central nervous system (CNS).
- Vasculitis and associated ischemic necrosis of gray and particularly white matter is widespread.
- The pathogenesis of disease is suspected to be the direct effects of a neurotropic strain of EHV-1 associated with an immune-mediated Arthus-type reaction in the vessel walls.
- The duration and magnitude of viremia determine the occurrence of myeloencephalitis.
- Disease outbreak may be caused by one or both of the following: recrudescence of neuropathogenic EHV-1 strain or mutation to virulent biotype and shedding of a formerly low-risk variant.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Equine protozoal myeloencephalitis (EPM)
- Arboviral diseases (Eastern equine encephalitis, Western equine encephalitis, Venezuelan equine encephalitis, West Nile virus)
- Cervical vertebral malformation
- Trauma: Brain, spinal cord
- Botulism
- Equine degenerative myeloencephalopathy
- Rabies
- Toxicities
- Focal spinal cord lesions: Abscess and aberrant parasite migration

INITIAL DATABASE

Rule out other conditions based on physical and neurologic examinations.

ADVANCED OR CONFIRMATORY TESTING

- Viral isolation or polymerase chain reaction: Nasal swabs, tracheal fluids, and blood buffy coat. Sample both affected and in-contact horses to increase the chance of detection.
- Cerebrospinal fluid (CSF): Best obtained from the lumbosacral site; xanthochromia and elevated protein but usually very few cells are seen.

ElibVet.com

- EHV-1 serum (and possibly CSF) titers: Helpful in making a diagnosis on a herd basis, but in individual animals, interpretation can be problematic. Collect acute and convalescent serum (2- to 3-week interval) to demonstrate a fourfold increase in antibody. High acute titers may be confirmatory.
- Histopathology: Widespread focal hemorrhage throughout the CNS; vasculitis, congestion, and ischemic necrosis of neural tissue; axonal swelling and malacia of gray and white matter.
- Immunofluorescent antibody testing: Brain and spinal cord.

TREATMENT

THERAPEUTIC GOAL(S)

- Strictly isolate suspected cases until the condition is ruled out.
- Antiinflammatory drugs may help ameliorate neurologic signs.
- Broad-spectrum antibiotic therapy is indicated to manage bacterial pulmonary superinfection and possible cystitis from chronic urinary bladder catheterization.
- Antiviral drugs may be of use.
- Provide supportive care.

ACUTE GENERAL TREATMENT

- Antiinflammatory drugs: Nonsteroidal antiinflammatory drugs; flunixin meglumine (1 mg/kg q12h)
- Dimethyl sulfoxide: 0.5 to 1.0 g/kg IV q12–24h; must be diluted to a 10% solution or less in an isotonic balanced electrolyte solution
- Corticosteroids (controversial): Dexamethasone (0.05–0.1 mg/kg PO, IV, or IM q12h tapering down over 3 days) or prednisolone (1–2 mg/kg IV or PO q24h)
- Antimicrobials: Trimethoprim-sulfonamide (2.2 mg/kg IM or IV q12–24h), ceftiofur (15–30 mg/kg IM or IV q12–24h)
- Acyclovir: 20 mg/kg PO q8h for 5 days; variable absorption and plasma levels
- Valacyclovir: 30 mg/kg PO q8h for 2 days, then 20 mg/kg PO q12h
- Supportive therapies: IV fluids; enteral or parenteral nutrition
- Bladder catheterization, manual evacuation of feces
- Leg wraps, head protectants
- Encourage the horse to stand if able; a sling is useful as an aid to standing but not as complete support

CHRONIC TREATMENT

- Adult horses are unable to tolerate prolonged periods of recumbency. It is essential to reposition the horse every 4 to 6 hours to minimize decubital ulcers over bony prominences.
- Great care must be taken when a sling is used because although some horses learn to use the sling to assist standing, urination, and defecation, some resort to using the sling as complete support, resulting in significant respiratory impairment and pressure sores.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Decubital ulceration
- Corneal ulceration
- Cystitis
- Constipation

PROGNOSIS AND OUTCOME

- Ambulatory horses usually improve over a few days to a few months and often return to normal.
- Recumbent horses have recovered completely with dedicated nursing care; however, secondary complications may be severe with prolonged recumbency, necessitating euthanasia.
- Residual neurologic deficits may occur.

PEARLS & CONSIDERATIONS

COMMENTS

- Prevention is difficult because the majority of horses are latently infected with virus.
- Vaccination aims to decrease nasal shedding of virus.
- In the face of an outbreak, diagnose early, prevent spread, and treat clinical cases.

PREVENTION

- Modified-live and inactivated vaccines are available for protection against respiratory and abortion strains, although they have not been proven protective against the neurologic syndrome.
- New arrivals: Isolate for at least 3 weeks. Ensure that their vaccination status is current.
- Minimize comingling of resident horses with recent arrivals.
- Minimize management practices, nutritional plane, and concurrent diseases as stressors.
- Outbreak: Efficacy of vaccination in the face of outbreak is unknown. May be deleterious because of immune-mediated pathogenesis of disease. However, no reports exist of deleterious effects of vaccination in this situation.
- Neuropathic strains may spread in aerosol up to 10 m.
- Isolate the facility for 28 days after last clinical case onset.

CLIENT EDUCATION

Preexisting EHV-1 serum neutralization titers are not protective.

AUTHOR: **PETER R. MORRESEY**

EDITOR: **STEPHEN M. REED**

Myeloencephalopathy, Equine Degenerative

BASIC INFORMATION

DEFINITION

Progressive, symmetrical neurologic condition with prominent ataxia and weakness resulting from widespread degeneration of the spinal cord and brainstem

SYNONYM(S)

Neuroaxonal dystrophy of Morgan horses is a related condition with similar, but more localized, degenerative histologic changes.

ElibeVet.com

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Domestic and captive Equids
- Onset from 1 month to several years of age; most cases, younger than 6 months of age

GENETICS AND BREED PREDISPOSITION

- Most breeds of domestic horses have been affected.
- Familial or hereditary basis suspected: Arabian, Appaloosa, Thoroughbred, Standardbred, Paso Fino and Morgan horses, and exotic Equidae (zebra, Przewalskii's horse).

RISK FACTORS

- Prolonged exposure to dry dirt lots with no grass.
- Feeding of heated, pelleted feed and sun-baked forages with very low vitamin E content (<5 U/kg dry matter).
- A familial tendency has been observed, suggesting vitamin E deficiency has a greater effect in genetically predisposed animals.
- Some chronically affected animals have been found to have normal serum vitamin E concentrations because of subsequent pasture exposure.
- Use of insecticide and exposure to wood preservative has been identified (with others) as risk factors in equine degenerative myeloencephalopathy (EDM), although a causal relationship has not been established.

GEOGRAPHY AND SEASONALITY

- United States: Northeastern states predominantly, but the occurrence is widespread
- British Isles and Europe

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Signs are first seen in suckling and weanling foals younger than 6 months.
- Signs are usually insidious in onset and slowly progressive. However, an acute onset of severe ataxia and weakness in the pelvis or all four limbs may occur.
- Clinical signs occasionally progress to recumbency, although most frequently the clinical signs plateau with maturity of the horse and chronicity of the condition.

PHYSICAL EXAM FINDINGS

- Neurologic examination reveals upper motor neuron and general proprioceptive deficits: symmetrical ataxia, and weakness and hypometria affecting all limbs but often worse in the pelvic limbs (compare with equine motor neuron disease).
- Severely affected patients may assume a "dog-sitting" posture.
- Marked hyporeflexia or areflexia involving the thoracolaryngeal (slap), local cervical, and cutaneous trunci reflexes may occur without loss of sensation or regional muscle atrophy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Neuroaxonal dystrophy: Spinal cord and brainstem. Sensory, proprioceptive, and neuronal fiber degeneration within ascending and descending spinal cord pathways. Most prominent in the thoracolumbar region.
- High oxygen demand, high metabolic rate, and high content of polyunsaturated fats within the central nervous system (CNS) make it susceptible to oxidative damage from abundant free radical production.
- Neurotransmitter metabolism is another source of oxygen-derived free radicals.
- EDM is thought to be caused by a relative lack of antioxidant molecules (including vitamin E).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cervical vertebral malformation.
- Equine protozoal myeloencephalitis (EPM)

INITIAL DATABASE

- Routine blood tests, cervical radiography, cerebrospinal fluid (CSF), and electromyography do not aid diagnosis. Reports of increased CSF creatine kinase enzyme activity exist.
- Early in the course of the disease, young affected animals and unaffected foals on the same farm may have reduced serum vitamin E concentrations; however, mature animals with chronic disease may have normal levels if they have access to fresh green forage.

ADVANCED OR CONFIRMATORY TESTING

- Necropsy: Gross evaluation is unremarkable.
- Histopathology: Symmetrical neuronal fiber degeneration throughout the spinal cord, especially the medial and ventral parts of ventral funiculi and spinocerebellar tracts. Demyelination is prominent. Astrocytosis, astrogliosis, vacuolation, and axonal swelling are noted. Accumulation of endothelial lipopigment in the CNS occurs.

TREATMENT

THERAPEUTIC GOAL(S)

- Stabilize the horse's clinical signs.
- Cure is unlikely; treatment is of doubtful benefit.

ACUTE GENERAL TREATMENT

- Vitamin E supplementation: Affected horses may stabilize with 6000 to 10,000 U/d. Treatment should be continued until the patient is 3 years old.
- There is an improved probability of success if treatment initiated at the first signs of disease.

PROGNOSIS AND OUTCOME

- The disease is progressive; however, signs may stabilize with treatment.
- After it is evident, clinical signs do not resolve.
- Euthanasia is the likely outcome.

PEARLS & CONSIDERATIONS

COMMENTS

- An earlier onset indicates a more severe disease process and a more rapid progression.
- A later onset of signs suggests less severe disease and a slower progression.

PREVENTION

- Vitamin E supplementation: Lack of pasture, insecticide or wood preservative exposure, processed feeds, and familial disposition are risk factors, suggesting that supplementation in these situations may be protective. The incidence in foals on affected properties has been shown to be reduced with supplementation of 1500 U/d of vitamin E.
- Supplementation of groups of horses in which there has been a high prevalence of the disease with adequate vitamin E (≥2000 IU q24h) has been associated with cessation of new cases.
- Maintain vitamin E dietary intake of 500 to 1000 IU/kg of dry weight of feed.

EDITOR: **STEPHEN M. REED**

ElibeVet.com

Myocarditis

BASIC INFORMATION

DEFINITION

Any disease process causing active inflammation of the heart muscle. Myocarditis is an uncommon sequela that may occur secondary to a variety of causes.

EPIDEMIOLOGY

RISK FACTORS

- Myocarditis may result from an extension of infection or inflammation associated with other sources. Risk factors include:
  - Recent infection (bacterial, viral, or parasitic) of the respiratory tract
  - Systemic inflammation, such as bacteremia or septicemia
  - Pericardial disease or endocardial disease
- Exposure to various toxins, including ionophore antimicrobials (eg, monensin, lasalocid, salinomycin), heavy metals, various cardiotoxic plants (eg, gossypol, *Cassia occidentalis*, *Philaria* spp., yew, oleander, white snakeroot, foxglove, lily of the valley, rhododendron), cantharidin toxicosis, recent snakebite envenomation
- Nutritional imbalances, including vitamin E and selenium deficiency (neuromuscular degeneration), copper deficiency, excess molybdenum, excess sulfates
- Hyperthermia or heat stroke

GEOGRAPHY AND SEASONALITY

- Sporadic
- Myocarditis associated with vitamin E or selenium deficiency is usually seen in horses younger than 1 year old and in geographic locations with low soil selenium (northeast, eastern seaboard, northwest United States).
- Snakebite envenomation is more common in certain areas of the country (southwest, southeast) and more likely when snakes are active in the spring and summer.
- Cantharidin exposure is more likely with the consumption of alfalfa hay harvested in the southwest (Texas, Oklahoma), particularly later cuttings or certain processing methods such as crimping of hay during cutting.

ASSOCIATED CONDITIONS AND DISORDERS

- Arrhythmias are commonly associated with myocarditis. Chronic myocarditis may lead to cardiomyopathy.
- In addition, clinical signs associated with the primary disease process might be present. These may include evidence of recent infection, snakebite, or clinical signs associated with the toxic effects of the ingested plant or toxin (weakness, colic, diarrhea, renal disease).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES In other species, three phases (acute, subacute and chronic) have been recognized. This has not been well characterized in horses.

HISTORY, CHIEF COMPLAINT

- Historical findings and presenting complaints may either be specific to the cardiovascular system or vague and associated with the causative factor.
- Exercise intolerance or poor performance
- Syncope or sudden death
- Fever, lethargy, inappetence, respiratory abnormalities (tachypnea, dyspnea), distress, colic, colitis, lameness, ataxia

PHYSICAL EXAM FINDINGS

- Tachycardia, arrhythmias, gallop rhythm
- Cardiac murmurs
- Tachypnea, dyspnea, nostril flare, cough
- Myalgia, reluctance to move
- Weak systemic pulses, jugular pulses, jugular distension, syncope
- Nonspecific signs associated with primary disease process, including fever, anorexia, weakness, colic, diarrhea, nasal discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- Inflammation of the myocardium may be caused by:
  - Bacterial infection: Staphylococcus aureus, Streptococcus equi, Clostridium chauvoei, Mycobacterium spp.
  - Viral infection: Equine infectious anemia, equine viral arteritis, equine influenza, African horse sickness, equine herpesvirus-1 (EHV-1)
  - Parasitic infection: Strongylosis, onchocerciasis, babesiosis
  - Bacteremia, septicemia, or the spread of contiguous disease from the pericardium or endocardium
  - Other infiltrative or inflammatory diseases
- Exposure to various toxins, including ionophore antimicrobials (eg, monensin, lasalocid, salinomycin), heavy metals, various cardiotoxic plants (eg, gossypol, *C. occidentalis*, *Philaria* spp., yew, oleander, white snakeroot, foxglove, lily of the valley, rhododendron), cantharidin toxicosis, recent snakebite envenomation.
- Nutritional imbalances: Vitamin E and selenium deficiency (neuromuscular degeneration), copper deficiency, excess molybdenum, excess sulfates.
- Hyperthermia or heat stroke.
- Inflammation associated with infection or infiltrative diseases may lead to conduction disturbances, chamber dilatation, and decreased systolic function.
- The pathophysiology of the individual etiology (toxins, nutritional imbalances) is associated with the specific mechanism of action of each toxic principle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- For exercise intolerance, lethargy, weakness: Abnormalities in respiratory or musculoskeletal systems; neuromuscular diseases
- For arrhythmias: Systemic diseases, electrolyte abnormalities, primary valvular or congenital heart diseases with chamber enlargement
- For heart failure: Primary valvular or pericardial diseases, congenital heart diseases
- For respiratory signs: Primary pulmonary or pleural diseases

INITIAL DATABASE

- Complete blood count: Normal or changes consistent with inflammation or infection (leukocytosis, neutrophilia, lymphopenia, anemia of chronic disease, hyperfibrinogenemia, hyperproteinemia).
- Chemistry panel: Changes consistent with passive congestion from right-sided heart failure (increased liver enzymes) or changes consistent with organ dysfunction caused by decreased cardiac output (azotemia). Electrolyte abnormalities concurrent with the primary disease process (eg, hypocalcemia with cantharidin toxicosis). Elevated lactate concentration in association with poor systemic perfusion. Elevations in creatine kinase may be seen secondary to neuromuscular degeneration (selenium deficiency) or cantharidin exposure.
- Urinalysis: Hemoglobinuria is consistent with certain toxicities or nutritional myodegeneration. Hematuria may be seen with snakebite, cantharidin toxicosis.
- Electrocardiogram (ECG): May be normal or show any arrhythmia

ElibEVet.com

FIGURE 1 Base-apex electrocardiogram from a horse with idiopathic myocarditis showing underlying sinus tachycardia (heart rate, 83 beats/min) and a paroxysm of ventricular tachycardia. Amplitude, 5 mm/mV; paper speed, 25 mm/sec.

(premature atrial contractions, premature ventricular contractions, supraventricular tachycardia, ventricular tachycardia, atrial fibrillation) (Figure 1)
- 24-hour ECG (Holter) monitoring: More accurately identifies the occurrence and prevalence of arrhythmias than a single rhythm strip.
- Cardiac troponin I: Likely elevated in cases of myocarditis associated with myocardial necrosis.
- Echocardiogram: May be normal or show evidence of myocardial inflammation such as thick or thin myocardial walls, heteroechogenicity of myocardial walls, or reduced systolic and diastolic function.

ADVANCED OR CONFIRMATORY TESTING

- Culture and antimicrobial sensitivity testing of blood, pericardial fluid, tracheal wash fluid, or pleural fluid as indicated (bacterial infections)
- Pursuit of viral etiology such as:
  - Serology (equine viral arteritis, equine influenza, EHV-1).
  - Polymerase chain reaction (EHV-1).
  - Antibody binding assays such as enzyme-linked immunosorbent assay (equine influenza)
  - Agar-gel immunodiffusion (AGID) test (Coggins test) for equine infectious anemia
  - Virus isolation
- Evaluation of pasture for exposure to toxic plants and feed for ionophore antimicrobials such as monensin.
- Evaluation of gastric contents or body fluids for oleandrin and serum digoxin concentrations (cardiac glycoside containing plants). If the patient is not receiving digoxin therapy, should have no detectable concentrations.
- Evaluation of urine or gastric contents for cantharidin.
- Pursuit of potential nutritional imbalances such as selenium deficiency (blood concentrations).
- Pursuit of heavy metal exposure.
- Endomyocardial biopsy with histopathologic evaluation is the gold standard for diagnosis in human medicine, however, because of its invasive nature, it is currently not performed in clinical equine practice.

TREATMENT

THERAPEUTIC GOAL(S)

Normalize cardiac function by reducing arrhythmias, providing inotropic support, and treating heart failure while ultimately correcting or controlling the underlying disease process.

ACUTE GENERAL TREATMENT

- Arrhythmias: Treat with antiarrhythmic drugs (AADs) as dictated by the arrhythmias documented on the ECG. Use AADs for arrhythmias that are hemodynamically significant (ie, causing clinical signs attributable to the arrhythmia) or are likely to progress to fatal arrhythmias.
- Congestive heart failure: Treat with furosemide (1–2 mg/kg IV as needed) and intranasal oxygen; minimize stress (see "Cardiac Failure" in this section).
- Systolic failure: Administer positive inotropes (eg, dobutamine 1–5 µg/kg/min IV) and vasodilators (eg, hydralazine 0.5–1.5 mg/kg PO) (see "Cardiac Failure" in this section).
- Suspected recent feed intoxication or toxic plant ingestion: Remove all suspected contaminated feed; remove horse from pasture. Administer activated charcoal, mineral oil, or both via nasogastric intubation.
- Suspected monensin intoxication: Administer high levels of vitamin E and selenium to stabilize cell membranes.
- Suspected cardiac glycoside toxicosis (eg, oleander ingestion): Digoxin should not be used to control heart rate or rhythm. May consider administering antidigoxin immune antibodies (Digibind), although this is likely prohibitively expensive in an adult horse.
- Antimicrobial therapy as warranted for specific disease (see appropriate infectious disease chapter for recommendations).
- Provide appropriate supportive care for the underlying disease (eg, crystalloid or colloid fluid therapy, electrolyte replacement, nonsteroidal antiinflammatory drugs, nutritional support).
- Address mineral deficiencies (eg, provide selenium supplementation and vitamin E if needed).

CHRONIC TREATMENT

- Arrhythmias: AADs can be given orally if necessary to treat persistent arrhythmias.
- Standard treatment for congestive heart failure (see "Cardiac Failure" in this section).
- After an active infection has been ruled out, treatment with corticosteroids is indicated to decrease inflammatory or immune-mediated responses.
- Strict stall rest until clinical and echocardiographic signs of myocarditis completely resolve.

DRUG INTERACTIONS

- Digoxin should not be used in cases of monensin intoxication or in exposure to plants containing cardiac glycosides (eg, oleander, foxglove) because they cause an increase in intracellular calcium; this may enhance myocardial cell death, leading to arrhythmias.
- Corticosteroids should only be used after active infections are ruled out.

POSSIBLE COMPLICATIONS

- Any AAD can be proarrhythmic and have other cardiovascular side effects such as hypotension.
- Until the disease has fully resolved, sudden cardiac death in horses is always possible during treatment for myocarditis.
- Chronic myocarditis can progress to dilated cardiomyopathy.

RECOMMENDED MONITORING

- Acute monitoring
  - Arrhythmias: Continuous ECG monitoring using radiotelemetry, particularly if treating arrhythmias
  - Monitoring clinical signs such as heart rate, respiratory rate, and respiratory effort
  - Serum lactate concentrations may be used as an indicator of tissue perfusion.
  - Blood pressure monitoring (direct or indirect) may be performed.
- Chronic monitoring:
  - Monitoring heart rate, respiratory rate, and respiratory effort should continue at home after the horse is discharged from the hospital. Any

ElibeVet.com

change in status should prompt a repeat complete cardiovascular examination.
  - Cardiac troponin I is relatively labile and can therefore reflect changes from day to day in the degree of myocardial cell injury or necrosis.
  - Monitoring as needed for the primary disease process.
  - Therapeutic drug levels and standard monitoring of chronic cardiac drug therapy (see "Cardiac Failure" in this section).
  - Periodic echocardiograms to assess resolution of disease. These should be repeated every 3 to 6 months after the horse is discharged from the hospital until return to normal function.
  - Periodic 24-hour ECG (Holter) monitoring.
  - Exercising ECG to determine whether exercise-induced arrhythmias are present and to assess the safety of use as a riding horse (after clinical disease has resolved and before being used as a riding horse).
  - Monitoring exercise tolerance after the horse is no longer on stall rest.

PROGNOSIS AND OUTCOME

- Fair to good if myocarditis is secondary to a disease process that can be addressed and it is recognized early before permanent damage has occurred
- Guarded to poor if cardiomyopathy and heart failure occurs

PEARLS & CONSIDERATIONS

COMMENTS

Myocarditis is often labelled idiopathic because we cannot determine the underlying etiology. As our diagnostics improve, we should be able to more specifically diagnose various causes of myocarditis. Myocarditis may also go unrecognized until clinical signs become severe, resulting in a worse prognosis.

PREVENTION

- Maintenance of a good vaccination and deworming program to decrease the risk of predisposing viral infections and parasitic infestations.
- Monensin intoxication: Use a reputable feed supplier, preferably one that does not mix equine feed in the same location as poultry or cattle feed.
- Plant intoxications: Know the content of pastures on which horses are kept.
- Selenium deficient areas: Have soil tested and supplement if needed for the area.

CLIENT EDUCATION

If owners note nonspecific signs within a few weeks of a respiratory tract infection, consultation with a veterinarian should be sought.

EDITOR: **MARY M. DURANDO**

Myonecrosis, Clostridial

BASIC INFORMATION

DEFINITION

An acute, life-threatening disease of horses caused by infection of muscle with any of a variety of *Clostridium* spp. that elaborate dermonecrotizing and vasoactive toxins, leading to gas production, extensive tissue damage, and life-threatening systemic toxemia

SYNONYM(S)

- Clostridial myositis or cellulitis
- Malignant edema
- Gas gangrene

EPIDEMIOLOGY

RISK FACTORS

- Puncture wound or intramuscular injection.
- The most frequently incriminated pharmacologic agent is flunixin meglumine.
- The most common injection site is the cervical musculature.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Onset of signs within 48 hours of injection of a pharmacologic or biologic agent in the affected area of the body.
- Incriminated medications include nonsteroidal antiinflammatory drugs, antihistamines, multivitamins, antipyretics, dewormers, vaccines, diuretics, and synthetic prostaglandins.
- Depression, lethargy, and inappetence are chief signs.
- Swelling and crepitus of the affected area.

PHYSICAL EXAM FINDINGS

- Rapidly progressive soft tissue swelling with subcutaneous and deeper soft tissue emphysema
- Fever
- Tachycardia
- Tachypnea
- Depression
- Toxic mucous membranes with prolonged capillary refill time
- Occasionally, signs of a hemolytic crisis: hemoglobinuria, icterus
- Possible signs consistent with multiorgan failure

ETIOLOGY AND PATHOPHYSIOLOGY

- Most commonly, the etiologic agent is *Clostridium perfringens.*
- *Clostridium septicum, Clostridium chauvoei, Clostridium novyi,* and others are occasionally incriminated.
- Infection may originate from introduction of surface bacteria into soft tissue at the time of injection.
- Alternatively, dormant spores may be present in the muscle and convert to vegetative form when anaerobic conditions develop secondary to injection-site inflammation.
- α-Toxins from *C. perfringens* are dermonecrotic and considered critical in development of the disease.
- Toxins lead to systemic toxemia, cardiovascular collapse, and multiorgan dysfunction.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Any soft tissue infection or injection site inflammation or abscess

ElibeVet.com

INITIAL DATABASE

- Complete blood count findings consistent with toxemia and dehydration:
  - Neutropenia, left shift with toxic changes
  - Increased packed cell volume, total solids
  - Moderate to marked anemia if hemolysis is occurring
- Serum biochemical profile to assess organ function
  - Azotemia common
  - Marked increase in serum creatine kinase activity
- Ultrasonography to identify affected areas in deeper tissues

ADVANCED OR CONFIRMATORY TESTING

- Gram stain of aspirates from affected subcutaneous areas reveals large numbers of gram-positive rods.
- Anaerobic culture of fluid aspirates for definitive diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Eliminate the infection.
- Provide supportive treatment for systemic toxemia and multiorgan failure.

ACUTE GENERAL TREATMENT

- A combination of aggressive medical and surgical treatment is required.
- High-dose antimicrobial therapy such as potassium penicillin at 88,000 IU/kg q2h (minimum, 22,000 IU/kg q6h).
- Oral metronidazole (25 mg/kg q6h) should be administered if the use of oral medication is possible.
- Oxytetracycline is an alternative IV antimicrobial agent (6.6 mg/kg IV q12–24h).
- Fenestrate affected soft tissues by aggressive incising areas of subcutaneous emphysema, extending incisions into deeper tissues and adjoining areas of healthy tissue.
- Local infusions of penicillin at the margins of infected tissue may be of benefit.
- Intensive fluid, electrolyte, and cardiovascular support should be provided in the acute stages of disease.

CHRONIC TREATMENT

- Horses that survive acute disease may have significant soft tissue and skin sloughing over the next days to weeks.
- Long-term wound care is required.
- Many patients may require weeks to months for granulation and second-intention skin healing to be complete.

POSSIBLE COMPLICATIONS

Extensive tissue sloughing is common.

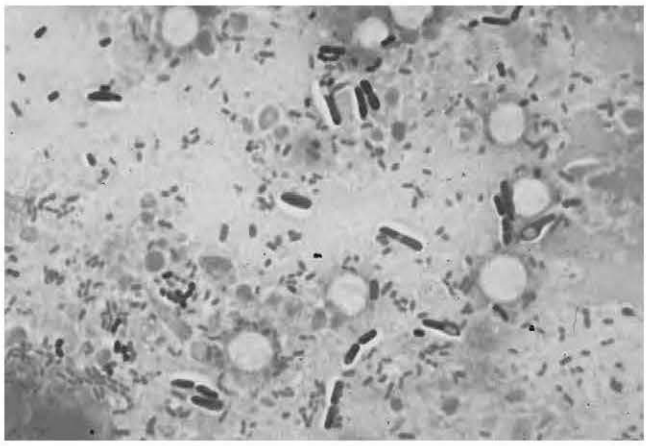

FIGURE 1 Gram stain of aspirate from subcutaneous tissues of horse with acute clostridial myonecrosis. Notice the numerous, large, gram-positive rods. (From Sellon DC, Long MT: *Equine infectious diseases.* St Louis, 2007, Saunders.)

FIGURE 2 Fasciotomy/myotomy incisions in gluteal region of 2-year-old Quarter Horse filly that developed clostridial myonecrosis secondary to vaccination at the site. (Courtesy Dr. Susan Semrad. From Sellon DC, Long MT: *Equine infectious diseases.* St Louis, 2007, Saunders.)

FIGURE 3 **A,** Mature Quarter Horse gelding showing skin and muscle sloughing 2 weeks after surgical fenestration of an area of clostridial myonecrosis in the cervical region. **B,** The same horse approximately 30 days after surgical fenestration showing near-complete granulation bed in prior area of clostridial myonecrosis. (From Sellon DC, Long MT: *Equine infectious diseases.* St Louis, 2007, Saunders.)

ElibVet.com

RECOMMENDED MONITORING

- Monitor the patient's cardiovascular status; hypotension, tachycardia, and shock are common in the acute stages.
- Monitor electrolyte, acid-base, and fluid balance.
- Monitor renal function. Multiorgan failure, toxemia, and pigmenturia from damaged muscle may result in acute renal insufficiency.
- Frequently reevaluate site of infection and extend surgical fenestrations as needed.

PROGNOSIS AND OUTCOME

- The prognosis varies depending on the species of *Clostridium* involved.
- Horses with *C. perfringens* infection have a survival rate of 80% if treated aggressively.
- Horses with *C. septicum* or *C. chauvoei* infections have a significantly poorer prognosis.
- Some horses may heal with pigmentation changes and significant cicatrix formation.
- Most horses that die will succumb in the first few days of infection.

PEARLS & CONSIDERATIONS

COMMENTS

- Although there is no protective effect demonstrated from skin disinfection, hair clipping, or disinfection of the top of multidose vials before IM injection, proper injection technique for all IM injections is recommended.
- When administering potentially irritant substances, particularly flunixin meglumine, it may be advisable to encourage use of the larger, better vascularized, caudal thigh musculature rather than the cervical musculature.

CLIENT EDUCATION

Clients should be encouraged to report all injection-site reactions to their veterinarian as soon as they are noticed and to monitor closely for changes in condition suggestive of clostridial infection.

Nasal Polyps

BASIC INFORMATION

DEFINITION

Fibrous, inflammatory growths arising from the nasal (septal or conchal) mucosa. They are often pedunculated and may contain cystic cavities.

SYNONYM(S)

Sinonasal polyps, inflammatory polyps

EPIDEMIOLOGY

SPECIES, AGE, SEX Most commonly diagnosed in older horses

ASSOCIATED CONDITIONS AND DISORDERS Progressive ethmoid hematomas have been described as hemorrhagic nasal polyps, and they share histologic similarities with true nasal polyps.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Polyps can develop as firm, fibrous masses on long stalks or consist of a fibrous capsule surrounding a single or polycystic, fluid-filled cavity. They are most often unilateral and occur as singular or multiple masses.
- Polyps can also originate from paranasal sinus mucosa or far less likely from the pulpal tissues (hyperplastic pulpitis) of the upper cheek teeth and extend into the nasal passage on pedicles.

HISTORY, CHIEF COMPLAINT

- Owners may notice a nasal discharge, reduced airflow at the nares, and abnormal respiratory noise developing and worsening over a prolonged period of time.
- The nasal discharge may be malodorous and can be mucoid to purulent. Head shaking may be a reported concern.
- The onset of clinical signs can be insidious, and lesions may be present weeks to years before veterinary attention is sought.

PHYSICAL EXAM FINDINGS Malodorous nasal discharge (mucoid to purulent); reduced nasal airflow; increased respiratory noise localized to the nasal passage; enlarged submandibular lymph nodes; external facial swelling (uncommon); white, pink, or yellow mass visible at the external nares

ETIOLOGY AND PATHOPHYSIOLOGY

- Probably an inflammatory origin (maybe allergies) with the inciting cause not determined.
- Inflamed nasal or sinus mucosal epithelial glands become occluded, leading to their enlargement, dilatation, and rupture.
- Leaking glandular fluid may cause ongoing inflammation and the development of a granulomatous reaction with cystic cavities.
- Slowly growing masses gradually occlude the nasal passage and expand rostrally, caudally, or both.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Progressive ethmoid hematoma
- Granuloma
- Paranasal sinus cyst extending into the nasal passage
- Fungal rhinitis
- Sinonasal neoplasia
- Nasal epidermal inclusion cyst (atheroma)
- Amyloidosis

INITIAL DATABASE

- Complete blood count and chemistry panel: Expected to be normal; not indicated.
- Rhinoscopy: Smooth-walled; white, pink, or yellow; bulbous structure occluding and distorting the nasal passage and septal and conchal tissues. Lesions are located a variable distance from the external nares; a pedunculated attachment to the nasal mucosa is often visualized. If the nasal polyp originates from the sinus mucosa, increased drainage at the nasomaxillary opening can be expected if it can be visualized.

ElibVet.com

- Radiography: A nonspecific soft tissue mass effect obliterating the nasal meati, nasal septum deviation, paranasal air-fluid interface, may be bony changes associated with the mass, increased periapical opacity.

ADVANCED OR CONFIRMATORY TESTING

- Sinoscopy: May confirm a secondary sinusitis and the origin of a sinus-based polyp; useful for biopsying mass.
- Computed tomography provides the most detailed imaging of polyps and their exact anatomic location and structures involved; however, it is usually not required.
- Histopathology of removed tissue confirms the diagnosis: Granulation tissue, myxomatous connective tissue, inflammatory cells, secretory epithelium lining cystic cavities, inflamed epithelial glands.

TREATMENT

THERAPEUTIC GOAL(S)

- Complete removal of the polyp is required to restore normal air flow and function of the nasal passage and prevent recurrence.
- Resolve any concurrent secondary paranasal sinusitis.

ACUTE GENERAL TREATMENT

- Rarely, a horse may require an emergency tracheotomy to provide comfortable airflow and allow manipulations of the nasal passage without undue respiratory distress.
- Surgical removal of the polyp
  - Endoscopically guided wire or electrocautery snaring and extraction of pedunculated polyps; varying degrees of bleeding at the site of mucosal attachment should be expected.
  - Transendoscopic laser ablation of small polyps or laser excision of pedunculated polyps and ablation of the mucosal base.
  - Incising the nostril and alar cartilage can improve exposure and access to a rostrally located large polyp.
  - Sinusotomy may be required for removal of polyps known to arise in the paranasal sinus.
  - Polyps of dental origin may require specific tooth extraction.
- Treatment of a secondary paranasal sinusitis: Systemic broad-spectrum antimicrobials or culture and sensitivity-guided antimicrobial therapy and sinus lavage for 7 to 10 days.

CHRONIC TREATMENT

Follow-up laser ablation of residual tissue may be indicated at 2 to 4 weeks.

POSSIBLE COMPLICATIONS

- Inexperienced use of lasers may result in adjacent normal tissue destruction, leading to nasal passage disfiguration, increased scarring, and possibly granulation tissue formation that requires subsequent management to remove.
- Hemorrhage may be severe in some cases.
- Sinusotomy and dental extractions have associated complications.

RECOMMENDED MONITORING

- After any removal procedure, reexamination via endoscopy is recommended at 2 weeks and then subsequently at 2 months and 6 months if no further treatment is required.
- Additional procedures may be required at 2 weeks to remove residual tissue. Reexamination should be as described above after no signs of abnormal tissue remain.
- Nasal discharge should resolve within 2 weeks if all polypoid tissue is removed. Monitoring for this is important to detect ongoing disease or disease recurrence in the future.
- Airflow and airway noise are also monitored for any abnormal signs to suggest recurrence or new disease.

PROGNOSIS AND OUTCOME

Excellent prognosis with complete removal of the polyp; recurrence is rare in these cases

PEARLS & CONSIDERATIONS

COMMENTS

- A very infrequently encountered cause of nasal discharge and airflow obstruction in horses
- Careful assessment may be required to differentiate among ethmoid hematomas, nasal tumors, or expansile paranasal sinus cysts.
- Laser excision and ablation of polyps is the preferred treatment if available because of reduced hemorrhage and complete removal of tissue.

CLIENT EDUCATION

- Occurrence of polyps appears to be sporadic and of unknown cause.
- Polyps are locally benign, expanding masses.
- At the first sign of abnormal nasal discharge, reduction in nasal airflow, or increase in airway respiratory sounds, consult a veterinarian.

Neck Pain (Cervical Dysfunction)

BASIC INFORMATION

DEFINITION

Abnormal cervical function characterized by soft tissue, bony, or articular pain; muscle hypertonicity; or neck stiffness. Severe cases include neurologic deficits of ataxia, spasticity, or weakness.

SYNONYM(S)

- Cervical hyperesthesia
- Cervical hyperpathia
- Neck stiffness
- Cervical osteoarthritis
- Cervical vertebral compressive myelopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cervical vertebral compressive myelopathy has an increased prevalence in young horses (<4 yr).

ElibeVet.com

- Young horses have an increased susceptibility for vertebral column trauma.
- Males have increased risk for developmental orthopedic disease (DOD) and cervical vertebral compressive myelopathy.

GENETICS AND BREED PREDISPOSITION
- Genetic predisposition for cervical vertebral compressive myelopathy in Thoroughbreds, Tennessee Walking Horses, and Warmbloods
- Familial predisposition for equine degenerative myelopathy in Standardbreds and Appaloosas
- Breed predisposition for enthesopathy of the nuchal ligament in Warmbloods

RISK FACTORS
- Trauma
- Vertebral malformations
- Nutritional factors linked to osteochondrosis development include overfeeding (high protein and carbohydrates), calcium-phosphorous imbalance, copper or manganese deficiency, and zinc excess.
- Cervical vertebral instability or chronic microtrauma
- Abnormal biomechanical forces associated with the ill-fitting or improper use of draw reins or other restraint or training devices
- Exposure to environmental oxidants and vitamin E deficiency

CONTAGION AND ZOONOSIS Cranial and caudal nuchal bursitis (poll evil) and diskospondylitis have zoonotic potentials if caused by *Brucella abortus* infections.

ASSOCIATED CONDITIONS AND DISORDERS Forelimb lameness caused by brachial plexus injury or avulsion

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Congenital: Occipitoatlantoaxial malformation (OAAM) in Arabians
- Developmental: Osteochondrosis of articular processes, vertebral canal stenosis
- Degenerative: Osteoarthritis of cervical synovial articulations
- Traumatic: Cervical fractures, penetrating wounds
- Infectious (neurologic): Equine protozoal myelitis (EPM)
- Infectious (osseous): Discospondylitis, vertebral osteomyelitis
- Inflammatory: Intramuscular vaccine reactions
- Nutritional: High-protein and high-carbohydrate diets, vitamin E deficiency
- Neoplasia: Cervical vertebral myeloma
- Vascular: Thrombophlebitis of the external jugular vein
- Iatrogenic: Improper fit or use of training devices used for restraining head and neck position

HISTORY, CHIEF COMPLAINT
- History of having the head or neck caught in a fence
- History of a fall or running into a solid obstacle or jump
- Abnormal conformation or head and neck carriage
- Neck pain or stiffness
- Neck held in a fixed or guarded position
- Inability to raise or lower the head and neck
- History of recent intramuscular injection
- Pronounced heat or soft tissue swelling
- Head shyness or resentful of palpation of the poll region
- History of pulling back in the crossties or flipping over
- Unwillingness to work on the bit
- Difficulty or resistance in turning in one direction
- Weakness or ataxia
- History of recent respiratory infections or abortions on the farm

PHYSICAL EXAM FINDINGS
- Abnormal head and neck posture
- Pain elicited on palpation of the cervical musculature
- Localized heat or soft tissue swelling
- Local muscle atrophy or regional lack of cervical muscle development
- Cervical muscle hypertonicity, fasciculations, or fibrosis
- Neck stiffness
- Resentment of poll flexion or extension
- Pain elicited on manipulation of the head or neck
- Audible or palpable crepitus with induced neck motion
- Lateral bending joint range of motion (ROM) asymmetry
- Loss of local skin sensation along the lateral neck
- Focal or patchy neck sweating (caused by focal sympathetic degeneration)
- Base-wide stance at rest
- Ataxia, spasticity, or weakness (pelvic limbs more affected than the thoracic limbs)
- Stumbling, toe dragging, circumduction of the pelvic limbs, or truncal sway
- Delayed response to proprioceptive challenges or abnormal limb positioning

ETIOLOGY AND PATHOPHYSIOLOGY Numerous tissues may be the source of neck pain or stiffness
- Soft tissue
  - Trauma: Lacerations; penetrating wounds; Contusions caused by bites or kicks
  - Infection: Myositis, abscessation
  - Inflammation: Intramuscular vaccine reaction, enthesopathy of the nuchal ligament, cranial or caudal nuchal bursitis (poll evil)
  - Metabolic: Polysaccharide storage myopathy (PSSM)
  - Vascular: Thrombophlebitis of the external jugular vein
- Vertebral column
  - Congenital: OAAM, torticollis caused by in utero malpositioning
  - Developmental: Cervical vertebral malformation causing constant or intermittent spinal cord compression
  - Degeneration: Osteoarthritis, intervertebral disk degeneration
  - Trauma: Atlantoaxial subluxation, vertebral fractures
  - Infection: Discospondylitis
  - Nutritional: High-protein and high-carbohydrate diet, calcium–phosphorus imbalance, copper deficiency, vitamin E or selenium deficiency
  - Neoplasia: Cervical vertebral myeloma
- Neurologic
  - Trauma: Cervical spinal cord compression
  - Developmental: Vertebral canal stenosis
  - Acquired: Vertebral instability
  - Infection: Equine herpesvirus type 1 (EHV-1) myelitis, verminous encephalomyelitis
  - Nutritional: Exposure to environmental oxidants, vitamin E deficiency
  - Space-occupying mass: Articular process osteophytosis and ligamentum flava hypertrophy

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Neck pain or dysfunction is a nonspecific clinical sign. Diagnosis is based on exclusion of soft tissue, orthopedic, and neurologic disorders of the cervical region.
- Cervical soft tissues
  - Enthesopathy of the nuchal ligament
  - Penetrating wound or laceration
  - Traumatic muscle injury
  - Intramuscular vaccine reactions or abscessation
  - PSSM
  - Recurrent exertional rhabdomyolysis
  - Thrombophlebitis of the external jugular vein
  - Perivascular injection of irritating substance (eg, phenylbutazone)
- Cervical vertebral column
  - Vertebral malformations: OAAM, ankylosis
  - C1-C2 subluxation: Agenesis of dens, luxated dens, or fractured dens

ElibeVet.com

- Vertebral malalignment: Instability, subluxation, or luxation
- Osteochondrosis of the articular processes
- Osteoarthritis of the cervical synovial articulations
- Joint capsule and ligamentum flavum proliferation
- Synovial cysts
- Intervertebral disk degeneration
- Vertebral fractures
- Discospondylitis
- Vertebral osteomyelitis

- Cervical spinal cord and peripheral nerves
  - Cervical vertebral compressive myelopathy: Continuous or intermittent
  - Spinal nerve compression at the cervical intervertebral foramen
  - Brachial plexus injury or avulsion
  - Bacterial or fungal meningitis
  - EPM
  - EHV-1 myelitis
  - Equine degenerative myelopathy
  - West Nile virus encephalitis
  - Verminous encephalomyelitis
  - Rabies
- Other regional disorders
  - Forelimb lameness
  - DOD causing physitis, osteochondrosis, and flexural limb deformities

INITIAL DATABASE

- Inspection of neck conformation, posture, muscle symmetry and development, and motor control
- Gait evaluation
- Lameness examination
- Neurologic examination
- Soft tissue and bony palpation
- Active and passive segmental cervical joint ROM
- Cervical radiography

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography of soft tissues and articular processes
- Ultrasound-guided intraarticular injection of the cervical synovial articulations
- Doppler ultrasonography of the external jugular vein
- Cervical myelography with neutral and flexed views to confirm spinal cord compression
- Cerebrospinal fluid analysis
- Nuclear scintigraphy
- Computed tomography
- Thermography
- Pressure algometry to assess mechanical nociceptive thresholds
- Electromyography to confirm myopathy or neuropathy
- Serology and virus isolation
- Serum vitamin E levels
- Therapeutic trial with high dosage of nonsteroidal antiinflammatory drug (NSAID) for 7 to 10 days

TREATMENT

THERAPEUTIC GOAL(S)

- Immobilize vertebral fractures or soft tissue instabilities
- Prevent secondary spinal cord injuries
- Reduce pain and inflammation
- Remove any source of infection
- Reduce muscle hypertonicity
- Restore normal neurologic function
- Promote full joint range of cervical motion in flexion-extension, lateral bending, and axial rotation
- Increase muscle mass and symmetry

ACUTE GENERAL TREATMENT

- Antiinflammatories: NSAIDs, corticosteroids, dimethyl sulfoxide (DMSO)
- Cryotherapy to minimize heat, swelling, or pain
- Stall confinement or exercise restriction to prevent reinjury and promote healing
- Neck brace or fiberglass neck cast to provide temporary stabilization of nondisplaced cervical fractures or soft tissue instability
- Surgical exploration or debridement of puncture wounds or draining tracts
- Surgical drainage of intramuscular or osseous abscess
- Spinal surgery to provide vertebral stabilization or decompression of the spinal cord
- Intraarticular corticosteroid injections
- Muscle relaxants
- Antibiotic therapy based on culture and sensitivity testing
- Antiprotozoal, antihelmintics, or antiviral medications, as indicated
- Antioxidant supplementation with vitamin E (IM initially; then PO long term)
- Chondroprotective agents
- Electroacupuncture or mesotherapy to reduce pain and muscle hypertonicity
- Electrical muscle stimulation to normalize muscle tone and maintain or stimulate development
- Elevation of water and feed to normal head height if the horse is not able to lower the head and neck
- Controlled handwalking

CHRONIC TREATMENT

- Active and passive neck stretching exercises to restore joint mobility
- Acupuncture to reduce pain
- Chiropractic treatment to increase segmental mobility
- Massage therapy
- Physical therapy and rehabilitation
- Moist heat therapy to reduce pain and muscle hypertonicity
- Extracorporeal shock-wave therapy
- Ground pole and Cavalletti exercises to stimulate proprioception and neuromuscular control
- Warm-up or flexibility exercises: "Long and low" on lunge line, circles, figure-8's, and serpentine movements
- Lunge in a chambon
- Active retraction stretches of the thoracic limb

DRUG INTERACTIONS

- Complications associated with long-term phenylbutazone use in horses include gastritis and right dorsal colitis.
- Gastric ulceration and renal failure
- NSAIDs should not be used in conjunction with corticosteroids

POSSIBLE COMPLICATIONS

- Adverse reaction to antiinflammatory medications.
- Neurologic complications associated with spinal surgery.
- Assess underlying predisposition and total dosage of corticosteroids to reduce the risk of corticosteroid-induced laminitis.

RECOMMENDED MONITORING

- Soft tissue palpation for resolution of cervical pain and muscle hypertonicity
- Repeat physical and chiropractic examination to assess the response to therapy or rehabilitation
- Repeat neurologic examinations to assess ataxia or paresis

PROGNOSIS AND OUTCOME

- Prognosis is often based on the early initiation of treatment and the response to therapy.
- Return to athletic function is highly variable depending on the specific etiology and the severity of the underlying disease process.
- Depends on severity and duration of neurologic deficits and intended use.

PEARLS & CONSIDERATIONS

COMMENTS

- Active and passive neck ROM exercises are useful for identifying affected vertebral levels and laterality of the cervical dysfunction.
- If appropriate and timely therapeutic responses are not noted with conservative care, then advanced diagnostics are warranted.

ElibeVet.com

PREVENTION

- Restricted protein and carbohydrate diet in foals (<1 year) with potential for rapid growth
- Provide quick releases or break-away fasteners to reduce the risk of pulling back and flipping over backward in cross-ties.
- Importance of maintaining neck flexibility and ROM exercises
- DNA testing and selective breeding to noncarriers of genetic-based diseases

CLIENT EDUCATION

- Monitor signs of pain, muscle hypotonicity, and stiffness.
- Avoid riding exercise in any horse with neurologic deficits.

AUTHOR: **KEVIN K. HAUSSLER**

EDITOR: **ANDRIS J. KANEPS**

Nematodiasis, Cerebrospinal

BASIC INFORMATION

DEFINITION

A central nervous system (CNS) dysfunction resulting from aberrant migration of nematode or larval parasites

SYNONYM(S)

- Aberrant parasite migration
- Meningeal worm
- Parasitic encephalomyelitis
- Verminous myelitis or encephalitis

EPIDEMIOLOGY

RISK FACTORS

- Exposure to white-tailed deer, which are commonly affected with the meningeal worm (*Parelaphostrongylus tenuis*)
- Immunocompromise, chronic, debilitating disease or prolonged recumbency (*Halicephalobus deletrix*)

CONTAGION AND ZOONOSIS

- Infections take place in incidental hosts or if aberrant parasite migration occurs in definitive hosts.
- Transmammary transmission of *H. deletrix* from a mare to her foal has been reported.

ASSOCIATED CONDITIONS AND DISORDERS

- Acquired scoliosis has been associated with *P. tenuis* infection.
- Horses affected with *H. deletrix* often have concurrent renal disease and osteolysis and granulomatous lesions involving the gingiva, mandible, or maxilla. Infections may also involve the udder, prepuce, lymph nodes, heart, stomach, lung, eye, or liver.
- Aberrant migration of *Strongylus vulgaris* may be more likely in horses with very poor deworming history and evidence of large strongyle migration, such as cranial mesenteric endarteritis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acquired scoliosis
- Ataxia (often asymmetrical)
- Blindness
- Cranial nerve deficits (dysphagia, head tilt, circling)
- Depression
- Granulomatous inflammation of the mouth, mandible, or maxilla
- Paresis
- Recumbency
- Seizures
- Weight loss
- Most cases are acute and rapidly progressive but may have an insidious onset

PHYSICAL EXAM FINDINGS

- Ataxia, paresis, or both (often asymmetrical)
- Behavioral changes
- Cranial nerve deficits: Blindness, circling, dysphagia, head tilt
- Granulomas of the mouth or nasal cavity
- Scoliosis: Cervical muscle flaccidity and cutaneous hypalgesia on the convex side of neck; ataxia ipsilateral or more severe on the convex side of scoliosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Clinical signs result from migration of parasites through the CNS, direct damage to neural tissue, and the resultant inflammatory response.
- *Draschia megastoma*
- *H. deletrix*
- *Hypoderma* spp.
- *P. tenuis*
- *Setaria* spp.
- *Strongylus equinus*
- *S. vulgaris*

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cervical vertebral malformation
- Equine degenerative myelopathy
- Equine herpesvirus-1 myelopathy
- Equine protozoal myeloencephalitis
- Leukoencephalomalacia
- Meningitis
- Neoplasia
- Temporohyoid osteoarthropathy
- Trauma
- Viral encephalitides (Eastern equine encephalitis, Western equine encephalitis, Venezuelan equine encephalitis, rabies, West Nile virus)

INITIAL DATABASE

- Complete blood count
- Serum chemistries
- Neurologic examination

ADVANCED OR CONFIRMATORY TESTING

- Radiographs of the skull, cervical spine, or both
- Cerebrospinal fluid (CSF) analysis and cytology: Xanthochromia, pleocytosis, and elevated protein concentration
- Magnetic resonance imaging
- Biopsy of granulomas may reveal *H. deletrix* nematodes.
- Postmortem examination, histopathology, and microscopic parasite morphology are most useful for a definitive diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- Kill migrating parasites.
- Control and reduce CNS inflammation.
- Provide supportive care until the horse's neurologic function improves.

ACUTE GENERAL TREATMENT

- Fenbendazole: 50 mg/kg PO q24h for 5 days
- Ivermectin: 0.2 mg/kg PO; some authors recommend treatment q24h for 5 days
- Moxidectin: 0.4 mg/kg PO; has improved lipid solubility compared

ElibeVet.com

with ivermectin and may better cross the blood-brain barrier
- Corticosteroids: Dexamethasone (0.05–0.2 mg/kg IV q12–24h) or methylprednisolone sodium succinate (1.0–2.5 mg/kg IV q6h); the dose and interval depend on the severity of clinical signs
- Flunixin meglumine: 1.1 mg/kg IV q12–24h
- Dimethyl sulfoxide: 0.5 to 1.0 g/kg IV q12–24h; must be diluted to a 10% solution or less in an isotonic balanced electrolyte solution
- IV fluids in recumbent, dehydrated, or dysphagic horses

CHRONIC TREATMENT
- Flunixin meglumine (0.5–1.1 mg/kg PO q12–24h), phenylbutazone (1–2 mg/kg PO q12–24h), prednisolone (0.5–1.0 mg/kg PO q12–24h), or dexamethasone (0.05–0.2 mg/kg PO q12–24h) as needed for CNS inflammation.
- Diethylcarbamazine (20–50 mg/kg PO q24h for ≤10 days) has been recommended for killing microfilaria or migrating larval parasites.
- Horses that are unable to stand or get up on their own need to be placed into a sling periodically.

POSSIBLE COMPLICATIONS
Ivermectin and moxidectin do not normally cross the blood-brain barrier. Clinical signs of avermectin toxicity are possible if the blood-brain barrier has been significantly damaged by migrating parasites.

RECOMMENDED MONITORING
- Periodic repeat neurologic examinations to assess response to therapy
- Packed cell volume, total protein, blood urea nitrogen, and creatinine concentrations to monitor hydration and renal function with possible nephrotoxic drugs

PROGNOSIS AND OUTCOME
- The overall prognosis for complete recovery is guarded to poor. Most cases are rapidly progressive after clinical signs begin.
- Horses that are recumbent or unable to stand or support themselves in a sling for longer than 2 to 3 days are unlikely to recover.
- Horses that survive may have permanent neurologic deficits or scoliosis.

PEARLS & CONSIDERATIONS
COMMENTS
Cerebrospinal fluid pleocytosis and eosinophilia are reportedly inconsistent findings. However, CSF eosinophilia along with consistent clinical signs is strongly suggestive of cerebrospinal nematodiasis.

PREVENTION
- Ivermectin and moxidectin are highly effective against *S. vulgaris*.
- Regular deworming may reduce numbers of migrating larvae in the host, environmental exposure to parasite eggs, and overall parasite burden.
- Avoiding possible ingestion of terrestrial snails and slugs on pasture and grazing with white-tailed deer may decrease the risk of *P. tenuis* infection.
- Because most cases involve incidental infections or aberrant parasite migration, no preventive strategy is likely to be efficacious or beneficial.

AUTHOR: **BRYAN M. WALDRIDGE**

EDITOR: **STEPHEN M. REED**

Neonatal Colic

BASIC INFORMATION
DEFINITION
Colic is the descriptive term used for abdominal pain and can have many causes.

EPIDEMIOLOGY
SPECIES, AGE, SEX There is no gender predisposition for most forms of neonatal colic. Meconium impactions are suggested to occur more commonly in colts because of their smaller pelvic opening diameter.

GENETICS AND BREED PREDISPOSITION For most causes of neonatal colic, there is no genetic or breed predilection. Overo lethal white syndrome (OLWS) occurs in breeds that commonly carry the mutation, including American Paint Horses, Miniature Horses, Pintos, and less commonly Quarter Horses.

RISK FACTORS For colic caused by enteritis, unsanitary farm conditions and failure of passive transfer are contributory.

CONTAGION AND ZOONOSIS Infectious causes of enteritis include infection with *Salmonella* spp., *Campylobacter* spp., *Escherichia coli*, and *Clostridium* spp.

ASSOCIATED CONDITIONS AND DISORDERS Failure of passive transfer, peritonitis, pneumonia, enteritis

CLINICAL PRESENTATION
DISEASE FORMS/SUBTYPES Neonatal colic can be caused by congenital abnormalities for which there is no treatment (atresia coli, OLWS); medical causes such as enteritis and meconium impactions; and causes that require surgery such as small intestinal volvulus, hernias, and (rarely) meconium impactions refractory to medical treatment.

HISTORY, CHIEF COMPLAINT Failure to nurse, lethargy, recumbency, failure to pass feces, fever, rolling on back, abdominal distension

PHYSICAL EXAM FINDINGS Variable depending on condition and severity. Elevated (>100 beats/min) heart rate, reduced borborygmi, and abdominal bloating are common. If enteritis is a component of the colic episode, fever (>102° F), dehydration, and clinical signs of endotoxemia are present. Digital palpation may reveal meconium impactions or a lack of any fecal output (atresia coli, OLWS).

ETIOLOGY AND PATHOPHYSIOLOGY
- Atresia coli is the result of incomplete formation of the intestinal tract, but the cause is unknown.
- OLWS is caused by a genetic mutation resulting in abnormal autonomic innervation of the intestinal tract.
- Meconium impactions are caused by large amounts or very sticky and tenacious meconium.
- Enteritis often has an infectious component.

ElibVet.com

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Uroperitoneum
- Enteritis
- Sepsis

INITIAL DATABASE

- Complete blood count, serum chemistry, serum immunoglobulin G concentration
- Physical examination, including digital examination, enema, and nasogastric intubation
- Percutaneous abdominal ultrasonography

ADVANCED OR CONFIRMATORY TESTING

- Abdominal radiography, which may include positive contrast material
- Rectal endoscopy for suspected cases of atresia coli
- Abdominocentesis
- Exploratory laparotomy

TREATMENT

THERAPEUTIC GOAL(S)

- Determination of the cause of colic
- Alleviation of pain
- Surgical correction of the cause if necessary

ACUTE GENERAL TREATMENT

- Exploratory laparotomy if pain cannot be controlled
- Medical therapy for ileus and enteritis, including IV fluid therapy, feeding restrictions, and intestinal protectants

CHRONIC TREATMENT

Most neonatal colic episodes are acute and do not require long-term therapy. One exception is gastric ulcer syndrome, which is treated with drugs to increase gastric pH such as omeprazole and cimetidine. Sucralfate can also be used to provide local ulcer therapy.

POSSIBLE COMPLICATIONS

Abdominal adhesions may result from either medical or surgical colic treatment if there is sufficient peritoneal inflammation.

PROGNOSIS AND OUTCOME

For most neonatal colic (meconium impactions, gastric ulcers, and promptly treated surgical lesions), the prognosis is good to excellent. The prognosis worsens for severe enteritis and delayed surgical conditions, and is nonexistent for OLWS and atresia coli.

PEARLS & CONSIDERATIONS

COMMENTS

- Medical therapy is much preferred for meconium impactions because of the risk of small colon adhesions when treated surgically.
- Functional and mechanical ileus can be difficult to discriminate between, and early laparotomy is preferred if a mechanical cause is suspected.

PREVENTION

- Consumption of sufficient colostrum is important for its laxative effects and should be ensured.
- Avoiding breeding carriers of the mutation responsible for OLWS will eliminate this condition.
- Good management, including hygiene and isolation of potentially infectious animals, will reduce the incidence of infectious enteritis, which can lead to ileus, diarrhea, and small intestinal surgical lesions.

Neonatal Flexural Deformities

BASIC INFORMATION

DEFINITION

Neonatal flexural deformities are abnormalities of limb posture that result in abnormal extension or flexion of limbs. A rare, severe, and uniformly fatal condition known as arthrogryposis results in deformities in many joints of the axial as well as appendicular skeleton.

SYNONYM(S)

Contracted tendons, calf knees, arthrogryposis

EPIDEMIOLOGY

SPECIES, AGE, SEX Age: Congenital

RISK FACTORS

- Speculative risk factors: Lack of fetal movement or reduced uterine space (flexural) and prematurity or dysmaturity (extensor).
- For arthrogryposis, ingestion of toxic plants such as locoweed or hybrid Sudan grass. Congenital hypothyroidism due to ingestion of nitrates may also result in flexural deformities.

ASSOCIATED CONDITIONS AND DISORDERS

- Because congenital flexural deformities may result in dystocia, asphyxia and its systemic effects often occur after a difficult delivery. Failure of passive transfer may occur in foals having difficulty standing to nurse and may lead to septic complications.
- Strain or rupture of the extensor tendons at the carpus is common in foals with forelimb flexural deformities, and crushing of the tarsal bones is commonly associated in foals with hindlimb extension deformities.
- Radial nerve injury rarely occurs with forelimb flexural deformities and may be the result of dystocia.
- Foals with arthrogryposis often have multiple abnormalities and either are born dead or die soon after birth.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Arthrogryposis is a rare, severe, diffuse, and untreatable form of congenital flexural deformity and will not be further discussed here. Congenital hypothyroidism is discussed in "Hypothyroidism" in this section. More common flexural and extensor deformities generally occur in either the forelimbs or the hindlimbs and can be unilateral or more commonly bilateral.

ElibeVet.com

- Flexural deformities in the forelimb most commonly involve the carpus and result in flexion of all joints distal to the carpus. Flexural deformities in the hindlimb generally involve only the fetlock and exhibit coffin joint extension.
- A rare form of flexural deformity in the hindlimbs involves only the tarsus.
- Both forelimb and hindlimb flexural deformities vary in severity from mild deformities that do not hinder ambulation to severe deformities that cannot be corrected.
- Extensor deformities in the forelimb result in hyperextension of the carpus and distal joints and in the hindlimb result in hock and stifle flexion and digital extension.

HISTORY, CHIEF COMPLAINT Inability to stand, difficulty in ambulation, abnormal limb posture

PHYSICAL EXAM FINDINGS

- Flexural deformities: Inability to manipulate the limb into normal extension, swellings of the lateral digital extensor tendon sheath in the forelimbs
- Extensor deformities: Excessive extension of the joints, lack of tension in the palmar or plantar soft tissues, reduced gluteal muscle mass

ETIOLOGY AND PATHOPHYSIOLOGY

- Flexural deformities: Speculated to be a lack of fetal movement or reduced uterine space, restricting movement
- Extensor deformities: Speculated to be the result of relative immaturity of the musculoskeletal system

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Congenital neurologic conditions, including vertebral abnormalities
- Septicemia

INITIAL DATABASE

- Physical examination is sufficient to diagnose flexural and extensor deformities; however, a determination of the serum immunoglobulin G concentration is appropriate to ensure passive transfer of immunoglobulins.
- If prematurity or dysmaturity is suspected, dorsopalmar radiography of the carpi and lateral-medial radiography of the tarsi can ascertain cuboidal bone maturity.

TREATMENT

THERAPEUTIC GOAL(S)

- Flexural deformities
  - Relax the palmar or plantar soft tissues.
  - Properly align the limb to allow body weight to stretch the palmar or plantar soft tissues.
  - Provide analgesia to promote weight-bearing.
- Extensor deformities
  - Properly align hyperextended joints.
  - Allow exercise to strengthen tissues but not to cause damage.

ACUTE GENERAL TREATMENT

The severity of the deformity dictates the level of treatment.

- Flexural deformities
  - Mild: Limb posture abnormal but can bear weight without assistance; usually no definitive treatment is necessary. Exercise should be cautiously provided to avoid pain. Cautious use of nonsteroidal anti-inflammatory drugs (NSAIDs) may be beneficial. Firm support bandages can be used to extend and protect the dorsal surface of the fetlock.
  - Moderate: Cannot bear weight unassisted; limb cannot be manually straightened. Oxytetracycline (50 mg/kg IV q24h) and limb splints (12-h limit daily) to load palmar or plantar soft tissues. Phenylbutazone (2–4 mg/kg IV q24h) or flunixin meglumine (1 mg/kg IV q24h) for analgesia. Application of acrylic toe extensions may be used to extend the digit.
  - Severe: Carpal flexion angles of 90 degrees and fetlock joints with no range of motion, tarsal flexion. Treatment as indicated for moderate deformities can be attempted but is difficult to achieve and rarely successful. Surgery to cut palmar or plantar soft tissues can be attempted but is also often unsuccessful. Euthanasia for humane reasons is a realistic option for foals with severe flexural deformities.
- Extensor deformities
  - Mild: Hyperextension of the digit; usually self-limiting. Trimming of rounded heels, quarters, and bars may promote a flat foot placement. Exercise should be cautiously provided to avoid pain and direct trauma to the limb. A light bandage may be applied to the heel bulbs to limit abrasions.
  - Moderate: Fetlock dropped but pastern above horizontal. Similar therapy to the mild cases with the addition of heel extensions to promote flat foot placement and limit hyperextension of limb; especially important if the cuboidal bones are immature.
  - Severe: Fetlock palmar or plantar surface on the ground; carpal joints hyperextended. Some form of coaptation is necessary to avoid crushing of bones because of abnormal loading. Exercise is necessary to promote musculotendinous strength but can cause permanent skeletal deformities. These foals are very difficult to manage successfully, and euthanasia may be appropriate.

CHRONIC TREATMENT

- Most flexural and extensor deformities improve within 1 week, so long-term therapy is unnecessary. However, because these limbs are not normal even if they have assumed an apparently normal posture, exercise should be cautiously reintroduced to allow tissues to adapt. The horse should be kept in a large double stall for the first 10 days and then in a very small paddock or round pen for the next 10 days before free exercise is allowed.
- Foals with very active dams should initially have limited time in the pasture after free exercise commences.
- For neglected moderate flexural deformities of the forelimb fetlock, inferior check ligament desmotomy may be performed with reasonable success expectations.

POSSIBLE COMPLICATIONS

- Most complications are traumatic in nature and are related to abnormal limb loading, coaptation injuries, or overexercise.
- Injuries seen include proximal sesamoid fractures, extensor tendon ruptures, crushed tarsal bones, damage to heel bulbs, and cast or bandage sores.
- Septic complications occur secondary to failure of passive transfer caused by an inability to nurse. Gastric ulceration may be the result of stress or treatment with NSAIDs.

PROGNOSIS AND OUTCOME

- Foals with mild to moderate flexural and extensor deformities have an excellent prognosis if treated immediately.
- Foals with severe deformities have a guarded to poor prognosis depending on the severity of the deformity.

PEARLS & CONSIDERATIONS

- Foals have extremely thin skin and are very susceptible to sores from coaptation. Splints and casts should be cautiously applied and removed when any sign of discomfort

ElibEVet.com

referable to the coaptation is noted. When splints are used to provide strong posture correction, they should be placed on limbs for 12 hours and then removed for 12 hours.
- The dose of oxytetracycline used to relax the soft tissues is very high and may be contraindicated in foals with renal compromise. In normal foals, its use once daily has been safe and effective, and it may be used several days consecutively. Its use may result in excessive relaxation, so the position of all limbs should be monitored.

Adams SB, Santschi EM: Congenital equine flexural deformities. *Proc Am Assoc Equine Pract* 46:117–125, 2000.

AUTHOR: **ELIZABETH M. SANTSCHI**

EDITORS: **PHOEBE A. SMITH** and **ELIZABETH M. SANTSCHI**

Neonatal Isoerythrolysis

BASIC INFORMATION

DEFINITION

Hemolytic anemia of newborn foals caused by alloantibodies directed against the foal's red blood cells (RBCs).

SYNONYM(S)

- Jaundiced foal syndrome
- Isoimmune hemolytic anemia
- Alloimmune hemolytic anemia

EPIDEMIOLOGY

SPECIES, AGE, SEX Newborn foals are affected, with clinical signs appearing at 1 to 8 days.

GENETICS AND BREED PREDISPOSITION Any breed may be affected, but Thoroughbreds, Standardbreds, and American Paint Horses are overrepresented. There is a higher incidence in mule foals than in horse foals because of a unique blood group antigen called "donkey factor."

RISK FACTORS
- Dams previously administered blood transfusions or other equine biologic agents
- Mares are exposed to fetal RBCs with each pregnancy; thus multiparous mares produce foals at higher risk than primiparous mares.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES
- Subclinical
- Peracute

HISTORY, CHIEF COMPLAINT
- Foal normal at birth, stood and nursed, acute or insidious onset of weakness, tachypnea, icterus. Presentation of clinical signs typically occurs 2 to 5 days after birth.
- Peracute cases may collapse 8 to 36 hours after nursing.

PHYSICAL EXAM FINDINGS
- Weakness, lethargy, tachypnea, tachycardia, pale or icteric mucous membranes, pigmenturia, cardiovascular collapse.
- Fever is variable.
- Death may occur before icterus develops in peracute cases.
- Mild cases result in subclinical disease.

ETIOLOGY AND PATHOPHYSIOLOGY
- NI occurs when a fetus inherits the RBC antigens of the stallion and the mare is negative for these RBC antigens. She develops alloantibodies to the offending RBC antigen of the foal through exposure by prior pregnancy, blood transfusion, or transplacental contamination with fetal blood earlier in the current pregnancy. At birth, the foal ingests colostrum containing the alloantibodies. The alloantibodies then bind to the RBCs of the foal, resulting in agglutination, lysis, or both.
- The most common factors (antigens) involved in neonatal isoerythrolysis (NI) are Qa and Aa; mares without Qa and Aa factors are at an increased risk of producing NI-causing antibodies.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Disseminated intravascular coagulation
- Hemolysis secondary to septicemia
- Transfusion reaction

INITIAL DATABASE

- Packed cell volume (PCV) and total solids (TS): PCV will be low with normal total solids.
- Jaundiced foal agglutination (JFA) assay: Serial dilutions of the mare's colostrum are centrifuged in the presence of the foal's RBCs. A positive reaction is indicated by clumping of RBCs at the bottom of the tube at dilutions of 1:16 or greater.
- Lactate above 5 mmol/L; not specific for NI.

ADVANCED OR CONFIRMATORY TESTING

- Hemolytic cross-match test
- Coomb's test: Not specific for NI

TREATMENT

THERAPEUTIC GOAL(S)

- Prevent further ingestion of alloantibodies in colostrum in foals less than 18 hours of age.
- Maintain adequate oxygen-carrying RBC mass.

ACUTE GENERAL TREATMENT

- Mild cases (mild tachypnea, still nursing, and ambulatory): Muzzle if younger than 18 hours old and give alternate source of colostrum or plasma if IgG is below 400 mg/dL; monitor for increase in severity of clinical signs; minimize exercise and stress.
- Moderate (weak, tachycardic and tachypneic) and severe cases (recumbent): Blood transfusion is indicated. Twice-washed RBCs from the dam, a cross-matched donor whose RBCs do not react with the foal's serum, or a known Qa- and Aa-negative donor are ideal choices. If typed donors and cross-matching are not possible, the donors least likely to contain Aa and Qa antibodies are geldings of Standardbred, Quarter Horse, or Morgan breeds.
- The volume of blood needed for transfusion can be calculated as Body weight (kg) × 150 mL/kg × (PCV desired – PCV observed)/PCV of donor.
- Milk out the mare while the foal is muzzled to ensure colostrum is removed from the mammary gland and to maintain milk production.

POSSIBLE COMPLICATIONS

- Hypoxic-ischemic damage to organs
- Seizures in severe cases
- Kernicterus (deposition of unconjugated bilirubin and neuronal necrosis of certain areas of the brain)

RECOMMENDED MONITORING

Monitor affected foals closely during and after transfusion. Transfused RBCs remain

ElibeVet.com

in circulation for approximately 3 to 9 days, allowing for oxygen delivery until the bone marrow responds adequately.

PROGNOSIS AND OUTCOME

Prognosis depends largely on the quantity of alloantibodies absorbed, the affinity of the antibody for the RBC antigen, and the time before initiation of treatment. In uncomplicated cases, the prognosis is generally good. Survival rates have been reported as 73% for all NI cases.

PEARLS & CONSIDERATIONS

COMMENTS

- Relying on PCV to dictate necessity for transfusion is difficult because plasma volume affects PCV, and oxygen carrying-capacity may not be accurately reflected by this number. Clinical signs of hypoxemia are best used to determine the need for transfusion.
- In cases requiring muzzling of the foal, continue to strip out the dam's udder to encourage milk production.

PREVENTION

- Screen mares for RBC antibodies against the major blood group antigens.
- Crossmatch antibody screened mares with stallions.
- JFA test should be done before the foal nurses in matings of unknown blood types or in mares delivering NI foals previously.
- Muzzle a foal for 18 to 24 hours born to a dam known to produce NI foals and administer alternate colostrum source or feed milk from another dam and administer IV plasma to provide immunoglobulins.

SUGGESTED READING

Whiting JL, David JB: Neonatal isoerythrolysis. *Compend Contin Educ Pract Vet* 22:968, 2000.

AUTHOR: **PHOEBE A. SMITH**

EDITORS: **PHOEBE A. SMITH** and **ELIZABETH M. SANTSCHI**

Neonatal Sepsis

BASIC INFORMATION

DEFINITION

Systemic inflammatory response (SIRS) secondary to microbial invasion of the bloodstream

SYNONYM(S)

Septicemia, blood poisoning

RISK FACTORS

- Prenatal: Dystocia, premature placental separation, placentitis, colic, other maternal illness
- Postnatal: Umbilical, gastrointestinal (GI), or respiratory infection; environmental conditions; altered gestation length

ASSOCIATED CONDITIONS AND DISORDERS Septic shock, multiple organ dysfunction syndrome (MODS)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Lethargy, decreased or poor affinity for the dam, weak suckle reflex, decreased nursing

PHYSICAL EXAM FINDINGS

- Dehydration: Sunken eyes, tacky mucous membranes, sluggish jugular fill, cool extremities
- Lethargy, weakness
- Hypothermia or hyperthermia
- Tachycardia or tachypnea (absence of these does not rule out sepsis)
- Mucous membranes: Injected, hyperemic with bounding pulse (hyperdynamic phase); pale and slow capillary refill time with weak pulse (hypodynamic phase)
- Localized signs of infection may be present: Diarrhea, reflux, ileus, dyspnea, uveitis, seizures, joint effusion, edema overlying joint or physis, omphalophlebitis, patent urachus

ETIOLOGY AND PATHOPHYSIOLOGY

- Microbes invade the immunologically naïve foal via the respiratory, GI, umbilicus, or skin; gain access to the bloodstream; and cause the release of inflammatory mediators. These increase microvascular permeability, creating a reduced effective circulating volume.
- Hypotension results from reduced systemic vascular resistance and arterial and venous dilatation. Induction of excess nitric oxide via endogenous pathways is responsible for these changes.
- Stimulation of the coagulation cascade and reduction of endogenous anticoagulants such as protein C and antithrombin may occur, leading to coagulopathies.
- Progression of sepsis results in reduced tissue perfusion; decreased oxygen delivery to tissues; and, ultimately, MODS and possibly death.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hypoxic-ischemic encephalopathy, (also called neonatal maladjustment syndrome or dummy foal): Foals may appear weak and depressed with poor affinity for the dam with both hypoxic-ischemic encephalopathy and neonatal sepsis.

INITIAL DATABASE

- Complete blood count: Leukopenia or leukocytosis; leukopenia characterized by neutropenia is most common; left shift and toxic neutrophils are common; thrombocytopenia is common in early disseminated intravascular coagulation (DIC)
- Blood lactate: Elevated in hypoperfusion and in sepsis; normal lactate in a 1- to 2-day-old foal is 2 to 5 mmol/L
- Arterial blood gas: Acidemia (respiratory, metabolic, or mixed), hypoxemia (PaO_2 <80 mm Hg), severe hypoxemia (PaO_2 <60 mm Hg), and hypercapnia ($PaCO_2$ >65 mm Hg) indicate ventilatory insufficiency
- Blood glucose: Low because of a lack of intake and dysregulation in sepsis
- Serum chemistry panel: Azotemia, hyperbilirubinemia common
- Blood culture: Gold standard for definitive diagnosis of sepsis; results available in 48 to 72 hours; negative blood culture results do not rule out sepsis
- Sepsis score calculation: Developed to aid in predicting septicemia before return of blood culture results; compiled physical examination and laboratory data are used

ADVANCED OR CONFIRMATORY TESTING

- Indirect blood pressure: Low blood pressure occurs with septic shock (mean arterial pressure <65 mm Hg).
- Pulse oximetry (SpO_2): Estimates oxygen saturation (SpO_2 of 95% cor-

ElibeVet.com

relates with PaO_2 of 80 mm Hg, and SpO_2 of 80% correlates with PaO_2 of 39 mm Hg); hypoxemia is common.
- Central venous pressure (CVP): Provides an estimate of preload and right heart function; elevations occur with iatrogenic fluid overload and right heart failure; trends are more significant than absolute numbers; estimated normal CVP for neonatal foals is 3 to 12 cm H_2O.
- Urine output: An indicator of renal blood flow; urine production should be at least 66% of fluid intake; indwelling urinary catheters can be used in recumbent neonates.
- Urine specific gravity: Normal neonatal foal urine is hyposthenuric (<1.008); dehydration results in concentrated urine in functioning kidneys.
- Umbilical ultrasonography: To measure umbilical structures for evidence of infection and initially for baseline values
- Thoracic and abdominal ultrasonography: To investigate both cavities for evidence of infection (pneumonia, peritonitis)
- Body weight: Serial measurements (daily or twice daily) help to estimate fluid balance and nutritional status.

TREATMENT

THERAPEUTIC GOAL(S)

- Eradicate infection and prevent secondary localized infection (septic physitis, arthritis, pneumonia)
- Maintain organ perfusion
- Maintain adequate nutrition

ACUTE GENERAL TREATMENT

- Antibiotic therapy
  - Broad-spectrum coverage should be initiated in all septic foals; coverage can be altered if results of blood culture and sensitivity indicate.
  - Avoid aminoglycosides in azotemic foals (consider a cephalosporin in azotemic foals); the minimum course of therapy recommended is 2 weeks; if localized signs of infection occur, a minimum of 4 weeks therapy is recommended.
  - Gram-negative isolates are more common than gram-positive isolates; more gram-negative isolates in septic foals are sensitive to amikacin than to gentamicin. Common regimens include penicillin (potassium penicillin 22,000 IU/kg IV q6h) and amikacin (22–25 mg/kg IV q24h) or a third-generation cephalosporin (cefotaxime 40 mg/kg IV q6h) with or without amikacin. Fluoroquinolones are associated with arthropathies in foals and should be reserved for cases with documented resistance to other antimicrobial agents and with owner consent.
- Nutrition
  - If too weak to nurse effectively, feeding via an indwelling nasogastric tube is recommended provided the GI tract tolerates feeding. Close monitoring of tube position and checking for reflux are essential.
  - Begin feeding with small volumes of 100 mL of milk to ensure that feeding will be tolerated; increase the volume slowly to achieve 20% body weight per day (divided into hourly or every 2-hour feedings).
  - If greater than 6 to 10 mL of reflux present, do not feed and investigate GI tract ultrasonographically; foals not tolerating enteral feeding require parenteral nutrition.
- Cardiovascular support
  - Fluid therapy is critical in foals with dehydration, acid-base derangements, and hypotension; IV crystalloids (lactated Ringer's solution, Normosol) supplemented with 2.5% to 10% dextrose are commonly used for emergency resuscitation.
  - After normovolemia has been established, most foals require an average of 100 mL/kg/d of IV crystalloids to maintain adequate hydration.

POSSIBLE COMPLICATIONS

- Short term: Acute renal failure, DIC, acute respiratory distress syndrome, intractable hypotension leading to cardiac arrest
- Long term: Localization of bacteria to joint, physis, diaphysis, brain, lung, eye, or other organ

RECOMMENDED MONITORING

- Vital parameters every 2 to 4 hours
- Blood gases, lactate, electrolytes as needed
- Urine production
- Body weight
- Joints, eyes, limbs for evidence of localized infection

PROGNOSIS AND OUTCOME

- Short-term survival has been reported to be 35% to 72%.
- Development of septic arthritis or physitis reduces the prognosis for long-term survival and future athleticism but is a viable option for committed clients.

PEARLS & CONSIDERATIONS

COMMENTS

- Early diagnosis and aggressive therapy provide the best opportunity for survival.
- Treatment and monitoring are intensive, so referral to a 24-hour hospital is common.

PREVENTION

Diagnose and treat failure of passive transfer early. This does not ensure that sepsis will not occur, but it decreases the likelihood.

SUGGESTED READING

Corley KTT: Evaluation of a score used to predict sepsis in foals. *J Vet Emerg Crit Care* 21:2, 2005.

Sanchez C: Neonatal sepsis. In Sanchez C (ed). *Neonatal medicine and surgery*, Philadelphia, 2005, Saunders Elsevier, pp 273–294.

AUTHOR: **PHOEBE A. SMITH**

EDITORS: **ELIZABETH M. SANTSCHI** and **PHOEBE A. SMITH**

ElibeVet.com

Neonatal Septic Arthritis and Osteomyelitis

BASIC INFORMATION

DEFINITION

Orthopedic infection in neonates caused by hematogenous delivery of bacteria to joints and growth centers

SYNONYM(S)

Navel ill

EPIDEMIOLOGY

RISK FACTORS Failure of passive transfer; other septic processes, including septicemia, pneumonia, gastroenteritis, and omphalophlebitis

CONTAGION AND ZOONOSIS Enteritis from infectious causes such as *Salmonella* spp., rotavirus, and *Clostridium difficile*

ASSOCIATED CONDITIONS AND DISORDERS Failure of passive transfer; other septic processes, including septicemia, pneumonia, gastroenteritis, and omphalophlebitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Osteomyelitis has been classified by location, but these descriptive classifications are only relevant to treatment and outcome when discriminating between articular and nonarticular infections.

HISTORY, CHIEF COMPLAINT The foal's history may include dystocia, failure of passive transfer, and diarrhea. The chief complaint is usually lameness but may be stiffness, swollen joints, or recumbency.

PHYSICAL EXAM FINDINGS Lameness, limb swelling (especially around growth plates), joint effusion

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacteria cause the infections and reach the musculoskeletal system because of a failure of normal barriers to infection such as mucosal barriers and the immune system.
- Most commonly, bacteria causing orthopedic infection are gram negative, but gram-positive and mixed infections do occur. Anaerobic bacteria are uncommon. Cultures of synovial fluid and affected bone should be performed to identify the organism(s) involved.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Immune-mediated synovitis

INITIAL DATABASE

- Complete blood count, serum chemistry, and immunoglobulin G concentration
- Radiography may be useful in determining if bone infection exists, but it takes several days after infection to show definitive radiographic changes.
- Cytologic examination of joint fluid can confirm if infection is present.
- Blood cell counts greater than 10,000 white blood cells/dL that are predominantly polymorphonuclear leukocytes indicate infection is likely.

ADVANCED OR CONFIRMATORY TESTING

- Aerobic and anaerobic bacterial culture of joint fluid, blood, or physeal aspirate may reveal causative bacteria.
- Cross-sectional imaging modalities such as computed tomography and magnetic resonance imaging may reveal bone destruction before it is radiographically apparent.

TREATMENT

THERAPEUTIC GOAL(S)

Immediate elimination of the causative organism to limit damage to critical structures

ACUTE GENERAL TREATMENT

- Administration of supplemental IV plasma to deliver immunoglobulins, complement, and other beneficial factors
- IV administration of broad-spectrum bactericidal antimicrobials
- Physical removal of bacteria and products of inflammation in joints and growth plates
- Regional treatment (intraarticular injection, regional IV perfusion, intralesional injection) of infected foci with antimicrobial drugs if possible

CHRONIC TREATMENT

- Implantation of beads containing antimicrobials
- Long-term (≥4 weeks) administration of oral antimicrobial agents

POSSIBLE COMPLICATIONS

The greatest complication is damage to structures critical to ambulation such as articular cartilage, subchondral bone, tendons, and tendon sheaths.

PROGNOSIS AND OUTCOME

- Prognosis for performance is good for infections successfully treated before damage to cartilage and subchondral bone occurs.
- Prognosis is worse when several locations are involved and when any joint surface is degraded.

PEARLS & CONSIDERATIONS

COMMENTS

- Aggressive therapy is indicated as soon as septic arthritis is suspected and at a minimum includes joint lavage and systemic antimicrobial therapy.
- Local therapy with antimicrobials should also be considered and may be delivered by intraarticular injection, regional IV perfusion, local injection, or implantation of antimicrobial-containing beads.

CLIENT EDUCATION

- Ensuring passive transfer of immunoglobulins and clean husbandry are important.
- Early identification of lameness is critical if infection occurs.

ElibeVet.com

Neoplasia, Abdominal

BASIC INFORMATION

DEFINITION

Neoplasia of the abdominal (peritoneal) cavity

EPIDEMIOLOGY

SPECIES, AGE, SEX More likely in older horses

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Typical signs associated with abdominal neoplasia include:

- Chronic weight loss
- Poor appetite
- Abdominal discomfort; chronic or recurrent colic
- Lethargy and exercise intolerance
- Ascites or edema may occur in some cases

Acute colic caused by intestinal strangulation may occur with mesenteric lipomas, which are frequently pedunculated.

PHYSICAL EXAM FINDINGS

- The physical examination findings confirm the presenting signs, which are weight loss with or without signs of abdominal pain. Persistent or intermittent pyrexia may occur with advanced neoplasia.
- Physical examination of the horse is often unrewarding but is essential, together with a thorough history, to eliminate other more common causes of weight loss such as:
  - Inadequate or unsuitable feeding
  - Dental or swallowing disorders
  - Excessive exercise or energy demands
  - Parasitism

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common neoplasm of the abdominal cavity is mesenteric lipoma, which is common in older horses and especially ponies (>15 years). However, it is often clinically insignificant. When significant, the lipoma may produce signs only related to its physical properties, namely as a space-occupying mass causing a simple intestinal obstruction (caused by compression of the intestine), or more commonly as a pedunculated mass causing an acute strangulating intestinal obstruction.
- Other primary tumors originating in the peritoneal cavity are rare. Mesothelioma is a rare tumor of the mesothelial surfaces. It is most commonly reported in the thoracic cavity, although there have been a few reported cases in which the tumor appeared to develop within the peritoneal cavity.
- There have been isolated reports of omental leiomyoma and mesenteric myofibroblastoma in horses.
- Many other tumors may metastasize to the abdominal cavity. These include lymphoma (lymphosarcoma), squamous cell carcinoma, leiomyoma or leiomyosarcoma (gastrointestinal stromal tumors), adenocarcinoma, melanoma, testicular seminoma, teratoma, transitional cell carcinoma, hepatoblastoma, adrenocortical carcinoma, metastatic granulosa cell tumor, myxosarcoma, and hemangiosarcoma.
- Pheochromocytoma has been associated with acute colic in a small number of horses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of chronic weight loss and chronic or recurrent colic

INITIAL DATABASE

- The diagnostic evaluation should consist of a complete physical examination, including rectal examination, routine bloodwork (complete blood count, serum chemistry panel), urinalysis, and peritoneal fluid analysis.
- Many horses with abdominal neoplasia have anemia (as a result of chronic disease or blood loss), leukocytosis (as a result of chronic inflammation), and hyperfibrinogenemia. In a small number of cases of lymphoma, abnormal lymphocytes may be present in the peripheral blood.
- Immune-mediated anemia or thrombocytopenia may occur secondary to neoplasia, especially lymphoma.
- Some affected horses have hypoalbuminemia and hypoproteinemia caused by malabsorption, bowel inflammation, and protein exudation, but other horses have hyperglobulinemia (as a result of chronic inflammation).
- Increased concentrations of the intestinal fraction of the alkaline phosphatase enzyme (IAP) may also indicate the presence of intestinal disease.
- Hypercalcemia has been reported in association with both lymphoma and gastric carcinoma.
- Rectal examination is essential in the investigation of any horse with suspected abdominal neoplasia. Although normal findings may be present in many animals, an increased volume of peritoneal fluid, distension of the intestine, or an abnormal tissue mass or masses increase the index of suspicion of abdominal neoplasia and allow further directed investigations to be selected.
- Peritoneal fluid varies from normal to an exudate. Neoplastic cells from a primary abdominal neoplasm (eg, mesothelioma or lymphoma) are occasionally observed in a sample of peritoneal fluid. In one study comparing the diagnostic features of cases of abdominal neoplasia and abdominal abscesses, peritoneal fluid was classified as an exudate in 12 of 15 horses with intraabdominal abscesses and 14 of 25 horses with intraabdominal neoplasms. Cytologic examination of peritoneal fluid yielded an accurate diagnosis in 11 of 25 horses with neoplasia and in three of 15 horses with abscesses. A mean number of 1.45 cytologic analyses per horse was needed to diagnose neoplasms in the 11 horses in which the analysis was successful in definitively diagnosing the condition.
- In some cases, peritoneal fluid is serosanguineous or frankly hemorrhagic.
- In cases of malignant melanoma of the peritoneal cavity, the peritoneal fluid may be discolored black.
- Neoplastic cells may also be identified in samples of pleural fluid if a pleural effusion is present.
- Pheochromocytoma should be considered in older horses with signs of abdominal pain, sweating, muscle fasciculations, ataxia, azotemia, and intraperitoneal hemorrhage. Identification by per rectum palpation of retroperitoneal swelling in the dorsal aspect of the abdomen also should alert the diagnostician to the possibility of a ruptured pheochromocytoma.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography, laparoscopy, and laparotomy may be used to further evaluate the patient.
- Percutaneous or per rectum ultrasonography may provide information about the volume and character of the peritoneal fluid. Intestinal distension may be recognized together with abnormal bowel wall thickening and abnormal tissue masses. Ultrasonography also allows guided collection of fluid or tissue samples for further evaluation.

ElibeVet.com

FIGURE 1 Mesenteric carcinoma identified at exploratory laparotomy.

FIGURE 2 Mesenteric lymphoma masses identified at postmortem examination.

- Laparoscopy or exploratory laparotomy may be used to identify and biopsy tumor deposits in the abdominal cavity.
- Pleuroscopy (thoracoscopy) allows examination of the thoracic cavity in cases with evidence of spread of tumor to the thorax.
- Serum immunoglobulin (Ig) M is low in some cases of lymphoma; some also have low IgG and IgA levels.

TREATMENT

THERAPEUTIC GOAL(S)

- Surgical excision of the neoplastic mass if possible
- Chemotherapeutic treatment of the neoplasia if possible

ACUTE GENERAL TREATMENT

- Early surgical removal of mesenteric lipomas causing intestinal obstruction is frequently successful.
- Systemic corticosteroids, although not curative, may have a short-term beneficial effect on horses with lymphoma and may help treat secondary immune-mediated anemia and thrombocytopenia that may occur in association with lymphoma.

ElibeVet.com

- Surgical removal of solitary neoplastic masses can be curative. Care should be taken that all the neoplastic tissue is removed during surgery, but this may be difficult because the limits of the neoplastic tissue may not be grossly visible.

CHRONIC TREATMENT

The systemic use of antineoplastic agents for the treatment of abdominal tumors in horses has received little attention and has unproven long-term efficacy. However, multiple drug protocols are available for palliative chemotherapy of multicentric lymphoma.

- The following is a suggested multiple agent induction protocol for horses with lymphoma:
  - Cytosine arabinoside: 200 to 300 mg/m^2 SC or IM once every 1 to 2 weeks
  - Chlorambucil: 20 mg/m^2 PO once every 2 weeks
  - Prednisone: 1.1 to 2.32 mg/kg PO every other day
- Alternatively, 200 mg/m^2 IV cyclophosphamide once every 2 to 3 weeks may be substituted for chlorambucil. Antineoplastic agents are typically given on alternating weeks but have been given on the same day without apparent ill effects. A response to this induction therapy should occur within 2 to 4 weeks. If no response is observed, adding vincristine (0.5 mg/m^2 IV once a week) has been recommended.
- Horses in remission should be maintained on the induction protocol for a total of 2 to 3 months before being switched to a maintenance protocol. The first cycle of maintenance therapy increases the treatment interval for each antineoplastic agent by 1 week. Prednisone is continued for the duration of therapy (but may be gradually reduced in dose). If the horse remains in remission after 2 to 3 months on the first cycle, the second cycle is begun by adding 1 more week to the treatment intervals of each agent. Several cycles of maintenance therapy may be given. Signs of toxicity, including bone marrow suppression and gastrointestinal irritation, have been rarely recognized using this protocol.
- Other protocols include:
  - Single-agent L-asparaginase: 10,000 to 40,000 IU/ m^2 IM once every 2 to 3 weeks
  - Single-agent cyclophosphamide: given as described above
  - Combinations of either cytosine arabinoside or cyclophosphamide with prednisone

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of pain, dehydration, and weight loss.

PROGNOSIS AND OUTCOME

- In most cases, the prognosis is poor.
- If a focal neoplasm that is amenable to surgical excision is present, then curative treatment may be possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Abdominal neoplasia should be considered in all horses demonstrating signs of weight loss and chronic or recurrent colic.
- In all cases of neoplasia, the quality of life, economic issues, prognosis, and owner expectations must be carefully considered and discussed before any treatment is attempted.

Neoplasia, Esophageal

BASIC INFORMATION

DEFINITION

Neoplasia of the esophagus

EPIDEMIOLOGY

SPECIES, AGE, SEX More likely in older horses

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of recurrent esophageal obstruction.
- Weight loss.
- Inappetence or anorexia may be present in advanced cases.
- Recurrent colic (often associated with feeding) may be seen in some cases, especially if the patient has neoplastic involvement of the stomach as well as the esophagus.
- There may be a fetid odor around the mouth or nares.

PHYSICAL EXAM FINDINGS

- The findings on physical examination confirm the presenting signs, which include repeated bouts of esophageal dysphagia, hypersalivation, nasal discharge of saliva and food, retching, and bruxism.
- Persistent or intermittent pyrexia may occur with advanced neoplasia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Squamous cell carcinoma is the most commonly reported neoplasm affecting the esophagus. In addition, extension of gastric squamous cell carcinoma into the distal esophagus may occur.
- In one reported case, squamous cell carcinoma developed within an esophageal diverticulum.

ElibVet.com

- Leiomyosarcoma has also been reported in association with gastric neoplasia.
- Exuberant granulation tissue in the esophagus without evidence of neoplasia has been reported in one horse.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition), including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophageal stricture, intramural esophageal cysts, esophageal rupture, and equine grass sickness.

INITIAL DATABASE

- The leukogram and hematology results are likely to be normal unless there is dehydration from chronic esophagitis or changes secondary to neoplasia elsewhere.
- Esophagoscopy reveals a mass obstructing the esophageal lumen. Biopsy of the mass may be possible via the endoscope. Squamous cell carcinoma typically has an ulcerated, cobblestone, or florid appearance.
- Contrast (or double-contrast) radiography is useful to confirm the position and extent of a filling defect in the esophagus.
- Gastroscopy, thoracic radiography, and a complete physical examination should be performed to identify the presence of neoplasia in other sites.

ADVANCED OR CONFIRMATORY TESTING

Pleuroscopy (thoracoscopy) allows examination of the thoracic portion of the esophagus and may permit surgical biopsy of esophageal tumors located in this region.

TREATMENT

THERAPEUTIC GOAL(S)

- Surgical excision of the neoplastic mass if possible
- Chemotherapeutic treatment of the neoplasia if possible

ACUTE GENERAL TREATMENT

- Transendoscopic excision and ablation of granulation tissue in the esophagus using a neodymium: yttrium-aluminum-garnet laser has been described. A similar treatment modality may be applicable to focal neoplasms in the esophagus.
- There have been no reports of chemotherapy or radiotherapy for the treatment of esophageal neoplasia, although these forms of treatment could be considered in appropriate cases.

CHRONIC TREATMENT

- Frequent small meals of moistened pellets or fresh grass should be fed.
- Piroxicam (0.2 mg/kg PO q24h) for squamous cell carcinoma.

POSSIBLE COMPLICATIONS

Complications include esophageal stricture and esophageal impaction.

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of dehydration and weight loss.

PROGNOSIS AND OUTCOME

- In most cases, the prognosis is poor.
- If a focal neoplasm that is amenable to laser ablation is present, then curative treatment may be possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Esophageal neoplasia is rare but should be considered in horses presenting with recurrent esophageal obstruction.
- In all cases of neoplasia, the quality of life, economic issues, prognosis, and owner expectations must be carefully considered and discussed before any treatment is attempted.

AUTHOR & EDITOR: **TIM MAIR**

Neoplasia, Gastric

BASIC INFORMATION

DEFINITION

Neoplasia of the stomach

EPIDEMIOLOGY

SPECIES, AGE, SEX More likely in older horses

RISK FACTORS Because gastric neoplasias are so uncommon in horses, contributing factors are not known.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Typical signs associated with gastric squamous cell carcinoma include:

- Chronic weight loss
- Poor appetite
- Abdominal discomfort
- Lethargy
- Ascites or edema may occur in some cases. If the esophagus is involved, dysphagia or ptyalism will be the predominant sign. Gastric squamous cell carcinoma involving the cardia may also result in dysphagia. Involvement at other sites in the stomach may result in signs of obstruction to outflow (colic) or weight loss.
- In some cases, tachypnea is a prominent sign, either because of metastasis to the thoracic cavity or pressure on the diaphragm from the tumor.

ElibeVet.com

- Recurrent colic, especially colic associated with feeding, may occur.

PHYSICAL EXAM FINDINGS The findings of physical examination confirm the presenting signs, which include weight loss with or without signs of esophageal dysphagia. Persistent or intermittent pyrexia may occur with advanced neoplasia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Squamous cell carcinoma is the most commonly reported neoplasm affecting the stomach.
- The rate of growth and aggressiveness of gastric squamous cell carcinoma in horses is variable. In some horses, the tumor remains localized within the stomach, but in others, the tumors may extend through the stomach wall and spread to other abdominal viscera or metastasize to other locations in the body.
- Leiomyosarcoma (gastrointestinal stromal tumors), adenocarcinoma, and lymphoma have also been reported in the equine stomach in many cases in association with neoplasia elsewhere in the body.
- Amyloid deposition in the stomach wall has been recorded secondary to myeloma (in association with amyloid deposition in other organs).
- Gastric hyperplastic polyp has been recorded in one horse.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of dysphagia (especially abnormalities of the pharyngeal and esophageal phases of deglutition), including pharyngeal paralysis, pharyngeal cysts, pharyngeal compression by strangles abscesses and guttural pouch empyema, subepiglottic cyst, fourth branchial arch defect, esophageal obstruction, megaesophagus, esophageal stricture, intramural esophageal cysts, esophageal rupture, and equine grass sickness.
- Other causes of chronic weight loss.
- Other causes of recurrent colic.

INITIAL DATABASE

- The diagnostic evaluation should consist of a complete physical examination, including rectal examination, routine blood work (complete blood count, serum chemistry panel), urinalysis, and peritoneal fluid analysis.
- Many horses with squamous cell carcinoma have anemia, leukocytosis, and hyperfibrinogenemia. Some have hypoproteinemia because of bowel inflammation and protein exudation; other horses have hyperglobulinemia.
- Gastroscopy reveals a mass within the stomach protruding from the mucosa. Biopsy of the mass may be possible via the endoscope. Squamous cell carcinoma originates from the squamous mucosa and typically has the appearance of an ulcerated, cobblestone, or florid mass.
- Peritoneal fluid varies from normal, if the tumor is confined within the stomach, to an exudate if the tumor has spread. Neoplastic cells from a primary gastric squamous cell carcinoma are occasionally observed in a sample of peritoneal fluid and are large, poorly differentiated epithelial cells with a bluish, ground-glass–appearing cytoplasm (Wright's stain).
- Neoplastic cells may also be identified in samples of pleural fluid if a pleural effusion is present.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography, laparoscopy, and laparotomy may be used to further evaluate the patient.
- Abdominal ultrasonography (transcutaneous) may be used to determine whether there is excessive abdominal fluid and possibly to identify a mass associated with the stomach wall. Occasionally, gastric squamous cell carcinoma will metastasize to the spleen or liver, which may be seen by ultrasonography.
- Laparoscopy or exploratory laparotomy may be used to identify and biopsy tumor deposits in the abdominal cavity.
- If gastric squamous cell carcinoma is suspected, cytology of aspirated stomach contents may reveal large, poorly differentiated squamous carcinoma cells.
- Pleuroscopy (thoracoscopy) allows examination of the thoracic portion of the esophagus and may permit surgical biopsy of esophageal tumors located in this region.

TREATMENT

THERAPEUTIC GOAL(S)

- Surgical excision of the neoplastic mass if possible
- Chemotherapeutic treatment of the neoplasia if possible

ACUTE GENERAL TREATMENT

- Transendoscopic excision and ablation of small focal neoplastic masses in the stomach may be possible; however, in most cases, the tumor will be too large or extensive by the time the diagnosis is reached.
- There have been no reports of chemotherapy for treatment of gastric neoplasia, although this form of treatment could be considered in appropriate cases.
- Intralesional injection of cisplatin can be successful for cutaneous squamous cell carcinoma and could be done through an endoscope to treat gastric squamous cell carcinoma.

CHRONIC TREATMENT

- Frequent small meals of moistened pellets or fresh grass should be fed.
- Piroxicam (0.2 mg/kg PO q24h) for squamous cell carcinoma.

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of dehydration and weight loss.

PROGNOSIS AND OUTCOME

- In most cases, the prognosis is poor.
- If a focal neoplasm amenable to laser ablation is present, then curative treatment may be possible.

PEARLS & CONSIDERATIONS

- Gastric squamous cell carcinoma and other forms of gastric neoplasia are rare, and by the time disease is recognized, treatment is rarely possible.
- In all cases of neoplasia, the quality of life, economic issues, prognosis, and owner expectations must be carefully considered and discussed before any treatment is attempted.

AUTHOR & EDITOR: **TIM MAIR**

Neoplasia, Hepatic

BASIC INFORMATION

DEFINITION

The liver may be affected by primary hepatic or metastatic neoplasms.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Hepatic neoplasia has been recorded in a number of breeds, and there does not appear to be a gender predisposition.
- Hepatocellular carcinomas and hepatoblastomas affect animals younger than 3 years of age.
- Cholangiocarcinomas occur more commonly in older horses.

RISK FACTORS Hepatic neoplasia is rare in horses.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Primary hepatic neoplasms that have been reported in horses include cholangiocarcinoma, hepatocellular carcinoma, and hepatoblastoma. Of these, cholangiocarcinoma is the most common. Lymphomas and other tumor types may occasionally metastasize to the liver.

HISTORY, CHIEF COMPLAINT Presenting complaints commonly include weight loss and inappetence. Depression, lethargy, intermittent fever, and mild signs of colic are frequently reported historically.

PHYSICAL EXAM FINDINGS

- Clinical signs are typically nonspecific and rarely evident until tumor growth is advanced.
- Findings on physical examination often include poor body condition, depression, weakness, and fever.
- Mild intermittent signs of abdominal discomfort are commonly reported, and young animals may present with abdominal distension.
- Horses with severe liver dysfunction may demonstrate signs of hepatic encephalopathy.
- In some cases of hepatic neoplasia, horses present with signs suggestive of thoracic disease as a result of pulmonary metastases or pleural effusion, which may occur in the absence of metastatic lung disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Predisposing factors or conditions causing hepatic neoplasia in horses are unknown and remain speculative in light of the low number of cases.
- Colic may be caused by distension of the hepatic capsule or indicate a primary gastrointestinal neoplasia with hepatic metastases.
- Pleural effusion may occur as a consequence of direct pulmonary involvement (ie, metastasis). Other suggested mechanisms include lymphatic obstruction, increased venous hydrostatic pressure, and erythrocytosis.
- Erythrocytosis is well documented in some horses with liver disease and neoplasia. The mechanism is unknown; extramedullary hemopoiesis and tumor production of erythropoietin (or an erythropoietin-like substance) has been suggested.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- The differential list for hepatic neoplasia should include more common causes of chronic liver disease, weight loss, and chronic low-grade colic.
- Causes of pleuropneumonia should be included in the differential list for horses presenting with signs of respiratory disease.

INITIAL DATABASE

- Complete blood count: Normal to anemia of chronic disease and leukocytosis
- Fibrinogen concentration: Normal to increased
- Hepatic specific enzymes: May be normal to mildly increased
- Serum bile acid concentration: May be normal to mildly increased
- Abdominocentesis indicated in horses with signs of colic or excessive peritoneal fluid

ADVANCED OR CONFIRMATORY TESTING

- Peritoneal or pleural effusions may occasionally reveal neoplastic cells, confirming the diagnosis.
- Ultrasonographic examination of the liver may support a diagnosis of neoplasia.
- Definitive diagnosis requires histopathologic examination of biopsy samples.

TREATMENT

THERAPEUTIC GOAL(S)

Unfortunately, tumor growth is usually advanced at the time of diagnosis, and treatment is palliative at best. Chemotherapeutic regimens for some neoplastic conditions have been described for horses, but there is little evidence of their efficacy, and expense precludes their use in many cases.

ACUTE GENERAL TREATMENT

- Supportive, symptomatic therapy may be required in some cases to allow definitive antemortem diagnosis.
- Hypoglycemia should be treated with IV dextrose administration.

PROGNOSIS AND OUTCOME

Prognosis is uniformly poor for most neoplastic conditions in horses.

PEARLS & CONSIDERATIONS

Because hepatic neoplasia is rare, diagnostic efforts are often directed elsewhere initially. It is not uncommon to make a final diagnosis at postmortem.

AUTHOR: **BRETT TENNENT-BROWN**

EDITOR: **MICHELLE HENRY BARTON**

Neoplasia, Intestinal

BASIC INFORMATION

DEFINITION

Neoplasia of the intestine

EPIDEMIOLOGY

SPECIES, AGE, SEX More common in older horses

RISK FACTORS Contributing factors are not known. Previous reports of equine pathology studies suggest an estimated incidence of gastrointestinal (GI) neoplasia of less than 0.1% in routine postmortem examinations and about 5% of horses with clinical signs of abdominal disease (excluding mesenteric lipoma).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Typical signs associated with intestinal neoplasia include:
  - Chronic weight loss
  - Poor appetite
  - Abdominal discomfort or recurrent colic
  - Lethargy and exercise intolerance
  - Ascites or edema in some cases
  - Diarrhea in some cases
- Acute colic caused by intestinal strangulation may occur with mesenteric lipomas, which are frequently pedunculated. Other solitary neoplasms may initiate intestinal intussusception, with the development of acute colic.

PHYSICAL EXAM FINDINGS

- The findings of physical examination confirm the presenting signs, including weight loss with or without signs of abdominal pain and diarrhea. Persistent or intermittent pyrexia may occur with advanced neoplasia.
- Physical examination of the horse is often unrewarding but is essential, together with a thorough history, to eliminate other more common causes of weight loss such as:
  - Inadequate or unsuitable feeding
  - Dental or swallowing disorders
  - Excessive exercise or energy demands
  - Parasitism

ETIOLOGY AND PATHOPHYSIOLOGY

- Intestinal neoplasms are usually classified according to their cell type and site of origin. Primary neoplasms are most common, although metastases to the intestine from other sites may also occur.
- The most common neoplasm of the intestinal tract is the mesenteric lipoma, which is common in older horses and especially ponies (>15 years). However, it is often clinically insignificant. When significant, the lipoma may produce signs only related to its physical properties, namely as a space-occupying mass causing a simple intestinal obstruction (caused by compression of the intestine) or more commonly as a pedunculated mass causing an acute strangulating intestinal obstruction.
- Excluding lipomas, lymphoma (lymphosarcoma), leiomyoma and leiomyosarcoma (GI stromal tumors), and adenocarcinoma are the most commonly reported neoplasms affecting the GI tract.
- Lymphoma may affect any age of horse, not infrequently young adults.
- Lymphoma may take the form of discrete masses affecting the intestine and its associated mesentery (usually associated with signs of recurrent colic), or a diffuse infiltrate in the intestinal wall (especially the small intestine), resulting in progressive weight loss associated with malabsorption syndrome. There may be diarrhea if the tumor infiltrates the large intestine wall.
- Amyloid deposition in the intestinal wall has been recorded secondary to myeloma (in association with amyloid deposition in other organs).
- Occasionally, inflammatory hyperplastic polyps cause signs similar to those of neoplasms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of chronic weight loss, chronic or recurrent colic, or diarrhea

INITIAL DATABASE

- The diagnostic evaluation should consist of a complete physical examination, including rectal examination, routine blood work (complete blood count, serum chemistry panel), urinalysis, and peritoneal fluid analysis.
- Many horses with intestinal neoplasia have anemia (as a result of chronic disease or blood loss), leukocytosis (as a result of chronic inflammation), and hyperfibrinogenemia. In cases of intestinal lymphoma, rarely abnormal lymphocytes may be present in the peripheral blood.
- Immune-mediated anemia or thrombocytopenia may occur secondary to intestinal neoplasia, especially lymphoma.
- Some affected horses have hypoalbuminemia and hypoproteinemia because of malabsorption, bowel inflammation, and protein exudation; other horses have hyperglobulinemia (as a result of chronic inflammation).
- Increased concentrations of the intestinal fraction of the alkaline phosphatase enzyme (IAP) may also indicate the presence of intestinal disease.
- Hypercalcemia has been reported in association with both lymphoma and gastric carcinoma.
- Gastroscopy and duodenoscopy may reveal a mass or masses within the stomach or duodenum only if the neoplasms have involved that region of the GI tact. Biopsy of the mass may be possible via the endoscope.
- Rectal examination is essential in the investigation of any case with suspected GI neoplasia. Although normal findings may be present in many animals, an increased volume of peritoneal fluid, distension of the intestine, or an abnormal tissue mass or masses increase the index of suspicion of intestinal disease and allow further directed investigations to be selected.
- Peritoneal fluid varies from normal, if the tumor is confined to the intestinal wall, to an exudate if the tumor has spread. Neoplastic cells from a primary intestinal neoplasm (eg, lymphoma) are occasionally observed in a sample of peritoneal fluid.
- Neoplastic cells may also be identified in samples of pleural fluid if pleural effusion is present.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography, laparoscopy, and laparotomy may be used to further evaluate the patient.

ElibeVet.com

- Percutaneous or per rectum ultrasonography may provide information about the volume and character of the peritoneal fluid. Intestinal distension may be recognized together with abnormal bowel wall thickening and abnormal tissue masses. Ultrasonography also allows guided collection of fluid or tissue samples for further evaluation.
- Laparoscopy or exploratory laparotomy may be used to identify and biopsy tumor deposits in the abdominal cavity. Full-thickness bowel wall biopsies may be necessary to diagnose diffuse alimentary lymphoma. (The intestine may look grossly normal with lymphoma infiltration.)
- Pleuroscopy (thoracoscopy) allows examination of the thoracic cavity when there is evidence of tumor spread to the thorax.
- Glucose or xylose absorption tests are useful to demonstrate a state of malabsorption from the small intestine, which may occur with a diffuse intestinal lymphoma. Although not diagnostic, a reduced sugar uptake curve is highly suggestive of an infiltrative condition of the small intestine.
- Histopathologic examination of a rectal biopsy may be helpful if the horse has diarrhea.
- Serum immunoglobulin M (IgM) is low in some cases of lymphoma; some also have low IgG and IgA levels.

TREATMENT

THERAPEUTIC GOAL(S)

- Surgical excision of the neoplastic mass if possible
- Chemotherapeutic treatment of the neoplasia if possible

ACUTE GENERAL TREATMENT

- Early surgical removal of mesenteric lipomas that are causing intestinal obstruction is frequently successful.
- Systemic corticosteroids, although not curative, may have a short-term beneficial effect in horses with intestinal lymphoma, and these drugs may help to treat secondary immune-mediated anemia and thrombocytopenia that may occur in association with lymphoma.
- Surgical treatment by removal of solitary lymphoma, adenocarcinoma, leiomyoma or sarcoma, and neurofibroma may be curative. Care should be taken that all neoplastic tissue is removed during surgery, but this may be difficult, especially in horses with lymphoma, in which the limits of the neoplastic tissue may not be grossly visible.

CHRONIC TREATMENT

- The systemic use of antineoplastic agents for the treatment of GI tumors in horses has received little attention and has unproven long-term efficacy. However, multiple drug protocols are available for palliative chemotherapy of multicentric lymphoma. The following is a suggested multiple-agent induction protocol for horses with lymphoma.
  - Cytosine arabinoside: 200 to 300 mg/m^2 SC or IM once every 1 to 2 weeks
  - Chlorambucil: 20 mg/m^2 PO once every 2 weeks
  - Prednisone: 1.1 to 2.32 mg/kg PO every other day
- Alternatively, cyclophosphamide 200 mg/m^2 IV once every 2 to 3 weeks can be substituted for chlorambucil. Antineoplastic agents are typically given on alternating weeks but have been given on the same day without apparent ill effects. A response to this induction therapy should occur within 2 to 4 weeks. If no response is observed, adding vincristine (0.5 mg/m^2 IV once a week) has been recommended.
- Horses in remission should be maintained on the induction protocol for 2 to 3 months before switching to a maintenance protocol. The first cycle of maintenance therapy increases the treatment interval for each antineoplastic agent by 1 week. Prednisone is continued for the duration of therapy (but can be gradually reduced in dose). If the horse remains in remission after 2 to 3 months on the first cycle, the second cycle is begun by adding 1 more week to the treatment intervals of each agent. Several cycles of maintenance therapy can be given. Signs of toxicity, including bone marrow suppression and GI irritation, have been rarely recognized using this protocol.
- Other protocols include:
  - Single-agent L-asparaginase: 10,000 to 40,000 IU/m^2 IMV once every 2 to 3 weeks
  - Single-agent cyclophosphamide (give as described above)
  - Combinations of either cytosine arabinoside or cyclophosphamide with prednisone

RECOMMENDED MONITORING

During treatment, horses should be monitored for signs of pain, dehydration, and weight loss.

PROGNOSIS AND OUTCOME

- In most cases, the prognosis is poor.
- If a focal neoplasm that is amenable to surgical excision is present, then curative treatment may be possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Intestinal neoplasia should be considered in all horses demonstrating signs of weight loss and recurrent colic.
- In all cases of neoplasia, the quality of life, economic issues, prognosis, and owner expectations must be carefully considered and discussed before any treatment is attempted.

ElibeVet.com

Neoplasia, Nasal and Paranasal

BASIC INFORMATION

DEFINITION

Tumors of the nasal passage and paranasal sinuses are uncommon and include a wide range of tumor types, reflecting the diverse tissues present in the head. Squamous cell carcinoma (SCC) is the most commonly diagnosed sinonasal tumor. Paranasal tumors are more common than nasal tumors. Most tumors are unilateral in occurrence.

SYNONYM(S)

Sinonasal neoplasia

EPIDEMIOLOGY

SPECIES, AGE, SEX Surface and glandular epithelial tumors are more common in teenage and older horses. Young and immature horses are more likely to be diagnosed with fibro-osseous and bone tumors.

ASSOCIATED CONDITIONS AND DISORDERS

- Secondary paranasal sinusitis is common with primary neoplasia of the sinuses because of disruption of normal sinus drainage mechanisms and the presence of necrotic tissue and secondary bacterial infection.
- Paranasal sinus cysts commonly present with similar clinical signs of nasal discharge and external facial swelling.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES SCC, adenoma, adenocarcinoma, lymphoma, chondrosarcoma, fibroma, fibrosarcoma, osteoma (hamartoma), osteosarcoma, fibro-osseous tumors (fibrous dysplasia and ossifying fibroma), undifferentiated carcinomas and sarcomas, tumors of dental origin (eg, ameloblastoma), hemangioma, melanoma, mast cell tumor

HISTORY, CHIEF COMPLAINT

- Most sinonasal tumors are slowly growing with an insidious onset of clinical signs. Horses typically have a history of developing nasal discharge (mucoid to purulent; maybe bloody) that persists and perhaps has a foul odor.
- The presence of an expanding external facial swelling is also a common presenting complaint.
- An increased respiratory noise and reduced nasal airflow may be reported.
- Some horses may be presented for head shaking.
- Clinical signs may advance over weeks to months before veterinary attention is sought.

PHYSICAL EXAM FINDINGS Nasal discharge: Malodorous, mucoid to purulent, and often bloody; unilateral or bilateral; reduced nasal airflow; increased respiratory noise localized to the nasal passage; dyspnea; external facial swelling (frontal and maxillary regions) is common with advanced disease; enlarged submandibular lymph nodes; epiphora; exophthalmos; ocular discharge; neurologic deficits; halitosis; dysphagia; inappetence.

ETIOLOGY AND PATHOPHYSIOLOGY

- SCC and bone tumors are more common in the maxillary sinus. Glandular epithelial tumors (eg, adenocarcinoma) are more likely to arise from the frontal and ethmoidal sinuses.
- The frontal and ethmoidal sinuses have a greater density of mucosal glands, which may account for the increased incidence of glandular epithelial tumors in these locations compared with other sinus regions.
- Distant metastasis is rare; in addition to locally invasive and destructive growth, carcinomas frequently spread to other sites in the head (nasopharynx, oropharynx, periorbital, cranium, guttural pouch), resulting in diverse clinical signs.
- Osteomas are benign, generally well-circumscribed masses and are not infiltrative.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Paranasal sinus cyst, possibly extending into nasal passage
- Sinonasal polyp
- Ethmoid hematoma
- Fungal rhinitis or sinusitis
- Granuloma
- Nasal epidermal inclusion cyst (atheroma)
- Amyloidosis
- Infection with *Halicephalobus gingivalis* (a saprophytic nematode)

INITIAL DATABASE

- Complete blood count and chemistry panel: May see increased fibrinogen and mature leukocytosis if significant secondary bacterial infection is present; decreased red blood cell indices occur with anemia of chronic disease and in the presence of hemangioma.
- Upper airway endoscopy: Distorted, compressed nasal passage; variable-sized mass in the nasal passage; abnormal discharge at the nasomaxillary opening.
- Radiographs: Soft tissue, bony, or heterogenous mass effect in the paranasal sinuses, nasal passages, or both; air-fluid interface in the paranasal sinuses may be apparent with secondary sinusitis or blood accumulation from a bleeding tumor; deviated nasal septum; displaced cheek teeth; lysis and distortion of facial bones; soft tissue swelling; gas opacities in soft tissues.
- Contrast paranasal sinusography is helpful to delineate masses but is rarely used.

ADVANCED OR CONFIRMATORY TESTING

- Sinoscopy: Presence of mass and fluid in the paranasal sinuses; may obtain a biopsy specimen.
- Fine-needle aspirate of enlarged submandibular lymph nodes most commonly reveals inflammatory changes secondary to infection and tumor necrosis rather than metastatic tumor cells.
- Computed tomography provides the most detailed imaging of the location and extent of the tumor and assists with any intended surgical or radiation therapy planning.
- Head scintigraphy may help identify subclinical, early tumor development but is not indicated in the typical case of advanced disease.
- Histopathology is required for definitive diagnosis and should be performed before any therapeutic options are considered; some tumors are very difficult to classify.

TREATMENT

THERAPEUTIC GOAL(S)

- If possible, treatment is targeted at improving the horse's quality of life and preventing further destruction or invasion by the tumor. For many horses, effective treatment of advanced tumor growth in the head, diagnosed months after its onset, is impractical and unwarranted, and humane euthanasia is often chosen for these animals.
- For a minority of tumors, complete removal is possible and curative.

ACUTE GENERAL TREATMENT

- Rarely, a horse may require an emergency tracheotomy if it is presented

ElibeVet.com

with severe airflow reduction and obvious respiratory distress.
- Cytoreductive surgery of invasive tumors is significantly complicated by inaccessibility and hemorrhage.
- Sinusotomy and complete excision are practical for osteomas of the paranasal sinuses.
- A localized tumor of the nasal septum may be amenable to complete removal by nasal septum resection.
- Palliative or therapeutic radiotherapy is a strong consideration for radiosensitive tumors, particularly lymphoma and SCC.
- Laser ablation and cryotherapy are considerations for early-onset, small tumors.
- Nonsteroidal antiinflammatory drugs and antimicrobials contribute to horse comfort and limit secondary bacterial infections.

CHRONIC TREATMENT

Palliative radiation treatments may be used periodically in an ongoing therapeutic plan.

POSSIBLE COMPLICATIONS

Side effects of radiation therapy include development of white hair, hair loss, scaly skin, superficial skin necrosis, increased nasal drainage, temporary local lymphadenopathy, and bone remodeling.

RECOMMENDED MONITORING

- After any palliative or therapeutic measures, it is prudent to monitor for recurrence or persistence of initial clinical signs.
- Radiographic and endoscopic evaluation of the head may be indicated every 4 to 6 months after apparent tumor removal or regression.

PROGNOSIS AND OUTCOME

- Poor to guarded prognosis for advanced, invasive tumors; most horses are euthanized at diagnosis or when the quality of life is considered unacceptable.
- Guarded to fair prognosis for radiosensitive tumors that are accessible for radiotherapy.
- Good to excellent prognosis for benign, noninfiltrative tumors (eg, osteoma) that can be surgically removed in their entirety.

PEARLS & CONSIDERATIONS

COMMENTS

- Each horse should be considered on an individual basis with regard to possible treatment and outcome.
- Early diagnosis remains uncommon because tumors can expand considerably within the sinus space before clinical signs are readily apparent.
- Radiation therapy is becoming more frequently used and available and should always be considered.
- Accurate diagnosis is critical before any treatment plan is developed.

PREVENTION

- There are no known current preventive measures.
- Vaccination against certain tumors (eg, melanoma) may become the mainstay of future preventive management programs.

CLIENT EDUCATION

- At the first sign of abnormal nasal discharge, notable reduction in airflow, increase in airway respiratory sounds, foul odor to the breath, or external facial swelling, consult a veterinarian.
- Early diagnosis increases the chance of successful treatment.
- Geriatric horses are at increased risk of developing tumors and should receive thorough physical examinations at least twice a year.

EDITOR: **ERIC J. PARENTE**

Neoplasia, Urinary Tract

BASIC INFORMATION

DEFINITION

Epithelial tumors of the equine urinary tract include papilloma, adenoma, and carcinoma. Tumors are further classified as adenocarcinoma, transitional cell carcinoma (TCC), squamous cell carcinoma (SCC), and undifferentiated carcinomas.
- Renal cell carcinoma (RCC; adenocarcinoma) is the most common renal tumor and usually arises from the epithelium of the proximal convoluted tubules.
- Nephroblastoma is an embryonal tumor that develops from primitive nephrogenic tissue or dysplastic tissue from the uroepithelium of the renal pelvis or ureter.
- SCC is the most common bladder tumor in horses followed by TCC and leiomyosarcomas.
- Metastatic disease from lymphosarcoma, hemangiosarcoma, melanoma, adenocarcinoma, or adenoma can invade any region of the urinary tract.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Nephroblastoma occurs in young horses; other tumors tend to occur in older animals

ASSOCIATED CONDITIONS AND DISORDERS

- RCCs frequently metastasize to the lungs, liver, and other tissues. Metastasis is common with hemangiosarcoma, melanomas, and TCC of the bladder and kidney. Lymphosarcoma is often multicentric.
- A paraneoplastic process leading to severe hypoglycemia has been reported in two cases of equine RCC, probably caused by production of an insulin-like factor, an abnormal variant of insulin-like growth factor II, or less likely from excessive glucose utilization by the tumor.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- RCC (adenocarcinoma)
- Nephroblastoma
- TCC
- SCC
- Metastatic disease from lymphosarcoma, hemangiosarcoma, melanoma, adenocarcinoma, or adenoma

ElibeVet.com

HISTORY, CHIEF COMPLAINT

- Renal neoplasia
  - Hematuria
  - Weight loss
  - Chronic colic
  - Poor performance
  - Depression
  - Anorexia
  - Sudden death caused by hemorrhage from the neoplasm
- Bladder neoplasia
  - Hematuria
  - Weight loss
  - Stranguria
  - Pollakiuria
  - Depression
  - Anorexia
  - Unthriftiness

PHYSICAL EXAM FINDINGS

- Enlargement of the left or even the right kidney detected by rectal palpation in some cases of renal neoplasia. Pain may be evident on palpation of the mass per rectum or percutaneously through the flank.
- Bladder tumors can frequently be palpated rectally.

ETIOLOGY AND PATHOPHYSIOLOGY

- Nephroblastoma occurs in young horses.
- In other species, increased exposure to insecticides has been linked to bladder neoplasia.
- Chronic urinary tract infections may predispose to neoplasia in some cases.
- In horses, an underlying cause of urinary tract neoplasia is rarely determined.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- RCC (adenocarcinoma) is the most common primary renal tumor in horses followed by nephroblastoma. Whereas RCC tends to occur in older horses, nephroblastoma often occurs in young horses.
- Multiple myeloma involving the kidney has been reported, which resulted in hypercalcemia and elevated serum parathyroid hormone–related protein concentration.
- A young horse with a RCC has been reported to have increased production of insulin-like growth factor and secondary hypoglycemia.
- Mucinous hyperplasia of the renal pelvis and proximal urethral uroepithelium or a ureteropelvic polyp can result in renal masses that are not truly neoplastic but may result in obstruction of the kidney or ureter and hydronephrosis.
- The most common bladder tumor is SCC followed by TCC, which occur in middle-aged to older horses.
- Fibromatous polyps of the bladder may occur in young horses.
- Metastatic lymphosarcoma, hemangiosarcoma, adenoma, and melanoma can also involve the kidneys and rarely the bladder.
- Differential diagnoses for renal masses include abscesses, pyelonephritis, renal calculi, polycystic kidneys, and aberrant nematode migration.
- Cystitis or cystic calculi may cause stranguria and pollakiuria. Bladder paresis may lead to inadequate bladder emptying, urine stasis, and accumulation of sabulous concentrations ventrally in the bladder. Neoplasia may predispose to cystitis or cystic calculi and should be ruled out by careful cystoscopy.

INITIAL DATABASE

- Complete blood count is usually normal. Mild to moderate anemia associated with gross hematuria is possible, and anemia of chronic disease is common. Neutrophilia and thrombocytopenia occur occasionally.
- Serum biochemistry profile is usually normal. Decreased iron and increased fibrinogen concentrations secondary to inflammation are possible. Azotemia rarely occurs with renal neoplasia because the contralateral kidney maintains normal renal function. Hypoglycemia and hypoalbuminemia have been reported on occasion.
- Urinalysis: Hematuria and associated proteinuria are common. Neoplastic cells are more likely to be observed with bladder rather than renal tumors. Secondary cystitis with increased urine leukocytes and bacteriuria are possible, in which case a quantitative urine culture should then be performed (>10,000 CFU/mL is significant).
- Abdominocentesis is often abnormal, with nonspecific increases in white blood cell count and total protein concentration. Occasional neoplastic cells are observed.
- Transabdominal ultrasonography can be used to detect all but very small renal tumors. Biopsy of renal masses under ultrasonographic guidance can be used to obtain a definitive diagnosis.
- Transrectal ultrasonography can be used to image most bladder tumors, which can be viewed directly using cystoscopy. It is important to retroflex the endoscope to view the trigone region and bladder neck. Biopsy specimens can usually be obtained during cystoscopy.
- Thoracic radiography may detect pulmonary metastases.
- Abdominal ultrasonography may detect intraabdominal metastases.

ADVANCED OR CONFIRMATORY TESTING

Histopathology or cytology of biopsy specimens collected from the kidney or bladder can be used to obtain a definitive diagnosis.

TREATMENT

THERAPEUTIC GOAL(S)

- For unilateral renal neoplasia detected before metastasis, the treatment of choice is unilateral nephrectomy. Careful assessment should be done to ensure normal function of the contralateral kidney and to look for metastatic disease (thoracic radiography and abdominal and thoracic ultrasonography) before surgery. Nephrectomy is best performed in the standing horse. Laparoscopic visualization of the abdomen looking for metastatic disease is recommended. Nephrectomy can be performed via a flank incision or via hand-assisted laparoscopy.
- Bladder tumors have been treated with surgical excision via a caudal ventral midline laparotomy in mares and via a parainguinal approach in male horses.
- Topical therapy using intracystically instilled 5-fluorouracil or triethylenethiophosphoramide has been attempted to treat bladder tumors.
- Some horses with SCCs and TCCs have responded to piroxicam (nonselective cyclooxygenase inhibitor) in horses and other species. Such treatment is recommended after surgical resection.
- No reports of systemic chemotherapy for urogenital neoplasia have yet been published in horses.

ACUTE GENERAL TREATMENT

Secondary cystitis may be treated with antibiotics according to bacterial culture and sensitivity results.

CHRONIC TREATMENT

Long-term treatment with piroxicam (0.2–0.3 mg/kg PO q24h) should be monitored with sequential assessment of urine specific gravity, serum creatinine, and albumin concentrations because of the risk of possible renal damage or right dorsal colitis.

POSSIBLE COMPLICATIONS

- Renal neoplasia may erode into the vasculature and result in hemoabdomen and even sudden death from exsanguination.
- Bladder, urethral, renal, or ureteral neoplasia may result in uroabdomen or uroperitoneum if there is severe tissue destruction of the urinary tract.

ElibVet.com

RECOMMENDED MONITORING

- Signs of metastatic disease include weight loss, inappetence, depression, exercise intolerance, respiratory distress, or lameness.
- Elevations in liver enzymes or alkaline phosphatase may be used as indicators of hepatic or osseous metastatic disease.
- Periodic rectal examination and abdominal and thoracic ultrasonography may be warranted.
- Quality of life should be assessed and euthanasia recommended before the development of severe discomfort, chronic pain, or cachexia.

PROGNOSIS AND OUTCOME

- Generally, the prognosis is poor for all forms of urinary tract neoplasia in horses.
- Nephroblastomas are generally confined to the kidney and may be amenable to nephrectomy with a fair prognosis.
- As chemotherapeutic protocols become more widely used in equine practice, prognosis may improve. Unfortunately, diagnosis is often late in the disease process. Most tumors of the urinary tract are either locally aggressive with the tendency for transmural spread or highly metastatic. Early diagnosis, ideally as an incidental finding, provides the best opportunity for successful outcome for these conditions, which generally have a very poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Renal tumors are rare in horses (~1% of all equine tumors), and bladder tumors are uncommon.
- Adenocarcinomas are the most common renal tumor in horses and usually arise from the epithelium of the proximal convoluted tubules.
- SCCs are the most common bladder tumor in horses followed by TCCs.
- Primary and metastatic tumors of the kidney or bladder are frequently fatal.

CLIENT EDUCATION

Euthanasia is often performed at the initial diagnosis because tumors may be extensive and interfere with other organs. Early diagnosis may allow for surgical resection or chemotherapy.

EDITOR: **BRYAN M. WALDRIDGE**

Nephrolithiasis

BASIC INFORMATION

DEFINITION

A stone (urolith) within the kidney

SYNONYM(S)

- Renal calculi
- Stag-horn calculi

EPIDEMIOLOGY

SPECIES, AGE, SEX

Males, especially intact males, are reportedly more commonly affected.

GENETICS AND BREED PREDISPOSITION

Nephrolithiasis has been reported with increased frequency in Thoroughbred racehorses.

RISK FACTORS

Nonsteroidal antiinflammatory drug (NSAID) administration and subsequent subclinical renal medullary crest necrosis may be a risk factor.

ASSOCIATED CONDITIONS AND DISORDERS

- Urolithiasis
- Hematuria
- Hydronephrosis
- Chronic renal failure

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Unilateral or bilateral nephrolithiasis

HISTORY, CHIEF COMPLAINT

- Similar to chronic renal failure: Weight loss, anorexia, depression
- Colic
- Hematuria

PHYSICAL EXAM FINDINGS

- Weight loss
- Enlarged kidney (left) palpated during evaluation per rectum

ETIOLOGY AND PATHOPHYSIOLOGY

- Nephroliths begin as a nidus of damaged tissue (fibrosis, inflammation, or infection).
- Nephroliths are typically composed of calcium carbonate crystals but may also be composed of calcium phosphate.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic renal failure
- Ureterolithiasis
- Pyelonephritis
- Neoplasia
- Cystic calculi
- Chronic gastrointestinal pain (colic)

INITIAL DATABASE

- Complete blood count and fibrinogen concentration.
- Serum chemistries reveal azotemia (especially if bilateral disease).
- Urinalysis reveals macroscopic or microscopic hematuria.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasound examination of the affected kidney may show changes in echogenicity or acoustic shadowing suggestive of nephrolithiasis.
- Endoscopic evaluation of the urinary tract may reveal the origin of hematuria from one or both ureteral openings.
- Quantitative urine culture if pyelonephritis is suspected

TREATMENT

THERAPEUTIC GOAL(S)

- Supportive care of renal function (IV fluids, antibiotics, analgesics)
- Removal of the nephrolith via nephrectomy (if unilateral)

ACUTE GENERAL TREATMENT

- Support renal perfusion and urine production with IV fluids if the urinary tract is unobstructed.
- Analgesia as needed (avoid NSAIDs if azotemia is present)
- Broad-spectrum antibiotics if nephrectomy will be attempted

ElibeVet.com

- Nephrectomy if stones are unilateral and the contralateral kidney is normal.

RECOMMENDED MONITORING

- Regular monitoring of blood urea nitrogen and creatinine concentrations to assess renal function, especially if a kidney has been removed. Horses with bilateral nephrolithiasis should be monitored for decreasing renal function and worsening renal failure.
- The horse should be carefully monitored for normal urination and any signs of urinary obstruction.

PROGNOSIS AND OUTCOME

- Usually good if a nephrectomy can be performed and the contralateral kidney is normal
- Poor to grave if nephroliths are bilateral and renal function is decreased (azotemia)

PEARLS & CONSIDERATIONS

COMMENTS

- A retrospective study reported uroliths in the kidneys of 15 of 68 (22%) horses with urolithiasis, and more than 50% of these cases were bilateral. Approximately 9% of horses had uroliths in more than one location.
- Nephrolithiasis should be ruled out in horses with clinicopathologic indications of renal failure, chronic weight loss, and colic.

PREVENTION

Careful use and monitoring of kidney function with long-term or high doses of NSAIDs

CLIENT EDUCATION

Consult with a veterinarian before administration of NSAIDs.

SUGGESTED READING

AUTHOR: **JENNIFER TAINTOR**

EDITOR: **BRYAN M. WALDRIDGE**

Nephrotic Syndrome

BASIC INFORMATION

DEFINITION

A syndrome of hypoproteinemia, proteinuria, and edema formation caused by damaged glomerular basement membranes

SYNONYM(S)

Nephrosis

EPIDEMIOLOGY

RISK FACTORS

Hyperimmunized horses

ASSOCIATED CONDITIONS AND DISORDERS

- Amyloidosis
- Aortoiliac thrombosis
- Chronic antigenic stimulation or inflammatory disease
- Equine infectious anemia
- Immune mediated disease
- Purpura hemorrhagica or *Streptococcus equi* subsp. *equi* infection

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Weight loss
- Ventral edema
- Polyuria
- Polydipsia

PHYSICAL EXAM FINDINGS

- Abdominal distension
- Ascites
- Generalized or ventral midline edema
- Poor body condition
- Pleural or peritoneal effusion

ETIOLOGY AND PATHOPHYSIOLOGY

- Nephrotic syndrome can be the end stage outcome of glomerulonephritis.
- Severe glomerular damage affects the filtration pore size and membrane charge of the glomerulus and results in proteinuria.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute renal failure
- Chronic renal failure
- Diabetes insipidus
- Heart failure
- Pituitary pars intermedia dysfunction
- Psychogenic water drinking
- Purpura hemorrhagica

INITIAL DATABASE

- Complete blood count
- Serum chemistries
- Urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Renal ultrasound examination: The kidneys may appear small and shrunken.
- Renal biopsy: Specialized immunohistochemistry or electron microscopy may be needed to identify the cause and severity of disease.
- *S. equi* subsp. *equi* M (SeM) protein titer: Very high titers are found with purpura hemorrhagica (immune complex hypersensitivity) secondary to *S. equi* infection.
- Ultrasound examination may also reveal thoracic or abdominal effusion (or both).

TREATMENT

THERAPEUTIC GOAL(S)

- Reduce edema formation
- Reduce azotemia
- Maintain hydration

ACUTE GENERAL TREATMENT

- Treatment of any possible predisposing conditions
- IV fluids (60 mL/kg q24h) with electrolytes if needed for dehydration

CHRONIC TREATMENT

- Provide palliative, symptomatic therapy
- Restrict dietary salt intake
- Avoid excessive dietary protein (adult horses at maintenance require only 7% dietary protein)
- Feed a low-protein and low-calcium diet as recommended for patients with chronic renal failure (avoid legumes)

ElibVet.com

RECOMMENDED MONITORING

Periodic determination of blood urea nitrogen, creatinine, and total protein concentrations

PROGNOSIS AND OUTCOME

Poor

PEARLS & CONSIDERATIONS

- Pleural and abdominal effusion appears to be less common in horses with nephrotic syndrome than for other animals.
- Nephrotic syndrome likely indicates that end-stage kidney disease is present.

SUGGESTED READING

Bernard WV: Inflammatory, infectious, and immune diseases. In Colahan PT, Merritt AM, Moore JM, et al (eds). *Equine medicine and surgery*, ed 5, St Louis, 1998, Mosby, pp 1770–1772.

AUTHOR & EDITOR: **BRYAN M. WALDRIDGE**

Neurotoxic Plant (Miscellaneous) Toxicosis

BASIC INFORMATION

DEFINITION

Plants with the potential to cause neurologic poisoning in horses

SYNONYM(S)

- Buckeye, horse chestnut, red buckeye (*Aesculus* spp.)
- Carolina jessamine, woodbine, false jasmine (*Gelsemium sempervirens*)
- Carolina allspice, sweet shrub (*Calycanthus floridus*)
- Golden chain tree, bean tree (*Laburnum anagyroides*)
- Scotch broom, broom (*Cytisus scoparius*)

EPIDEMIOLOGY

GEOGRAPHY AND SEASONALITY

- Buckeye: Six *Aesculus* spp. native to North America; small to large trees with large palmate leaves and distinctive brown fruits
- Carolina jessamine: Woody evergreen, perennial vines with trumpet-shaped yellow flowers
- Carolina allspice: Perennial, branching shrubs with opposite leaves and maroon-brown colored aromatic flowers of the southeastern states
- Golden chain tree: Perennial, deciduous, small trees with palmate, compound leaves, numerous pendulous inflorescences with pea-like yellow flowers and seed pods
- Scotch broom: A nonnative, perennial, shrub or small tree with ribbed branches, palmate leaves, and yellow pea-like flowers and seed pods

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Incoordination
- Weakness
- Ataxia

PHYSICAL EXAM FINDINGS

- Buckeye: Incoordination, weakness, staggering gait, hypermetria, sawhorse stance, muscle spasms, gastroenteritis, colic
- Carolina jessamine: Incoordination, weakness, muscle convulsions, respiratory paralysis
- Carolina allspice: Muscle fasciculations, hypersensitivity, incoordination, recumbency, tetanic seizures, extensor rigidity
- Golden chain tree: Short-duration weakness, muscle tremors, incoordination, colic
- Scotch broom: Excitement, ataxia, incoordination, colic

ETIOLOGY AND PATHOPHYSIOLOGY

- Buckeye: Numerous triterpenoid saponins are found in new leaves and seeds.
- Carolina jessamine: Gelsemine and other alkaloids in all parts of the plant cause paralysis.
- Carolina allspice: Calycanthine and other alkaloids are potent stimulants of the nervous system, acting like strychnine.
- Golden chain tree: Quinolizidine cystine–like alkaloids are nicotinic receptor agonists causing ganglionic blockade similar to curare. Seeds are most toxic. Anagyrine in the seeds may be teratogenic.
- Scotch broom: Several quinolizidine alkaloids are similar to those in *Laburnum* spp. with similar activity on nicotinic receptors. Anagyrine in the seeds may be teratogenic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Encephalitis: Rabies, West Nile virus, eastern and western equine encephalitis virus
- Equine herpes virus
- Equine leukoencephalomalacia
- Sage poisoning
- Pyrrolizidine alkaloid toxicity
- Bracken fern and horsetail poisoning
- Strychnine poisoning

INITIAL DATABASE

No specific clinical pathologic findings with any of these plants

ADVANCED OR CONFIRMATORY TESTING

- Postmortem finding are generally nonspecific.
- Stomach contents should be submitted for plant identification.
- Golden chain tree and Scotch broom can cause skeletal myopathy histologically.

TREATMENT

THERAPEUTIC GOAL(S)

- Decontamination and administration of activated charcoal if recent ingestion
- Symptomatic and supportive care

ACUTE GENERAL TREATMENT

- Buckeye poisoning is self-limiting after ingestion of the plant ceases.
- Carolina jessamine: There is no specific antidote, and treatment should be symptomatic.
- Carolina allspice: Diazepam or pentobarbital to control seizures; dark and quiet environment
- Golden chain tree: Supportive treatment as necessary
- Scotch broom: Supportive treatment as necessary

PROGNOSIS AND OUTCOME

- Buckeye poisoning is rarely fatal.
- Carolina jessamine poisoning carries a guarded prognosis after clinical signs appear.
- Carolina allspice has a guarded prognosis after seizures occur.

ElibVet.com

- Golden chain tree and Scotch broom poisonings are usually of short duration unless consumption of the seeds continues.

PEARLS & CONSIDERATIONS

COMMENTS

Although horses have rarely been poisoned by these plants and published case reports are rare or nonexistent, the plants should still be considered potentially hazardous to horses.

PREVENTION

Do not plant any of these plants in or around horse pastures or corrals where horses have access to them.

EDITOR: **CYNTHIA L. GASKILL**

Nightshade Toxicosis

BASIC INFORMATION

DEFINITION

Nightshades are a large, diverse group of plants in the family Solanaceae that contain a variety of toxic alkaloids with profound effects on the nervous system and digestive tract. A few species, such as day- and night-blooming jessamine, cause excess calcification of the tissues.

SYNONYM(S)

- Black nightshade, poison berry, yerba mora (*Solanum nigrum*)
- Common or American nightshade (*Solanum americanum*)
- Silverleaf nightshade, desert nightshade, western or white horse nettle (*Solanum elaeagnifolium*)
- Horse or bull nettle, Carolina horse nettle, Sodom apple (*Solanum carolinense*)
- Hairy nightshade (*Solanum physalifolium*)
- Jimson weed, Datura, sacred Datura, thorn apple, Indian apple, tolguacha (*Datura* spp.)
- Tomato (*Lycopersicon esculentum*)
- Day or wild jessamine, day cestrum, Chinese inkberry (*Cestrum diurnum*)
- Night-blooming jessamine, huele de noche (*C. nocturnum*)

EPIDEMIOLOGY

RISK FACTORS

- Weedy hay containing dried nightshade species
- Grain contaminated with *Datura* seeds
- Horses given access to green tomato and potato vines

GEOGRAPHY AND SEASONALITY

- The nightshades, including *Datura* spp., are frost sensitive and tend to be annuals except in milder climates. There are at least 70 species of native and introduced *Solanum* spp. in North America.
- The common nightshades range from herbaceous, small, weedy, erect shrubs to small trees with alternate or opposite, hairy or smooth leaves, some with prominent spines, and with five-lobed, white to purple flowers that form round, fleshy berries or fruits that are usually green and turn yellow or black when mature (Figures 1 to 3).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clinical signs of colic within hours of eating the nightshade plants.
- Depending on the quantity of nightshade eaten, severe colic, recumbency, and seizures may develop.

PHYSICAL EXAM FINDINGS

Nightshades cause variable signs of colic because of intestinal stasis and gas accumulation. Gastric dilatation and death may occur.

ETIOLOGY AND PATHOPHYSIOLOGY

- Members of the Solanaceae family contain a variety of toxic compounds; the two that most often affect animals are glycoalkaloids and tropane alkaloids.
- Glycoalkaloids, common in the *Solanum* spp., are gastrointestinal (GI) irritants and are neurotoxic.
- Horses that have been eating silverleaf nightshade and are treated with ivermectin develop severe depression and die, apparently because of increased permeability of the blood-brain barrier to ivermectin.
- Tropane alkaloids found in *Datura* spp. are competitive antagonists of acetylcholine, causing dilated pupils,

FIGURE 1 American nightshade (*Solanum americanum*).

ElibeVet.com

FIGURE 2 Silverleaf nightshade (*Solanum elaeagnifolium*).

FIGURE 3 Jimson weed (*Datura stramonium*).

intestinal atony, decreased salivation, tachycardia, and tachypnea typical of the effects of atropine.
- Grain contaminated with *Datura* seeds (~600 seeds/kg of grain) cause poisoning in horses.
- Day- and night-blooming jessamines (*Cestrum* spp.) have a different effect and cause excess calcification of the tissues, leading to weight loss, lameness, and debilitation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Colic from other causes
- Calcification of tissues: Cholecalciferol or vitamin D toxicosis

INITIAL DATABASE

Hematocrit and serum biochemistry changes may be minimal initially.

ADVANCED OR CONFIRMATORY TESTING

- Stomach contents and urine can be analyzed for tropane alkaloids.
- Plants in stomach contents or feed sources can be identified both visually and microscopically.
- Postmortem lesions may show GI reddening or gaseous distension.

TREATMENT

THERAPEUTIC GOAL(S)

Decontaminate patient and provide symptomatic care

ACUTE GENERAL TREATMENT

- Place a nasogastric tube if gastric dilation is suspected.
- Adsorption of toxins with activated charcoal as early in the course of poisoning as possible
- Control seizures with diazepam.
- Do not use phenothiazine tranquilizers because of their anticholinergic effects.
- Cholinergics such as physostigmine may be useful.
- Supportive treatment should include IV fluids when dehydration and shock are evident.

RECOMMENDED MONITORING

Serum electrolytes and hematocrit to manage colic progress

PROGNOSIS AND OUTCOME

Horses recover in 1 or 2 days unless they have consumed large amounts of the nightshade.

PEARLS & CONSIDERATIONS

COMMENTS

- Nightshades are common weeds in pastures in some areas and are more often a problem for ruminants than for horses. Exposures in horses most commonly occur from ingestion of hay heavily contaminated with nightshade leaves and fruits or ingestion of tomato or potato vines.
- Poor-quality grain contaminated with *Datura* seeds is a significant cause for concern.

PREVENTION

Recognize the common nightshades and control them with appropriate herbicides or mowing.

CLIENT EDUCATION

- Inspect hay and grain for nightshade leaves, stems, berries, and seeds.
- Ensure horses have adequate and good-quality feeds and forages to prevent hungry horses from eating excessive amounts of weeds.

ElibeVet.com

Nocardiosis

BASIC INFORMATION

DEFINITION

A bacterial disease caused by opportunistic saprophytes of *Nocardia* spp. resulting in suppurative to granulomatous tissue reactions in a localized or disseminated manner

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No known breed or sex predilection
- Present in most environments as part of the normal soil microflora; found worldwide
- Prevalence of 0.009% in equine patients

RISK FACTORS

- Considered an opportunistic pathogen, infecting immunosuppressed individuals
- Primarily associated with severe combined immunodeficiency syndrome in Arabian foals and pituitary pars intermedia dysfunction (PPID) as immunosuppressive conditions
- Infection occurs via inhalation or direct inoculation through a wound.

CONTAGION AND ZOONOSIS

- Not contagious
- Infectious to humans but not transmitted directly from horses to humans

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES May be localized or disseminated:

- Pulmonary
- Disseminated
- Localized cutaneous
- Nocardia-induced mycetoma
- Abortion

HISTORY, CHIEF COMPLAINT Normally a chronic course of disease but can present acutely and be rapidly progressive

PHYSICAL EXAM FINDINGS

- Pulmonary nocardiosis: Increased respiratory rate and effort, cough, nasal discharge; may be acute or chronic; may result in pneumonia, abscess formation, or pleuritis.
- Disseminated nocardiosis: Widespread abscess formation in multiple organs; may occur secondary to pulmonary disease. In humans, most commonly affects the central nervous system, eyes, kidneys, joints, bone, heart, and skin or subcutaneous tissues.
- Localized cutaneous nocardiosis: Occasionally occurs without systemic lesions, usually after direct inoculation of the organism via trauma. Results in cellulitis or pyoderma, often becoming a circumscribed abscess. These lesions may ulcerate and have thick, odorless purulent discharge.
- Nocardia-induced mycetomas: Subcutaneous infection usually resulting from a traumatic injury. Generally starts with a painless nodule that chronically progresses in size and eventually becomes purulent and necrotic. Granulomatous inflammation surrounds the lesion, and secondary nodules and drainage tracts occur. Exudate may contain sandlike particles.
- Abortion: Rare; lesions are observed in the aborted fetuses within the lung and liver as well as in the placenta.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Nocardia* spp. bacteria are aerobic gram-positive actinomycetes that are saprophytic, non–spore-forming, and partially acid fast.
- Most infections are caused by members of the *Nocardia asteroides* complex; however, *Nocardia brasiliensis* has also been isolated.
- Infection cannot be eliminated by macrophages and neutrophils alone; protective responses appear to be T-cell mediated.
- L-form variants can survive dormant within macrophages and lead to occasional relapses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of bacterial pneumonia, including *Streptococcus* spp., *Actinobacillus* spp., *Pasteurella* spp., *Klebsiella pneumoniae, Rhodococcus equi, Escherichia coli, Staphylococcus aureus,* Bordetella *bronchiseptica, Bacteroides fragilis, Peptostreptococcus anaerobius,* and Fusobacterium spp.
- Fungal pneumonia
- Pulmonary parasite migration
- Other causes of mycetomas include fungal (*Curvularia geniculata, Pseudallescheria boydii*) and other bacteria (*Actinobacillus* spp., *Actinomyces* spp.)
- Cutaneous lesions may resemble those caused by *Staphylococcus* and *Streptococcus* spp. or cutaneous neoplasia such as sarcoids or squamous cell carcinoma.
- Other causes of abortion include bacterial or fungal placentitis, leptospirosis, and equine herpesvirus-1.

INITIAL DATABASE

- Results of complete blood count and serum chemistry are not specific and may reflect an inflammatory process as well as evidence of immunosuppression (lymphopenia, neutrophilia with left shift and toxic changes, hyperfibrinogenemia, and hyperglobulinemia or hypoglobulinemia).
- Gram-stained samples reveal gram-positive rod- to coccoid-shaped branching filaments. Acid-fast staining can confirm the partially acid-fast nature of most isolates.
- Culture can be performed, but refrigeration of samples should be avoided.

ADVANCED OR CONFIRMATORY TESTING

- Serology: Not routinely used because patients usually do not develop a significant antibody response.
- Speciation of *Nocardia* isolates is performed by polymerase chain reaction (PCR); a semi-nested PCR method is under investigation that could help detect L forms of *Nocardia* that are especially difficult to identify with culture.

TREATMENT

THERAPEUTIC GOAL(S)

Elimination of pathogenic organisms with antimicrobial therapy and surgical drainage of lesions

ACUTE GENERAL TREATMENT

- If possible, abscesses and exudative lesions should be drained, debrided, and lavaged.
- Proliferative granulomatous lesions may need to be resected.
- Antimicrobial susceptibility testing should be performed, but often in vitro results do not correlate well with clinical efficacy in these cases.
- The general recommendation for antibiotic therapy is the use of a trimethoprim-sulfonamide, ideally in combination with amikacin.
- Other antibiotics that have been used include amoxicillin-clavulanate, third-generation cephalosporins, newer macrolides, imipenem, and other aminoglycosides.

CHRONIC TREATMENT

- Although clinical improvement may be observed 5 to 10 days after institution of therapy, long-term treatment with antibiotics (ie, 6–12 months) may be required to prevent relapses.

ElibVet.com

- PPID can be managed with pergolide, which helps to limit the clinical manifestations of disease, including immunosuppression.

PROGNOSIS AND OUTCOME

- The prognosis is based primarily on host factors, specifically the severity of compromise to the immune system and the site and extent of the lesions.
- Pulmonary and disseminated nocardiosis carry a poor prognosis because of severe debilitation, but lesions limited to the skin have a good prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Nocardioform placentitis is a condition not actually caused by *Nocardia* spp. but rather *Crossiella equi* or *Cellulosimicrobium cellulans*, organisms unrelated to *Nocardia*.

PREVENTION

No method of prevention exists other than trying to prevent immunosuppression if possible (ie, by managing horses with PPID with pergolide).

Nonsteroidal Antiinflammatory Drug Toxicosis

BASIC INFORMATION

DEFINITION

- Adverse effects of the nonsteroidal antiinflammatory drugs (NSAIDs) are caused by cyclooxygenase (COX) inhibition in tissues where prostaglandins are beneficial and protective.
- Renal papillary necrosis (medullary crest necrosis), oral and gastrointestinal (GI) ulceration, and right dorsal colitis are common signs of NSAID toxicity in horses.
- Platelet aggregation is classically inhibited by NSAIDs that prevent thromboxane production via the COX-1 pathway.

EPIDEMIOLOGY

SPECIES, AGE, SEX Neonates and geriatrics are more at risk.

RISK FACTORS Renal insufficiency, dehydration, concurrent use of both phenylbutazone and flunixin meglumine, concurrent nephrotoxic drug therapy (eg, aminoglycosides), and history of previous NSAID toxicity

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- NSAID administered
  - NSAIDs approved for use in horses include aspirin, flunixin meglumine (Banamine, generics), ketoprofen (Ketofen, Anafen), diclofenac (topical, Surpass), phenylbutazone (generics), firocoxib (Equioxx), meclofenamic acid (Arquel), and vedaprofen (Quadrisol, Canada and Europe).
  - The highest incidence of toxicity is associated with phenylbutazone administration.
- Amount administered: Phenylbutazone may cause toxicity when administered according to the label dose. Other NSAIDs usually require an overdose to cause toxicity.

PHYSICAL EXAM FINDINGS

- Colic
- Anorexia
- Poor body condition
- Diarrhea
- Oral mucosal erosions, odontoprisis, sialism
- Regurgitation of milk and pain after nursing in foals
- Oliguria

ETIOLOGY AND PATHOPHYSIOLOGY

- Nephrotoxicity: NSAIDs typically have little effect on renal function in normal adult animals, but they decrease renal blood flow and glomerular filtration rate in patients with congestive heart failure, those that are hypotensive or hypovolemic (especially during anesthesia and surgery), and those that have chronic renal disease. Renal papillary necrosis is a severe dose-dependent toxicity most commonly associated with phenylbutazone. Although attributed to impaired renal blood flow, other mechanisms such as direct nephrotoxicity of the drug or its metabolites may be involved.
- GI toxicity: Reduced prostaglandin (PG) concentrations in the large colon may decrease colonic blood flow, resulting in mucosal atrophy, protein loss, ulceration, and inflammation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Stress-induced gastric ulceration
- Inflammatory bowel disease
- Other toxin-induced renal failure (eg, cantharidin)

INITIAL DATABASE

- In asymptomatic horses, consider obtaining baseline renal and hepatic function tests.
- In symptomatic horses, monitor:
  - Complete blood count and serum chemistries for anemia, neutrophilia or neutropenia, hypoproteinemia, hypoalbuminemia, hypocalcemia, and elevated liver enzymes
  - Arterial blood gases for metabolic acidosis
  - Renal function tests for azotemia, increased urine γ-glutamyl transferase (GGT), and increased urine GGT/urine creatinine ratio

ADVANCED OR CONFIRMATORY TESTING

- Nuclear scintigraphy with ^{99m}Tc-HMPAO labeled white blood cells or ^{99m}Tc-albumin are noninvasive methods for detecting right dorsal colitis caused by NSAID toxicity.
- Ultrasonography of the kidneys may show a medullary rim sign (a distinct curvilinear hyperechoic band parallel to the corticomedullary junction). This is thought to result from dystrophic calcification of the outer zone of the medulla parallel to the corticomedullary junction.

ElibVet.com

- Postmortem findings
  - Most common gross lesions
    - Oral erosions or ulcers
    - Gastric and duodenal ulcers
    - Right dorsal colon ulceration
  - Less frequent gross lesions
    - Renal crest necrosis
    - Focal to diffuse hepatic pallor
  - Histopathologic lesions
    - Mucosal atrophy to erosion and ulceration in the GI tract
    - Accumulation of plasma cells, lymphocytes, and macrophages in the lamina propria and submucosa
    - Moderate to severe villous atrophy and epithelial necrosis and mucosal inflammation
    - Renal proximal convoluted tubular degeneration
    - Chronic, active cholangiohepatitis

TREATMENT

THERAPEUTIC GOAL(S)

- Treatment of NSAID GI toxicity is intensive and mainly symptomatic.
- Patients with significant toxicity that develop severe acidosis may require supportive treatment with IV sodium bicarbonate.

ACUTE GENERAL TREATMENT

- Activated charcoal may bind and limit absorption of NSAIDs from the GI tract.
- Sodium bicarbonate is indicated for the treatment of recalcitrant acidosis (pH <7).
- Hypoproteinemia: Plasma infusion.
- Dehydration and electrolyte losses: Commercially available IV fluids.
- Sepsis: Broad-spectrum antimicrobial therapy.
- Pain: Further NSAID therapy must be avoided. Use a continuous butorphanol infusion at 13 µg/kg/h IV (diluted in lactated Ringer's solution) for colic pain control.
- Anti-ulcer medications may be beneficial and speed recovery.
  - Proton pump inhibitors (PPIs) appear to be the most effective therapies for both gastric ulcer prevention and treatment. Omeprazole (Gastrogard) paste should be administered at 4 mg/kg PO q24h for 4 weeks.
  - Histamine H2-receptor antagonists (cimetidine, ranitidine, famotidine) decrease gastric acid secretion but have a shorter duration of effect than PPIs and must be dosed more frequently. Oral bioavailability in horses is very low, so large doses are required.
  - Sucralfate may provide some protection against NSAID-induced gastric ulceration.
  - Antacids (aluminum hydroxide, magnesium oxide or hydroxide, and calcium carbonate) increase gastric pH but have a short duration of action and must be administered very frequently to be effective.

CHRONIC TREATMENT

- Corn oil supplementation may be an effective and inexpensive way to increase the protective properties of equine glandular gastric mucosa. When supplemented with 45 mL q24h of corn oil, ponies had significantly decreased acid output and significantly increased PGE2 and sodium outputs compared with those measured before corn oil supplementation.
- The ideal dietary management of horses with right dorsal colitis is unknown. Some veterinarians recommend feeding no roughage and only pelleted feeds, but others recommend feeding a high-roughage diet to stimulate production of specific short-chain volatile fatty acids (VFAs), which have been associated with intestinal mucosal protection in experimentally induced colitis. If hay is fed, alfalfa induces significantly higher pH and VFA concentrations in gastric juice than brome grass hay.

DRUG INTERACTIONS

- Concurrent administration of an aminoglycoside (eg, gentamicin) may increase the toxicity of both the aminoglycoside and the NSAID.
- Omeprazole in humans is metabolized by polymorphically expressed cytochrome P450, with populations of extensive, moderate and poor metabolizers. It is not known if equine metabolism of omeprazole is polymorphic. Omeprazole and cimetidine are known to inhibit the hepatic metabolism of other drugs metabolized by the cytochrome P450 system, but there are no reports of specific adverse drug interactions.
- All drugs that alter gastric acid pH have the potential to interfere with the normal absorption of other orally administered drugs.
- Antacids should not be administered concurrently with fluoroquinolones or tetracyclines because of binding to calcium and aluminum, reducing absorption.
- Sucralfate disassociates in the acidic environment of the stomach to sucrose octasulfate and aluminum hydroxide. If administered after other antiulcer drugs have increased the gastric acid pH, its activity will be reduced. If it is administered before the histamine H2-receptor antagonists, they adsorb to the aluminum hydroxide, and their absorption is reduced.

POSSIBLE COMPLICATIONS

- Surgical removal of damaged sections of stomach or colon may be necessary in some cases.
- Duodenal ulcers, duodenal strictures with gastric outflow obstruction, erosive esophagitis, and gastric rupture occur infrequently.

RECOMMENDED MONITORING

- Clinical signs
- Plasma protein concentrations

PROGNOSIS AND OUTCOME

Recovery is usually slow, and in severe cases, the prognosis is guarded. Alternative pain drugs must be used in horses that demonstrate sensitivity to NSAIDs.

PEARLS & CONSIDERATIONS

PREVENTION

Use the lowest effective dose and the longest possible dosing intervals for any NSAID in horses. Avoid phenylbutazone in high-risk foals and horses. Consider prophylactic use of omeprazole and feeding corn oil to high-risk patients.

CLIENT EDUCATION

Caution clients to not administer NSAIDs to horses without veterinary supervision. Horses receiving NSAIDs must have adequate water intake.

ElibeVet.com

Nutritional Myopathy

BASIC INFORMATION

DEFINITION

An acute to chronic myodegenerative disease of skeletal and cardiac muscle assumed to be caused by a dietary deficiency in selenium, vitamin E, or both

SYNONYM(S)

White muscle disease, nutritional muscular dystrophy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Horses and probably donkeys and mules may be affected.
- Foals seem to be more susceptible than adults.

GEOGRAPHY AND SEASONALITY Nutritional myopathies are found more often in areas of selenium deficient soils, including the Pacific Northwest; Great Lakes area; northeast and southeast Gulf Coast areas of North America; and parts of Europe, New Zealand, Australia, and Asia.

ASSOCIATED CONDITIONS AND DISORDERS Aspiration pneumonia, malnutrition and steatitis, impaired immune function

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES The type of disease depends on the muscle group affected and the horse's age.

- Acute disease: Cardiovascular collapse, sudden death
- Subacute disease in foals: Muscle weakness or dysphagia
- Chronic disease in adults: Dysphagia, weakness, muscle atrophy

HISTORY, CHIEF COMPLAINT Vary with muscle group affected and age

- Sudden death or recumbency
- Inability to eat
- Weakness or stiffness

PHYSICAL EXAM FINDINGS Vary with muscle group affected

- Cardiac muscle: Tachycardia, tachypnea, dyspnea, irregular heartbeat, unable to rise, sudden death
- Masseter muscles: Trismus, bruxism, weight loss, dysphagia, atrophy of muscles
- Lingual or pharyngeal muscles: Dysphagia, weight loss, aspiration pneumonia, quidding
- Muscles of locomotion: Weakness, stiffness, difficulty rising, weight loss, painful muscles, neck pain, trembling

ETIOLOGY AND PATHOPHYSIOLOGY Most cases are caused by a dietary deficiency in selenium and sometimes vitamin E. Muscle cell membranes may be destroyed by oxidative free radicals, which disrupts the integrity of the muscle cell. Selenium and vitamin E are antioxidants that can prevent this. Selenium destroys some of the peroxides that have been formed. Vitamin E is a lipid-soluble antioxidant that is active within the cell membrane. Lack of these antioxidants along with other factors may lead to muscle degeneration.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other cardiovascular disease
- Temporomandibular joint disease
- Toxicities caused by gossypol, ionophores, yew, oleander, and other cardiotoxic plants
- Exertional rhabdomyolysis
- Tetanus

INITIAL DATABASE

- Creatine kinase (CK) is usually increased to above 5000 IU/L except in chronic cases in which the muscle has already undergone fibrosis. CK has a short half-life, so levels may decrease over time if the degeneration stops and may be of prognostic value.
- Aspartate aminotransferase (AST) has a longer half-life and remains elevated longer.
- Lactate dehydrogenase (LDH) may also be elevated but is derived from tissues other than muscle, as is AST.
- Hyperkalemia may be present in foals along with hyponatremia and hypochloremia.
- Myoglobinuria may be present in foals.

ADVANCED OR CONFIRMATORY TESTING

- Whole-blood selenium, glutathione peroxidase, or serum selenium.
- Muscle biopsy and histopathology to identify hyalin degeneration or fibrosis of muscle.
- Serum vitamin E.
- Liver selenium concentration may be determined on tissue taken by biopsy or at postmortem. Normal liver concentrations should be 1.05 to 3.5 µg/g dry matter.

TREATMENT

THERAPEUTIC GOAL(S)

Prevent continued muscle degeneration and allow for regeneration of affected skeletal muscle.

ACUTE GENERAL TREATMENT

- Limit exertion that might promote cardiac failure.
- Provide selenium supplement to stop further degeneration.
- Treatment of horses with the acute form with cardiac failure is not often successful.

CHRONIC TREATMENT

- Give injectable selenium at 0.06 mg/kg body weight IM or SC.
- Warning: Selenium is a trace mineral with a narrow range of safety. There have been recent cases in which a large number of horses were killed by an overdose of selenium.
- Vitamin E as DL-α tocopherol can be added to the treatment, but the concentration in most combination products is not sufficient to increase blood levels because vitamin E is present only as a preservative.
- Provide supportive care such as providing rehydration and nutrition if the animal is unable to swallow.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia may occur in foals unable to swallow.
- Malnutrition may occur in horses unable to open their mouths or swallow.

PROGNOSIS AND OUTCOME

Guarded for any case; grave for cardiac cases and chronic cases with muscle fibrosis

PEARLS & CONSIDERATIONS

COMMENTS

Proving that a deficiency in selenium or vitamin E caused the degeneration may be difficult. Whole-blood selenium (which is preferred) or whole-blood glutathione peroxidase indicates the selenium status at the time the red blood

ElibeVet.com

cells were formed weeks to months before the appearance of clinical signs. Serum selenium indicates the selenium status at present and not necessarily at the time the degeneration started to occur. The serum or liver vitamin E concentration is related to the current dietary intake and not necessarily the amount available at the time the muscle was degenerating. Vitamin E levels in the serum also fluctuate throughout the day and vary with the season and diet.

PREVENTION

Prevention is achieved by supplementation of selenium and vitamin E, especially in selenium-deficient areas. Under current US regulations, the maximum selenium concentration of rations is 0.3 ppm, and the maximum concentration of mineral mixtures is 120 ppm. However, this may not be enough to prevent the condition in certain selenium-deficient areas. Oral supplementation of horses at 1 mg/d of selenium will increase blood levels to concentrations not associated with nutritional myodegeneration.

Oak Toxicosis

BASIC INFORMATION

DEFINITION

Oaks (*Quercus* spp.) in North America include approximately 85 native and introduced species and 100 named hybrids that occur as hardwood trees and woody perennial shrubs. In horses, oak toxicity is characterized primarily by gastrointestinal (GI) disease.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All horses are potentially susceptible with some individual variability.
- Compared with cattle, horses are less likely to exhibit renal effects.

RISK FACTORS

- Buds, twigs, leaves, and acorns are all potentially harmful.
- Most toxic ingestions involve young, immature leaves and freshly fallen acorns, although horses must typically consume very large quantities for 4 to 5 days or more to develop GI or renal disease.

GEOGRAPHY AND SEASONALITY Oaks are found nearly worldwide in a wide variety of habitats. Toxicosis most commonly occurs after spring storms when animals have access to young leaves or in autumn when acorns begin to fall.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- GI disease (most common form in horses)
- Kidney disease
- Hepatotoxicity

HISTORY, CHIEF COMPLAINT The primary signs observed in horses are GI, most commonly presenting as varying degrees of colic and diarrhea.

PHYSICAL EXAM FINDINGS

- Mildly affected horses will be depressed with reduced peristalsis and constipation.
- More severe cases may have tenesmus and hemorrhagic diarrhea. Hemoglobinuria, hematuria, and icterus may also be observed.

ETIOLOGY AND PATHOPHYSIOLOGY

- Immature oak leaves and freshly fallen acorns contain the highest concentrations of condensed and hydrolyzable tannins.
- Condensed tannins are resistant to hydrolysis and tend to pass through the GI tract unchanged without causing significant disease problems.
- Hydrolyzable tannins are hydrolyzed in the gut to their constituent phenolics and sugars. These tannins or their polyphenolic products have an irritant astringent effect on the small intestinal mucosa, favoring absorption.
- If absorbed in large quantities, tannin metabolites reach increased levels in the kidneys and can result in the destruction of renal tubular cells.
- Liver involvement may also be seen in horses when the capacity to conjugate phenolics is exceeded.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of GI disease or colic
- Kidney failure: Oxalate-containing plants
- Other hepatotoxins

INITIAL DATABASE

Abnormalities reported in one fatal case of equine acorn poisoning included dehydration, a mildly elevated serum creatine kinase concentration, hypoproteinemia, and hyperglycemia, along with decreased serum calcium and chloride and elevated phosphorus activity. The urine contained protein, blood, and hemoglobin casts. Prothrombin time, activated partial thromboplastin, and fibrin degradation products were increased.

ADVANCED OR CONFIRMATORY TESTING

- The most prominent necropsy lesions in horses are hemorrhagic enteritis and severe edema affecting the mesentery, cecum, and colon.
- Acorns have reportedly caused bowel obstruction, gastric rupture, and acute peritonitis.
- Acorn husks may be evident in the manure or GI contents.
- Histologically, renal tubular necrosis and hepatocellular degeneration may be observed.

TREATMENT

THERAPEUTIC GOAL(S)

- Treatment of GI disease
- Treatment of renal disease if present

ACUTE GENERAL TREATMENT

Symptomatic and supportive care should include IV electrolyte solutions for rehydration and support of renal function as well as pain relief.

ElibVet.com

PROGNOSIS AND OUTCOME

Prognosis depends on the severity of the GI disease

PEARLS & CONSIDERATIONS

- Most animals will not readily forage on oak leaves and acorns if other good-quality feed sources are available. Poisoning is most likely in the spring and fall when immature leaves and acorns are most likely to be easily accessible.
- Goats can be used to effectively control oak plants because they are unaffected by the tannins in oaks.

AUTHOR: **LISA A. MURPHY**

EDITOR: **CYNTHIA L. GASKILL**

Obstructive Disease of the Urinary Tract

BASIC INFORMATION

DEFINITION

Occlusion or impediment of urinary flow by a urolith or soft tissue obstruction

EPIDEMIOLOGY

SPECIES, AGE, SEX Males are more likely to develop urethral obstruction.

RISK FACTORS

- Urinary tract mucosal trauma (eg, dystocia, breeding injuries, surgery)
- Urine stasis or retention
- High dietary minerals or calcium (legumes)
- Administration of nephrotoxic drugs, especially nonsteroidal antiinflammatory drugs (NSAIDs)

ASSOCIATED CONDITIONS AND DISORDERS

- Urolithiasis
- Neoplasia
- Pyelonephritis
- Previous urethrostomy
- Stallion breeding injuries

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Abdominal pain
- Stranguria or dysuria
- Pollakiuria
- Hematuria
- Apparent urinary incontinence
- Abdominal distension
- Preputial swelling
- Poor body condition

PHYSICAL EXAM FINDINGS

- Balanoposthitis
- Preputial swelling, heat, and pain
- Occasionally, a urolith may be palpable in the urethra.
- Spasm of the urethra over the urethrolith
- Rectal palpation may reveal a swollen kidney(s), and the ureter(s) may also be palpable. The bladder may be enlarged with urethral occlusion.

ETIOLOGY AND PATHOPHYSIOLOGY

- Uroliths occasionally occlude the ureter, urethra, or renal pelvis.
- Urethral obstruction occurs most commonly in males when uroliths lodge at the ischial arch, where the urethra narrows.
- Scarring or mucosal proliferation can sometimes be a sequela of urinary tract surgery (urethrotomy) or trauma and result in obstruction.
- Postrenal azotemia occurs with occlusion of urinary outflow, backpressure in the collecting system, and resultant decreased renal blood flow.
- Extrusion through the floor of the vagina or prolapse and eversion of the bladder may occur in mares when straining during foaling or colic.
- Breeding injuries in stallions may cause hematomas from cavernous penile tissues that result in urethral obstruction.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Urolithiasis
- Estral behavior in females
- Neoplasia or granuloma of the urinary tract
- Acute abdominal pain (colic)

INITIAL DATABASE

- Complete blood count and fibrinogen concentration.
- Serum chemistries (blood urea nitrogen [BUN], creatinine, and electrolyte concentrations).
- Urinalysis
- Rectal palpation may reveal urolithiasis, an enlarged bladder, or palpable ureters
- Ultrasonography (transabdominal renal and transrectal of the bladder): Should show hydronephrosis, hydroureter, or an enlarged urinary bladder. Peritoneal effusion or fluid accumulation along the ureters or urethra indicates probable urinary tract rupture.

ADVANCED OR CONFIRMATORY TESTING

- The inability to completely pass a urinary catheter indicates urethral obstruction.
- Urethroscopy and cystoscopy: Ureteroscopy is difficult with most endoscopes, but urine may be observed exiting from the ureteral openings in the caudodorsal trigone of the bladder.
- Urine culture
- Intravenous pyelography, magnetic resonance imaging, or computed tomography in foals.

TREATMENT

THERAPEUTIC GOAL(S)

- Relieve urinary tract obstruction
- Resolve azotemia and any electrolyte abnormalities that may be present

ACUTE GENERAL TREATMENT

- Surgical removal of urinary tract obstruction
- Relieve spasm of the ureter or urethra
  - Acepromazine: 0.02 to 0.04 mg/kg IV q8h
  - Phenazopyridine: 4 mg/kg PO q8h
- Broad-spectrum antibiotics, especially those that are eliminated in the urine (penicillins, aminoglycosides, potentiated sulfonamides, cephalosporins)
- IV fluids (60 mL/kg q24h in adult horses) after the obstruction has been relieved to maintain urination and diuresis
- NSAIDs in non-azotemic and normally hydrated patients

ElibVet.com

RECOMMENDED MONITORING

- Urine output
- Serial BUN, creatinine, and electrolyte concentrations
- Repeated ultrasound examinations to determine if suspected urinary tract obstruction is causing leakage or accumulation of urine

PROGNOSIS AND OUTCOME

- Prognosis is good with resolution of urinary tract obstruction, especially if the urethra is occluded.
- Horses with obstructive lesions of the urinary tract may have chronic renal failure.

PEARLS & CONSIDERATIONS

COMMENTS

- Early recognition and treatment of urinary tract obstruction greatly improve prognosis and response to therapy.
- A retrospective study of urolithiasis in horses reported uroliths in the kidneys (22%), urethra (16%), and ureters (3%) of affected horses. Approximately 9% of horses had urolithiasis at more than one location.
- Obstruction of the urinary tract is an uncommon cause of abdominal pain.

PREVENTION

- Judicious use of potentially nephrotoxic drugs
- Avoidance of high mineral diets, especially calcium (legumes)

Oral Soft Tissue Trauma: Hard and Soft Palate

BASIC INFORMATION

DEFINITION

Traumatic injuries to the hard or soft palate

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS

- Severe head trauma
- Mandibular and maxillary fractures
- Associated fractures of the cheek teeth
- Oronasal fistulae

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of severe trauma
- The chief complaint may revolve around associated ataxia, dysphagia, or noise at exercise

PHYSICAL EXAM FINDINGS

- Obvious facial depression or facial deformity
- Feed material at the nares
- Evidence of dysphagia
- Mucosal lesions suggesting an underlying osseous pathology on oral examination
- Gross instability of the rostral portion of the head

ETIOLOGY AND PATHOPHYSIOLOGY

- Hard palate
  - Congenital abnormalities such as cleft palate
  - Traumatic injuries
- Soft palate
  - Congenital abnormalities such as cleft palate
  - Iatrogenic injuries: Complication of aryepiglottic fold surgery via the nose

DIAGNOSIS

INITIAL DATABASE

- Complete oral examination, including sedation, full-mouth speculum, and mirror with light source
- Manual examination (assuming the hand is small enough) and oropharyngeal endoscopy
- Radiography
- Endoscopy of the nasal passages and nasopharynx

ADVANCED OR CONFIRMATORY TESTING

Computed tomography

TREATMENT

THERAPEUTIC GOAL(S)

- Close oronasal fistulae
- Attempt repair of hard palate defect (sliding mucoperiosteal flap)
- Attempt closure of soft palate defect to return horse to being an obligate nasal breather

ACUTE GENERAL TREATMENT

- Sedation
- Complete initial database to obtain presurgical information
- General anesthesia and surgery if warranted, indicated, or financially viable

POSSIBLE COMPLICATIONS

Wound breakdown in the face of infection

RECOMMENDED MONITORING

Recheck endoscopy in 2 weeks.

PROGNOSIS AND OUTCOME

Prognosis is usually good assuming that gross instability is controlled. Repairs involving sliding mucoperiosteal flaps and soft palate surgery generally have a guarded prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Closure of the soft palate in at least two layers will significantly improve the likelihood of surgical success.

CLIENT EDUCATION

Congenital cleft palates present an ethical dilemma for equine surgeons because of the proposed heritable component.

Oral Soft Tissue Trauma: Lips and Cheeks

BASIC INFORMATION

DEFINITION

Traumatic injuries to the lips and cheeks associated with wire, bit, or other foreign bodies. Additionally, direct trauma in the form of a kick or bite may also cause significant damage.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT Trauma evidenced by bleeding, dysphagia, or protrusion of the tongue. In some cases, the traumatic episode was witnessed by the owner or caretaker; in most cases, however, it is not.

PHYSICAL EXAM FINDINGS Areas of partial- or full-thickness mucosal ulceration with underlying damage to musculature, vasculature, and in some cases osseous pathology

DIAGNOSIS

INITIAL DATABASE

- Complete oral examination
- Radiographs to determine whether there is a fracture of the underlying bone (including intraoral projections)

ADVANCED OR CONFIRMATORY TESTING

Sialogram if there is a possibility of involvement of the parotid duct or other salivary structure

TREATMENT

THERAPEUTIC GOAL(S)

To reoppose damaged tissue to effect healing

ACUTE GENERAL TREATMENT

- Sedation and appropriate nerve blocks to desensitize the region
- Close examination and debridement of gross debris and blood clots
- Determine if suturing is necessary or if the wound will heal satisfactorily by second intention
- Suture in three layers if possible (oral mucosa, muscle and fascial tissue, and skin)

POSSIBLE COMPLICATIONS

Wound breakdown in the face of infection (oral cavity) and continual bathing of the region by saliva

RECOMMENDED MONITORING

Recheck in 2 weeks

PROGNOSIS AND OUTCOME

Usually good. The relatively high blood supply to the face and oral cavity make surgical intervention relatively uncommon (assuming that gross anatomic distortion and injury have not occurred).

PEARLS & CONSIDERATIONS

COMMENTS

Sutured lips (especially at the commissure of the mouth) have to withstand significant tension and the forces of prehension and mastication. The placement of stented tension sutures (near-far-far-near or vertical mattress) can improve the likelihood of surgical success.

CLIENT EDUCATION

Horses with lip injuries should not be bitted for 2 to 3 weeks after surgical intervention, especially in cases with commissure wounds where the presence of the bit will irritate the sutures and underlying healing tissue. Failure may ensue.

Oral Soft Tissue Trauma: Salivary Glands and Ducts

BASIC INFORMATION

DEFINITION

Injuries involving either the salivary glands or their associated ducts

SYNONYM(S)

Sialocele

EPIDEMIOLOGY

RISK FACTORS Trauma

ASSOCIATED CONDITIONS AND DISORDERS

- Mandibular and maxillary fractures
- Associated fractures of the cheek teeth
- Trauma

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Trauma
- Visible tissue defect
- Fistula present

ETIOLOGY AND PATHOPHYSIOLOGY Trauma to the parotid duct (because it is relatively superficial) or the

ElibVet.com

duct as it crosses the ventral mandible may result in luminal transection. If second intention healing fails, a salivary cutaneous fistula may develop.

DIAGNOSIS

INITIAL DATABASE

- Complete oral examination (including sedation, full-mouth speculum, and mirror with light source)
- Radiography (if necessary)

ADVANCED OR CONFIRMATORY TESTING

Salivary duct cannulation if necessary

TREATMENT

THERAPEUTIC GOAL(S)

Reoppose the damaged duct such that fistulae do not occur.

ACUTE GENERAL TREATMENT

- Sedation
- Close examination and debridement of gross debris and blood clots
- Determination if the wound will heal satisfactorily by second intention or if skin suturing alone is sufficient

CHRONIC TREATMENT

Surgical intervention if conservative management is inadequate

POSSIBLE COMPLICATIONS

- Wound breakdown
- Salivary cutaneous fistula

PROGNOSIS AND OUTCOME

Usually good with conservative management. Prognosis good with surgical repair in the event that conservative therapy is unsuccessful. If surgical therapy is unsuccessful, then continued saliva drainage, especially during eating, is a greater aesthetic problem than it is a functional problem.

PEARLS & CONSIDERATIONS

Trauma or injury to the submandibular salivary gland is relatively rare compared with that of the parotid gland and its associated duct.

SUGGESTED READING

Greet TRC: The management of oral trauma. In Baker GJ, Easley J (eds). *Equine dentistry*, ed 2, St Louis, 2005, Saunders Elsevier, pp 79–86.

Dixon PM, Gerard MP: Oral cavity and salivary glands. In Auer JA, Stick JA (eds). *Equine surgery*, ed 3, St Louis, 2006, Saunders Elsevier, pp 321–351.

AUTHOR & EDITOR: **JAMES L. CARMALT**

Oral Soft Tissue Trauma: Tongue and Oral Mucosa

BASIC INFORMATION

DEFINITION

Traumatic injuries to the tongue and oral mucosa associated with wire, bits, or other foreign bodies. Additionally direct trauma in the form of a kick, bite, or misadventure may also cause significant damage.

EPIDEMIOLOGY

ASSOCIATED CONDITIONS AND DISORDERS

- Avulsion injuries to the incisors
- Mandibular and maxillary fractures
- Associated fractures of the cheek teeth

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES Tongue lacerations (partial or full thickness)

HISTORY, CHIEF COMPLAINT

- Trauma or bit-related history
- Presenting complaint of bleeding, dysphagia, or protrusion of the tongue

PHYSICAL EXAM FINDINGS

- Partial- or full-thickness laceration of the tongue
- Presence of foreign bodies within the mouth or jammed across the hard palate

DIAGNOSIS

INITIAL DATABASE

Radiography (if necessary)

TREATMENT

THERAPEUTIC GOAL(S)

Reoppose damaged lingual tissue or perform a partial glossectomy

ACUTE GENERAL TREATMENT

- Sedation appropriate nerve blocks to desensitize region (see "Anesthesia, Local Diagnostic" in Section II)
- Close examination and debridement of gross debris and blood clots
- Determination if suturing is necessary or if the wound will heal satisfactorily by second intention
- Induction of general anesthesia if suturing is necessary
- Suture in three layers if possible
  - Ventral mucosa (thin and poor holding capability)
  - Lingual musculature (one or two layers; this will address the bulk of the tension)
  - Dorsal mucosa (thick and has good suture retention characteristics; use a combination of simple interrupted and vertical mattress sutures).
- Oral mucosa injuries tend to heal well by second intention, assuming that the inciting causes (foreign bodies and fracture fragments) are removed.

POSSIBLE COMPLICATIONS

- Wound breakdown in the face of infection (oral cavity) and continual bathing of the region by saliva
- Necrosis of the tip of the tongue associated with vascular compromise

RECOMMENDED MONITORING

Recheck in 2 weeks

PROGNOSIS AND OUTCOME

Usually good. The relatively high blood supply to the face and oral cavity allow for good healing, assuming that tension can be addressed.

PEARLS & CONSIDERATIONS

COMMENTS

The placement of tension sutures (near-far-far-near or vertical mattress) will significantly improve the likelihood of surgical success.

ElibVet.com

CLIENT EDUCATION

Horses with tongue injuries should not be bitted for 2 to 3 weeks after surgical intervention or failure may ensue.
